Abstract

We use the Shapley value and the nucleolus to analyze the impact of three controversial pipeline projects on the power structure in the Eurasian trade of natural gas. Two pipelines, 'Nord Stream' and 'South Stream', allow Russian gas to bypass transit countries, Ukraine and Belarus. The third project, 'Nabucco', aims at diversifying Europe's gas imports by accessing producers in Middle East and Central Asia. For the Shapley Value we obtain a clear ranking of the projects which corresponds to the observed investment patterns. Nord Stream's strategic value is huge, easily justifying the high investment cost for Germany and Russia. The additional leverage obtained through South Stream is much smaller and Nabucco is not viable. For the nucleolus in contrast, none of the pipelines has any strategic relevance at all, which appears to be at odds with the empirical evidence.

Keywords: Cooperative games, Networks, Strategic Investment, Natural Gas, Shapley Value, Nucleolus

We thank Ekaterina Orlova for her contribution in programming the network model. We are also thankful to Johannes H. Reijniere for providing us with MATLAB code for calculating the nucleolus.

1 Introduction

Pipeline gas from the Russian Federation accounts for a quarter of the consumption in the European Union and for more than 40% of its imports. Until 2011 essentially all of these imports depended on transit through either Belarus or Ukraine, both being major importers of Russian gas themselves. On both routes conflicts over transit fees and gas prices led to several interruptions of supply, the most serious one in January 2009 when transport through Ukraine was shut down for three weeks with dire consequences for heating and power supply in the Balkan.¹ European policy makers are struggling to find a coherent response to these challenges. On the one hand, new pipeline links with Russia diversify transit routes for Russian gas. On the other hand, such pipelines have the potential to further increase the dependency on Russian gas and reduce the viability of investments securing supplies from alternative sources.

The Eurasian pipeline network can be seen as a specific example of a network, which enables the parties to trade. Its architecture determines not only the actual trade flows but also the power of the parties, i.e. how they will share the gains from trade. The more difficult it is to substitute for the resources and links which a player controls, the more powerful he will be. Hence, the actors are trying to shape the network to their own advantage. By opening new options for trade they can decrease the value of established links if substitutable, or increase their value if complementary.

That the formation or severance of trade links can be used to enhance the power of a nation has been recognized long ago (Hirschman (1969)). But no generally accepted approach for the assessment of power relations in networks has been established. Analyzing communication structures Myerson (1980) proposed to use cooperative game theory, and more specifically the Shapley value as a power index. Jackson & Wolinski (1996) and Jackson (2008) extended the idea to general networks and delineated two stages, a first, non-cooperative stage, where players can change the network architecture by adding or removing links, which is followed by a second stage, where the solution of a cooperative game, defined by the existing network, determines the final payoffs. Brandenburger & Nalebuff (2007) coined the term 'bi-form games' to emphasize that different approaches are used to determine outcomes at the two stages. Here we follow this distinction of two stages.

¹For a comprehensive account of major conflicts over transit through Belarus and Ukraine see Bruce (2005) and Pirani et al. (2009), respectively.

There are good reasons to analyze gas trade in the second stage within a cooperative game framework. Most pipeline gas is traded under negotiated, comprehensive price-quantity-contracts with so called ‘take-or-pay’ provisions. By stipulating prices and quantities contracts ensure the efficient usage of the existing capacities and avoid double marginalization (see Energy Charter Secretariat (2007) for details). Contracts with transit countries also cover tariffs and quantities. So it appears reasonable to assume that the pipeline system will be used efficiently and the surplus is shared through negotiations among the partners.²

There is, however, no general consensus how to determine the power structure in such a setting. Brandenburger & Nalebuff (2007) argue that the cooperative stage should be solved with the core, instead of the Shapley value. The core, if not empty, is typically not unique, so they resort to an exogenous assumption on the the ‘players’ confidence’ in their own bargaining power to solve the indeterminacy.³ We prefer to avoid exogenous assumptions on the bargaining power and consider the nucleolus as an alternative to the Shapley value. The nucleolus is unique and in the core, provided the latter is not empty.

When the network is changed through a new pipeline, we obtain a different game entailing gains for some and losses for other players. We say that a project is a viable strategic option if the gains of the beneficiaries are larger than the cost of the pipeline. Strategic viability does not necessarily imply that the pipeline will be built. First, those players who would benefit, have to succeed in setting up a consortium, sharing costs and gains etc, which might be difficult if the gains spread over many regions or if some players cannot make credible long term commitments. Second, those players who are set to lose power might dissuade those who will gain from carrying out the project. Such a move might also require a substantial amount of cooperation. Again there is no generally accepted approach to determine the equilibrium network investments at the first stage. Obviously, some impediments to cooperation have to be assumed, otherwise the two stages can be collapsed into one big cooperative game. With imperfect coordination inefficiencies may arise: under-investment, due to potential hold up, and over-investment to improve bar-

²There is also a literature using large scale non-cooperative models of gas trade with players acting in a Cournot or Bertrand fashion. For a review see Smeers (2008) for a critic of the assumptions Hubert & Ikonnikova (2011a).

³In addition there is a growing literature on non-cooperative, decentralized bargaining in networks, which invokes specific bargaining protocols to single out particular solutions (e.g. Manea (2011), Elliott (2012)).

gaining position.⁴ In this paper we do not try to predict the equilibrium network structure. Instead we simply quantify the impact of a possible link on the power structure at the trading stage and compare it to its cost.

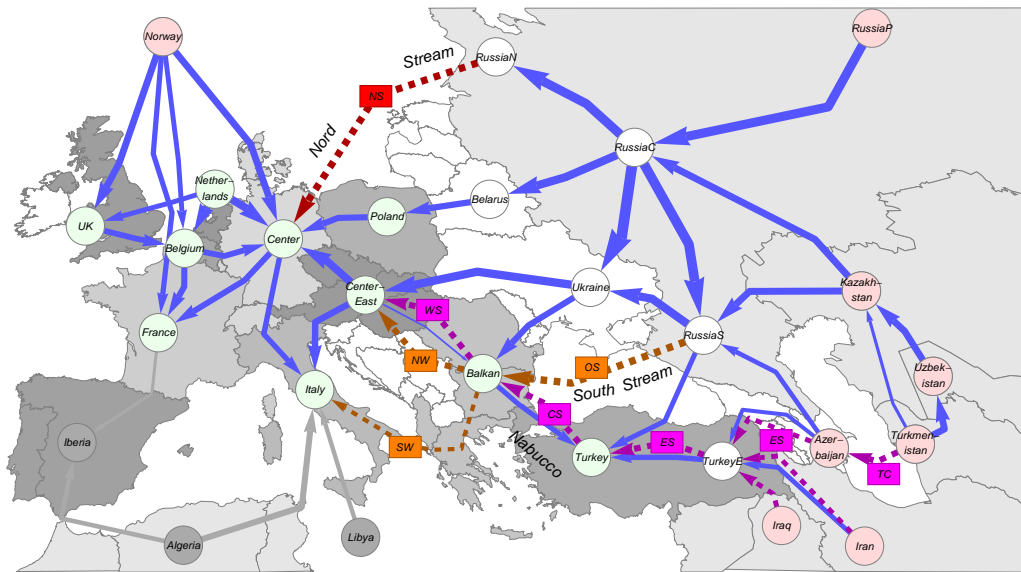

We use this framework to investigate three controversial pipeline projects, which have the potential to thoroughly transform the Eurasian supply system for natural gas (for an illustration see figure 1). In the North, the offshore twin-pipeline *Nord Stream* establishes a direct link between Russia and Germany through the Baltic Sea. Initiated in 2005, it faced strong opposition from Poland and some Baltic states. Nevertheless it received EU support as a strategic infrastructure project and was completed in 2012. Further to the South, Italy and Russia discuss another offshore pipeline through the Black Sea, called *South Stream*. If realized, it would provide a direct connection between Russia and Bulgaria, from where gas should flow to Central Europe, Italy and Turkey. By bypassing the transit countries, Belarus and Ukraine, both projects diversify transit routes for Russian gas. However, critics argue that they will also increase Europe's dependency on Russian exports and safeguard Russia's dominance in European markets by preempting investments into alternative gas supplies.⁵ EU support for South Stream has been lukewarm and the Commission clearly favors a third project, *Nabucco*, aiming at diversifying gas imports. It would open a southern corridor through Turkey connecting Europe to new suppliers in the Middle East and the Caspian region. Nabucco also offers a new transit option to producers in Central Asia, which currently ship gas through Russia. The EU made Nabucco a major strategic project under its Trans-European Energy Networks (TEN-E), but the project failed to raise sufficient support from national governments and the private sector. At the time of writing it appears very unlikely that the project is implemented any time soon.

Our focus is on the *strategic* role of the pipelines. Even if not needed to transport *additional* gas, pipelines may have a substantial impact on the balance of power in the network. In fact, the size of these projects appears out of range with both production possibilities and market demand. With 55 bcm/a and 63 bcm/a, respectively, Nord Stream and South Stream will increase transport capacities for Russian gas by 63% from app. 186 bcm/a to almost 304 bcm/a. If compared to the peak of actual gas deliveries in 2008, the increase is almost 80% (BP (2011)). Given growing domestic consumption and slow progress in developing new fields in Western

⁴For general networks see among others Bloch & Jackson (2005), Elliott (2012), for gas pipelines Hubert & Ikonnikova (2011b), Hubert & Suleymanova (2008).

⁵South Stream and Nabucco are often portrayed as competing projects, because South Stream might drain Nabucco of potential gas supplies in Central Asia.

Figure 1: The Network and the Projects

Those pipelines under construction or planning, which we consider in detail are dashed: Nord Stream in red (NS), South Stream in Orange (OS, NW, SW), and Nabucco in Magenta (TC, ES, CS, WS). Light red nodes represent producers. Transit nodes are white. Light blue points represent regions where we have a major transit node, which is linked to local production and local customers (the nodes are not shown separately). Solid arrows represent the main pipelines as existing in 2010. Grey nodes and pipelines are account for but not associated with a player in our analysis.

Siberia, Russia will not be able to produce enough gas to make use of the additional offshore transport capacity any time soon⁶ Taken together all three pipelines would increase the European import capacity by 150 bcm/a or 47%. While declining production in the EU makes an increase of imports a likely scenario, pipeline gas faces stiff competition from liquefied natural gas (LNG), which experienced a sharp drop in prices due to decreasing cost and competing supplies of non-conventional shale gas. Hence, we consider it as very unlikely that demand could take up so much additional pipeline gas in the foreseeable future.⁷

When assessing the power structure with the *Shapley Value* we find that Nord Stream's strategic value is huge, easily justifying the high investment cost for Germany and Russia. It severely curtails the power of the transit countries, Belarus

⁶For the long term perspectives for Russian gas production see Stern (2005).

⁷It is misleading to relate the projects to import needs projected for 2030 or later. While a pipeline might last more than 40 years, the decision to invest at a given time should be based on a much shorter forecasting range. Once the 'go ahead' is given, it will take 3-7 years before the pipeline is ready to deliver gas. Hence, if demand forecasted for a decade ahead is too low or too uncertain to justify the project, the investment should be *delayed* though not necessarily scrapped. For the option like nature of sunk investment under uncertainty see Dixit & Pindyck (1994).

and Ukraine, outside producer Norway, and the EU's main producer, Netherlands. In principle, South Stream fulfills a similar strategic role. However, with Nord Stream already in place, the additional leverage obtained through South Stream is too small to make the project viable for its main beneficiaries; Russia, Germany and some central European countries. Nabucco has a large potential to curtail Russia's power, but the benefits accrue mainly to Turkey, which will diversify its gas imports and become a major potential hub. The gains for the EU members, in contrast, are negligible. With financial support from Turkey some sections appear viable but our results cast doubts on the prospects of raising the necessary funds within the EU. Somewhat surprisingly, South Stream has little effect on Nabucco's attractiveness. The EU Commission's concern (or Russian hopes) that South Stream might pre-empt the investment in a southern corridor through Turkey appears unfounded. For the Shapley value our results nicely match real investment patterns. Nord Stream was swiftly build by those players for whom we predict large gains. South Stream, in contrast, has been faltering and is struggling to move on from the planning stage. After several postponements, it is still unclear whether the offshore section will be built. Nabucco failed to establish a consortium willing to launch the project.

When using the *nucleolus* as a power index instead, we receive results which are difficult to match with the empirical evidence: None of the projects has any strategic value at all. Nord Stream's and South Stream's impacts on the power structure are so tiny that no one would should be interested in the projects, even if investment cost were negligible. Nabucco has some minor effects but these are smaller than project cost by order of magnitude. Essentially, all these pipeline projects are completely irrelevant for the power structure if it is measured with the nucleolus.

Given that all projects attracted a great deal of interests, both from governments and the private sector, that resources have been spend on project consortia, feasibility studies etc. and that Nord Stream has been build, we conclude that the Shapley value gives a better prediction how major players in the industry assess the strategic impact of pipelines than the nucleolus.

2 The Framework

2.1 The Network Game

Network. The analysis is based on a quantitative model of the Eurasian gas network consisting of a set of nodes R , which may be production sites R_P , customers R_C , or pipeline inter-connectors R_T , and a set of directed links L . Each link $l = \{i, j\}$, $i \neq j \in R$ connects two nodes. Let f_{ij} denote gas flows, with negative values indicating a flow from j to i . For those links, which connect a producer to the network or the network to a customer, flows have to be positive ($f_{ij} \geq 0$, $\forall i \in R_P$ or $j \in R_C$). Links between inter-connectors (trunk pipelines) can be used in both directions. For each link $\{i, j\}$ we have a capacity limit k_{ij} and link specific transportation cost $T_{ij}(f_{ij})$, which includes production cost in case of $i \in R_P$. For existing capacities, transportation costs consist only of operation costs, because investment costs are sunk. When allowing for investments to increase k_{ij} , the annualized capital costs for new capacities are added to the transportation costs. Each customer is connected through a single dedicated link to the network. So consumption at node $j \in R_C$ is equal to f_{ij} . The inverse demand is $p_j(f_{ij})$.

Game. The inter-dependencies among the players can be represented by a game in value function form (N, v) , where N is the set of players and the value (or characteristic) function $v : 2^{|N|} \rightarrow R_+$ gives the maximal payoff, which a subset of players $S \subseteq N$, also called coalition, can achieve. The legal and regulatory framework determines the access rights of the various players. So for any coalition $S \subseteq N$ we have to determine to which links $L(S) \subseteq L$ the coalition S has access. Access to the link $\{i, j\}$, $i \in R_P$ is equivalent of having access to production at i . Access to $\{i, j\}$, $j \in R_C$ yields access to customer j . The value function is obtained by maximizing the joint surplus of the players in S using the gas-flows in the pipelines which are accessible for S :

$$v(S) := \max_{\{f_{ij} | \{i,j\} \in L(S)\}} \left\{ \sum_{\{i,j\} \in L(S), j \in R_C} \int_0^{f_{ij}} p_j(z) dz - \sum_{\{i,j\} \in L(S)} T_{ij}(f_{ij}) \right\} \quad (1)$$

subject to

$$\begin{aligned} \sum_i f_{it} &= \sum_j f_{tj}, & \forall t \in R_T(S) & \quad (\text{node-balancing}) \\ |f_{ij}| &\leq k_{ij}, & \forall \{i, j\} \in L(S) & \quad (\text{capacity constraints}) \\ f_{ij} &\geq 0, & \forall i \in R_P \text{ or } j \in R_C & \quad (\text{non-negativity}) \end{aligned}$$

The value function captures the essential economic features, such as the geography of the network, different cost of alternative pipelines, demand for gas in the different regions, production cost, etc. It also reflects the institutional framework, such as ownership titles and access rights through its dependence on $L(S)$. By adding a pipeline to the system we obtain a new network, which in turn defines a new value function.

Solutions. Cooperative game theory has developed a number of solutions for games in value function form. In the following we emphasize the Shapley value (Shapley (1953)), which assigns a unique payoff to each player $i \in N$. It is based on the contribution $v(S \cup i) - v(S)$ which a player i can make to the various subgroups of other players S . The Shapley Value nicely captures the intuition, that a player's payoff from cooperation, interpreted as his power in the game, should increase with his importance for other players, as measured by the value of his contributions.⁸ Formally, it is calculated as player i 's weighted contribution:

$$\phi_i = \sum_{S: i \notin S} P(S) [v(S \cup i) - v(S)] \quad (2)$$

where $P(S) = |S|!(|N| - |S| - 1)!/|N|!$ is the weight given to S . For convenience ϕ denotes the vector of Shapley Values and $\phi_S = \sum_{i \in S} \phi_i$ the sum of Shapley Values of a coalition S .

The other major solution concept for the cooperative games is the core. Let x be a payoff vector and $x_S := \sum_{i \in S} x_i$ be the total payment to the members of S . We consider only payoff vectors x which are efficient $\sum_{i \in N} x_i = v(N)$ and individually rational $x_i \geq v(i)$, so called imputations. The excess e is the difference between what a coalition can achieve alone and what it receives $e(S, x) := v(S) - x_S$. The larger the excess is, the 'worse' is the coalition doing under x . If the excess is positive, the coalition should reject (block/veto) a proposed x , because it can do

⁸The Shapley value has several axiomatic foundations. Surprisingly, it is the only rule of dividing the gains from cooperation featuring *monotonicity*: a player's share never decreases when his contributions weakly increase (Young (1985a), Young (1985b)). It is also the unique rule with so called *balanced contributions*: For any two players i and j it is true that i loses as much if j withdrew from the game, as j loses if i withdrew. Hence, if a player objects the Shapley allocation by pointing out the damage he can impose on another player through a boycott of cooperation, his opponent can always counter the argument (Myerson (1980)). In this sense it is often considered as a 'fair' division. Finally, the Shapley value can be considered as the expected utility of a player from participating in the game (Roth (1977)). The Shapley value can be supported as the subgame-perfect equilibrium of several non-cooperative models of structured bargaining processes, i.e. Gul (1989), Evans (1996), Stole & Zwiebel (1996a), Stole & Zwiebel (1996b), Inderst & Wey (2003).

better on its own. The core is the set of imputations for which no coalition has positive excess: $c(\epsilon) := \{x : e(S, x) \leq 0, \forall S \subset N\}$.

If not empty, the core is typically not unique and its characterization through $2^{|M|} - 2$ inequalities is cumbersome if the number of players is large. Instead, we use the nucleolus, which always exists, is unique and in the core if this is not empty. Moreover it can be interpreted as the lexicographic center of the game (Maschler & Peleg & Shapley (1979)). Originally, the nucleolus has been proposed as the imputation which minimizes ‘inequity’ among coalitions (Schmeidler (1969)). Let $\theta(x)$ be the vector of excesses arranged in decreasing order for a payoff vector x and let \leq stand for lexicographical smaller. The nucleolus, denoted μ , is defined as the imputation which minimizes the excess in lexicographic ordering: $\mu := \{x \in I : \theta(x) \leq \theta(y) \text{ for all } y \in I\}$, where I denotes the set of imputations. It can be computed by solving a nested sequence of linear optimization problems. First excess is made minimal for the coalitions, which are doing worst. Then excess is reduced for the coalitions, which come second, and so on.⁹

2.2 Specification & Calibration

Regional scope and players. To obtain a detailed representation of the various customers, owners of pipelines, gas producers, etc. we would like to consider a large set of players. Unfortunately, computational complexity increases fast in the number of players, as we have to solve $2^{|M|}$ optimization problems to calculate the value function. It is for computational reasons that we restrict the geographical scope by aggregating customers into large markets and leaving out producers which appear to be of minor strategic relevance.

As to producers, we focus on Russia, the supplier for Nord Stream and South Stream, its main competitor Norway, and those countries in the Middle East and Central Asia which have a potential to serve Nabucco: Iraq, Iran, Azerbaijan, and Turkmenistan. The player “Turkmenistan” embraces all production and transport in Central Asia (Uzbekistan, Kazakhstan, Turkmenistan). Transit countries are Belarus, Ukraine and Georgia. Turkey is a major consumer and a potential transit country for Middle Eastern and Caspian gas. We aggregate customers and producers within the EU into eight regional players. Each controls local production, access to local customers, and possibly transit through the region. France, Italy,

⁹In the terminology of operation research computation of the nucleolus is a ‘hard’ problem for which we use an algorithm proposed by Potters & Reijnen & Ansing (1996) who also provided us with the MATLAB code.

Table 1: Consumers

Regions	Consumption ^a [bcm]	Own gas ^b [bcm]	Import Dependency ^{a c} [%]	Import Dep. on Russia ^d [%]
Balkan ^e	19.4	11.3	41.9	83.0
Belgium	17.7	0.0	100	0.0

Poland	15.9	5.9	63.0	71.6
Turkey	35.1	0.7	98.1	50.1
UK	90.8	62.5	31.2	0.0

^a Compiled from OECD/IEA (2011) for 2009.

^b "Own gas" includes own production, LNG-imports and in some cases net-imports from pipelines, which are not considered to be strategic in this analysis. Compiled from OECD/IEA (2011).

^c Net imports/consumption

^d Imports from Russia for 2009 (BP (2010))/net imports for 2009 (OECD/IEA (2011))

^e Romania, Bulgaria and Greece

^f Germany, Denmark, Switzerland and Luxembourg

^g Austria, Hungary, Czech Republic and Slovakia

Poland, Netherlands, and Belgium correspond their respective countries. In each of these countries a national champion dominates imports and local supply (GDF, ENI, PNGiG, Gasunie and Botas, respectively). We collect Austria, Czech Republic, Slovakia and Hungary in one region called "Center-East". South Stream and Nabucco will end in Center-East, from where gas will be distributed to other European consumers. The countries in the region exhibit similar consumption and import dependency patterns. With very little alternative supplies the region depends with almost 90 % of its consumption on imports from Russia. The pipeline networks are largely privatized. The Austrian OMV can be seen as the dominant private supplier in the region. Germany, Switzerland, Denmark and Luxembourg are bundled to "Center". In terms of consumption the region is clearly dominated by Germany, which is also home of large gas suppliers, E.ON-Ruhrgas and Winterhall. The region covers more than three quarters of gas consumption by imports, but its imports are well diversified between Russia (40.2%), Norway (38.1%) and Netherlands (29.3%).¹⁰ Finally, we collect Romania, Bulgaria and Greece in a region called "Balkan". The region has only weak links to other European regions and

¹⁰BP (2010), OECD/IEA (2011).

its imports depend largely on Russian gas.

We aggregate all pipelines and interconnection points between any two players into one link. The arrows in figure 1 indicate the direction of net flows between regions according to IEA (2010). The new projects Nord Stream, South Stream and Nabucco are shown as dashed arrows. Their arrows display the direction of flow after the completion of the project, namely from East to West.

As to access rights, we assume that outside EU every country has unrestricted control over its pipelines and gas fields. For the regions within the EU, in contrast, we assume that common market rules ensure open third party access to the international high pressure transport pipelines. Hence, regions within the EU cannot derive bargaining power from blocking gas transit. Since this is an idealization of the current state of regulation, we briefly discuss the robustness of the results in the appendix. EU regions control local production and access to the local customers. Within EU only Netherlands is a major net exporter of gas. The other regions are mainly customers, who use Russian, Norwegian and Dutch gas to complement their own production and other imports, which are taken as given.

Temporal scope / network flexibility. We assume a stationary environment with constant demand, technology, production cost, etc. The value of a coalition, nevertheless, depends on the temporal scope of the model. In the short run, the pipeline network is essentially static. The longer one projects into the future, however, the more options to invest in pipes, compressors etc. can be exploited, hence the more flexible the transport system becomes. Here, we adopt a rather short horizon assuming that all pipelines can be made bi-directional, but capacities cannot be increased.

Cost and demand. The details of the numerical calibration are given in a technical appendix. Here we outline only the main idea. We calibrate the model using data for 2009 from IEA (2010a) on consumption and production in the regions and flows between the regions from November 2009 to October 2010 taken from IEA (2010b). We assume constant production cost and linear demand functions with the same intercept for all regions. The slope parameters are then estimated as to replicate the consumption in 2009, given our assumption on production and transportation cost. The most important implication of our calibration of demand in relation to cost is that the pipeline system as existing in 2009 is efficient. Given the willingness to pay and the cost of producing gas, it is able to deliver the efficient

amount of gas into the different consumption nodes. Thus, none of the expensive pipeline projects considered in this paper can be justified in narrow economic terms. The Grand coalition of all players, or a benevolent central planner maximizing welfare, would not invest in any of the projects. Only a subgroup of players might find investment beneficial because it increases their bargaining power at the cost of the others.

This approach also ensures that the main difference between the regions is consumption and how it relates to own production on which we have solid information and not our assumption on demand intercepts on which information is poor. The main difference between producers is production capacity and pipeline connections to the markets, for which data are reasonably good, and not differences in wellhead production cost, which are difficult to estimate.

A critical part of the calibration is the relation of demand intercept and production cost, which largely determines the overall surplus from gas trade. The relative shares of different players, measured in percent of total surplus tend to be rather robust with respect to an aggregate increase of demand in relation to production cost. However, the absolute values of their shares will increase, and as a result more pipeline projects will become strategically viable for given investment cost. As previous research has revealed strong incentives to invest for strategic reasons (Hubert & Ikonnikova (2011b)), we use a conservative approach. We annualize investment cost using a rather high discount rate of 15% to account for depreciation and the real option nature of the investment. In our base line scenario we assume a difference between demand intercept and supply cost of 1500 €/tcm.

3 Evaluating Network Power with the Shapley Value

Since a player's Shapley Value is the weighted sum of his contributions to the values of possible coalitions of other players, any change in bargaining power can be traced back to changes of these contributions. The value of a coalition depends on its access to pipelines, markets and gas fields. Hence, a player can increase the coalition value by providing additional markets, additional supply or by improving connections through transit. In any case, the value of his contribution will depend on how well his resources complement what is already at the coalition's disposal. Adding a market to other markets with no access to production helps little compared to making the same market available to several producers, which are short of customers. Generally speaking, a pipeline may benefit a player by improving his

access to complementary inputs and hurt him by improving his competitors access to such resources. The trade-off between access and competition is complicated by the fact that some countries play multiple roles. While Norway is a pure producer in our model, Russia and the Netherlands are producers as well as a customers. Belarus and Ukraine are main transit regions but they are also customers and Ukraine has own production. Moreover, the role of a player depends on the coalition against which he is evaluated. For example, Turkey is a net-importer when all players are in the coalition. However, it becomes a transit country for Russian gas in a smaller coalition, for which neither transit through Belarus nor Ukraine is available. Multiple and changing roles make it sometimes difficult to predict what the overall impact of a new pipeline on a player will be.

Given our calibration of demand, the new pipeline projects do not create value. They can only change the power structure. We indicate the redistribution of bargaining power with the change of the players' percentage shares in the total surplus. The advantage of this measure is that the players' shares are quite robust with respect to different calibrations of demand, hence surplus. Finally, we compare the absolute gains of those players, whose power is increased, to the investment cost of the pipeline to assess the strategic viability of the pipeline.

3.1 Nord Stream

Nord Stream bypasses the transit countries in the Northern corridor and connects Russia via a twin offshore pipeline through the Baltic Sea to Germany. The project was initiated by Russian Gazprom and German EON-Ruhrgas and Wintershall in 2005. Later French GDF Suez and Dutch Gasunie joined the consortium. The project was completed in 2012 providing a pipeline capacity of 55 bcm/a. Published figures on investment cost have been revised several times. We estimate total cost including complementary pipelines in Russia and Germany at 12 billion €.

Table 2 exhibits Nord Stream's effect on the players' relative power. For each player we report the Shapley value in percent of the total surplus without and with the pipeline as well as the difference between the two measuring the project's impact. The shares of suppliers reflect their production capacities as well as their dependency on the transit countries to access to consumer markets. Although Russia exports more gas than Norway to the European markets, Norway's surplus without Nord Stream (13.0%) is slightly larger than Russia's (12.8%). Norway has direct access to the European pipeline network, while Russia depends on the transit coun-

Table 2: Nord Stream's Impact on Bargaining Power

Players ^a	Shapleyvalue [%]		
	without Nord Stream	with Nord Stream	difference
Russia	12.8	15.9	3.0
Ukraine	9.4	6.9	-2.5
Belarus	6.7	5.9	-0.8

^aTurkmenistan, Iraq, Iran, Azerbaijan, and Georgia are omitted because they are not affected by the project. For full results see the technical appendix.

tries, Ukraine and Belarus, to ship gas to the European markets. Different transport capacities in Ukraine and Belarus are reflected in their shares 9.4% and 6.7%, respectively. The largest European producer, Netherlands obtains 6.0%. The other European regions are net importers, hence their benefits tend to increase with the size of their markets and their dependence on pipeline gas. The figures reflect the gains from trading gas, not the gains from consuming gas. A country whose own production or LNG imports are large enough to cover demand will gain little from participating in the gas trade even if its gas market is large. The EU as a whole obtains 48.8%, with Center, Center-East and France having the largest shares. Turkey benefits from its consumption of pipeline gas as well as its potential transit position between Balkan and suppliers such as Russia, Iran and Azerbaijan.

The last column in Table 2 presents Nord Stream's impact on the players' surplus in terms of the differences. Russia gains 3.0 percentage points, an increase of one fourth of its share in the benchmark case. Increased transport competition mitigates the power of Ukraine and Belarus, which lose 2.5 and 0.8, respectively. The transit countries together lose one fifth of their relative power in the benchmark case. Due to intensified supply competition in the European markets, Norway and Netherlands suffer losses of 2.5 and 0.9 points, respectively. The European players together

benefit from increased transport and supply competition, gaining 3.0 points. With 1.5 points Center has the largest increase in the EU.

Nord Stream's total strategic value for the initiators of the consortium, Wintershall and EON Ruhrgas of Germany and Gazprom of Russia (in our model Center and Russia), is huge. A gain of 4.5 percentage points translates into a gain of 7.6 bn €/a, which clearly exceeds the project's cost of 1.8 bn €/a (for similar results see Hubert & Ikonnikova (2003), Hubert & Ikonnikova (2011a), Hubert & Suleymanova (2008)). It is worth stressing that the project is profitable only because it increases the bargaining power of the consortium vis-a-vis other players. Given our calibration of demand, the pipeline is not needed to transport additional gas.¹¹.

3.2 South Stream

South Stream can be seen as the Black Sea twin of Nord Stream. Russia pushes the project to bypass Ukraine when supplying gas to central Europe and the Southwest. According to the initial planning it consisted of three sections: offshore, northwestern and southwestern.

OS: The offshore section crosses the Black Sea and connects Russia directly with Bulgaria with a capacity of 63 bcm/a. The consortium for the offshore section is composed by Gazprom of Russia, Eni of Italy and EDF of France. Onshore the pipeline splits in two sections.

NW: The northwestern section runs from Bulgaria to Baumgarten in Austria via Serbia and Hungary with a capacity of 30 bcm/a.

SW: The southwestern section connects Bulgaria to Italy via Greece and a short offshore pipeline through Adriatic Sea. It has a capacity of 10 bcm/a.

The subsections of the northwestern and southwestern track in the different countries were to be undertaken by a joint-venture between Gazprom and the national

¹¹After Russia and Germany kicked off the project, the consortium was joined by Gasunie of Netherlands and GDF Suez of France, each with a share of 9%. In view of our results, the participation of Gasunie is surprising, since Netherlands supplies 15% of the EU's consumption and is set to loose from intensified supply competition. Our interpretation is the following. Not being able to prevent Nord Stream, Gasunie joined in anticipation of its changing role in the system. Due to rapidly declining reserves, Netherlands will become a net importer around 2025. The country also intends to become a gas hub in Northwestern Europe transiting Russian gas from Germany to UK (Netherlands Ministry of Economic Affairs, Agriculture and Innovation (2010))

gas company of the respective country. In November 2012, Gazprom scaled down the project and abandoned the southwestern section.¹²

The offshore and the onshore pipeline sections are expected to cost 10 billion € and 5.5 billion €, respectively (South Stream (2010)). This figures can be considered as a very low limit as they do not include additional onshore upgradings in Russia.¹³ In January 2014 Gazprom started to order pipes for South Stream's offshore section although major issues such as the financing, the northwestern section's final route, etc. have not been cleared yet. First delivery through the offshore pipeline are now planned for late 2015 while the project will be in service with full capacity at the end of 2018.

Russia enjoys a very strong bargaining position in Southeastern Europe. Competing producers such as Norway or Netherlands cannot reach this region, since the transport capacities between Balkan and Central Europe are very small (1.7 bcm/a).¹⁴ The northwestern section improves the connection between Center and Balkan; thus, it has a potential to increase competition for Russian gas in Balkan and Turkey. However, we assume that the consortium will seek exemption from the European third party access (TPA) rules, so that Gazprom can prevent its competitors from using the pipeline.¹⁵

¹²However, a similar pipeline may still be build. The Trans Adriatic Pipeline was selected as a left-over from ambitious plans for a new Southern Corridor (Nabucco). It is scheduled to carry Caspian supplies through a slightly different route, but with the same capacity from the Turkish-Greek border to Southern Italy. The consortium includes Switzerland's Axpo (EGL), Norway's Statoil and Germany's E.ON (TAP (2013)).

¹³In 2013, Gazprom announced that the Russian domestic pipeline system has to be upgraded to serve South Stream, increasing the project's total investment cost by 12.5 billion € (Reuters (2013)).

¹⁴In January 2009, the gas dispute between Russia and Ukraine hit the Balkan countries severely because the bottleneck between Balkan and Central Europe prevents access of alternative suppliers in Northwestern Europe to the Balkans.

¹⁵To incentivize new investment in infrastructure projects, the European Commission (EC) can grant for so called 'regulatory holiday' (for details see EU (2009)). We also analyzed what would happen if South Stream's northwestern section were not exempted from rules on free TPA. In this case, Russia's strategic gains from bypassing Ukraine would be largely offset by losses due to increased competition from Dutch and Norwegian gas.

^a OS: offshore section with 63 bcm/a and investment cost of 8.6 billion €. NW: Northwestern section with 30 bcm/a and investment cost of 3.5 billion €. SW: Southwestern section with 10 bcm/a and investment cost of 3.4 billion €.

Since Nord Stream became operational, before the construction of South Stream even started, the impact of South Stream has to be assessed for a network which already includes Nord Stream (the right panel of Table 3). Nevertheless, it is instructive to study the counterfactual case first, which is presented in the left panel of Table 3. The comparison of left panel's last column in Table 3 and the last column in Table 2 shows that South Stream and Nord Stream alter the power structure in a similar way. It does not matter much whether Russian gas is injected at the German border or in the Balkans if TPA to the existing European network is assured while Russia's dominance in Southeastern Europe remains protected. However, the gains in bargaining power by Russia and its major customers in Europe are somewhat smaller than in the case of Nord Stream while the cost of South Stream would be larger, which explains why Nord Stream was given precedence.

What are the effects of South Stream once Nord Stream is already in place (the right panel of Table 3)? We start with the impact of the offshore section alone (the column headed 'OS'). The leverage gained is very small, since the gas could only be transported to Balkan, a small market, and Turkey, which is already accessible through Blue Stream. Without substantial onshore investments the offshore section is of little strategic use. If both complementary sections are added the picture, we obtain a scaled down version of the counterfactual case. Russia gains 0.8 points, while Ukraine and Belarus suffer from transit competition and Netherlands and Norway from intensified supply competition. Surprisingly, Center, which does not participate in the consortium obtains the largest gains in the EU. It is also worth noting that the southwestern section has very little impact on the power structure. With Nord Stream and the northwestern section in place, there is already a large amount of spare capacity to transport Russian gas to Central Europe and Italy.¹⁶ Adding a 10 bcm/a link through the Adriatic Sea makes hardly a difference. In view of this finding Gazprom's decision to abandon the southwestern section of South Stream appears rational.

Finally, we again ask whether the project is worth the cost. As an *alternative* to Nord Stream, South Stream would be viable for the members of the consortium (Russia, Italy, France, Center-East and Balkan) if the offshore section is combined with the northwestern section. The gains of 5.6 bn €/a justify the cost of 1.8 bn €/a. The incremental gains of the southwestern section (1.0 bn €/a) is worth the additional cost (0.5 bn €/a). With Nord Stream in place, however, South Stream's

¹⁶The northwestern and offshore sections of South Stream and Nord Stream together increase pipeline capacities between Russia and Europe (except Balkan) from 140 bcm/a to 225 bcm/a, while in 2008 the demand for Russian gas in the area was 108.3 bcm (BP (2009)).

impact on bargaining power is much diminished which casts doubts on its strategic viability. In the baseline scenario the consortium gains 2.2 bn €/a, which is less than the total project cost of 2.3 bn €/a.

In summary, considered as an alternative, both South Stream and Nord Stream have similar effects on the power structure, since both projects bypass the transit countries and allow Russia to compete more effectively with Norway and Netherlands, without losing its strong position in the Southeast. However, in the presence of Nord Stream's large capacities, South Stream provides much less additional leverage. The gains for the consortium appear too small to compensate for the project's high cost.

3.3 Nabucco

Plans for a new 'Southern Corridor' have been discussed for almost two decades. In the 1990s the US government pushed for a 'Trans-Caspian Pipeline' from Central Asia through the Caspian Sea, Azerbaijan and Georgia into Turkey and further on to Southern Europe. The strategic aim was twofold: to reduce Turkey's and Europe's dependency on Russian gas and to decrease Russia's leverage in the newly independent former Soviet republics. However, US energy companies dragged their feet over uncertain economic prospects. These worsened when Russia started to contract large volumes of gas from Turkmenistan in 2002 at much higher prices than before. With the US' support withering the Europeans took over the initiative. A consortium led by OMV of Austria and Botas of Turkey (later joined RWE of Germany) coined the new name 'Nabucco' in 2002.¹⁷ The focus of the new project has shifted, in the East from Central Asia towards suppliers in the Middle East and in the West towards extending the pipeline into the heart of Europe. The EU made the project a major strategic project under its Trans-European Energy Networks (TEN-E). The European Bank for Reconstruction and Development, the European Investment Bank, and IFC (a member of the World Bank Group) tentatively earmarked 4 billion € for funding.¹⁸ However, Nabucco had been postponed several times due to lack of supply commitments as well as its high investment cost. Facing competition from South Stream and other projects in the Southern Corridor, Nabucco's consortium downsized its project's range and capacity in May 2012. Called Nabucco-West, the new project would cover only the European sec-

¹⁷The consortium also included companies from transit countries: Bulgargaz of Bulgaria, Transgaz of Romania, and MOL of Hungary. In 2013, GDF Suez of France replaced RWE of Germany.

¹⁸For the position of the EU see EU (2006), EU (2007), and EurActiv (2011).

tion of the initial project and have one third of its capacity. In June 2013, the project was abandoned after Trans Adriatic was selected to carry Caspian supplies from Turkey to the Continental European markets.¹⁹

Here we consider the initial proposal for Nabucco, right after the last Russia-Ukraine gas dispute in January 2009. For the assessment of the pipeline's impact it is useful to divide it into four sections: Trans-Caspian, the eastern section, the central section and the western section.

TC: Trans-Caspian, for the purpose of this paper, is narrowly defined as the off-shore pipeline between Turkmenistan and Azerbaijan. With 30 bcm/a capacity it is estimated to cost 2.3 billion €. RWE of Germany and OMV of Austria, both also members of Nabucco's overall consortium, had the initiative. Currently, European companies have lost their interest in the project due to long lasting disputes between Azerbaijan and Turkmenistan over the Caspian seabed's division. The EC struggles to find European investors in the project.

ES: The Eastern section consists of several pipelines connecting Turkey with potential suppliers, Azerbaijan, Iran and Iraq. We include Iran even though at present this appears to be very unlikely for political reasons. The country has the second largest gas reserves in the world and Turkey already imports gas from Iran. Even though none of the parties involved in the project will openly admit, Iran is an important potential supplier for Nabucco. For the calculation we assume that the existing capacity of each feeder pipeline between Turkey and the suppliers is increased by 15 bcm/a, and the section from Turkey's East to the West is enlarged by 30 bcm/a. We estimate the cost at 12.2 billion €.

CS: The central section connects western Turkey with Balkan. It is important to note that existing pipelines with a capacity of app. 16 bcm/a are currently used to pump Russian gas into the opposite direction, from Balkan into Turkey. Nabucco will reverse the direction of the flow through the central section and expand its capacity by 30 bcm/a to an estimated total of 46 bcm/a. We estimate the cost of the central section at 1.9 billion €.

WS: The western section connects Balkan to Center with a planned capacity of 30 bcm/a and an estimated cost of 3.5 billion €. At present, Southeastern Europe is isolated from Central Europe since existing transport capacities

¹⁹For details on the competition between Nabucco-West and Trans Adriatic see Cobanli (2014).

between these regions are small (1.7 bcm/a). As a result, Russia faces no competition from Norway and Netherlands in the Southeast. The Nabucco consortium rallied political support in the EU arguing that it would help to integrate the region to other European markets by eliminating the bottleneck. The pipeline is designed for bidirectional use and shall be open for gas transport for all interested parties. So, we assume that every player has access to Nabucco's western section, whereas we assumed exclusive access for South Stream's northwestern section.

Nabucco's expected total cost is 17.6 billion € (19.9 billion € incl. TC). Since none of the potential suppliers is a member of either Nabucco's or Trans Caspian's consortium, producers are not expected to contribute to investment cost.²⁰

It is worth emphasizing, that Nabucco's commercial prospects are built on reversing flows in the present network. Currently, gas flows in small quantities from Center to Balkan and in substantial quantities from Balkan to Turkey. These flows have to be reversed before anybody will pay transport fees to Nabucco's owners. Considering the pipeline in isolation, it is easy to underestimate how much additional gas in Turkey is needed to justify its capacity. Let's consider the central section of Nabucco. First, some 10 bcm/a are needed to substitute for the current flow from Balkan to Turkey. Second, existing capacities can be made bidirectional at modest cost to pump some 16 bcm/a from Turkey to Balkan without new pipelines. Third, 30 bcm/a are needed to fill the additional pipeline capacities. In total it would require app. 55 bcm/a additional gas in Turkey to make fully use of the new pipeline. As with Nord Stream and South Stream, many observers raised serious doubts as to whether such quantities can be provided anytime soon. We, rather optimistically, assume that Iraq, Azerbaijan and Central Asia could supply an additional 56 bcm/a and Iran another 15 bcm/a compared to the output in 2009.²¹

In Table 4 we report selected results for the strategic impact of Nabucco. We focus on a scenario where Nord Stream is already completed and then Nabucco is added to the system (left panel). The first column shows the Shapley values for the completion of all sections in percent of the total surplus. It should be compared to column 2 in Table 2. The difference between the two, i.e., the impact of the whole

²⁰In principle, the suppliers can compensate the members of the consortium for investment cost by providing cheap gas under long term contracts. We doubt, however, that countries like Azerbaijan and Iraq, not to speak of Iran, can credibly make such long term commitments.

²¹Since Nabucco's project cost do not account for investment in new fields such as Shah Deniz II in Azerbaijan or South Pars in Iran, such an increase would have to be achieved from current production capacities.

Table 4: Nabucco's Impact on Bargaining Power

	<i>without South Stream</i>				<i>with South Stream</i>

^aThe sections are:

TC (Trans Caspian) with 30 bcm/a and investment cost of 2.3 bn €.

ES (eastern section) pipelines between east Turkey and Azerbaijan, Iran and Iraq, each increased by 15 bcm/a. East to West Turkey enlarged by 30 bcm/a. Total investment cost 12.2 billion €.

CS (central section) with 30 bcm/a and investment cost of 1.9 billion €.

WS (western section) with 30 bcm/a and investment cost of 3.5 billion €.

^bdifference to column 6 table 3

project, is shown in column 4 under the header 'TC+ES+CS+WS'.

By bringing in new suppliers in the East and connecting them with the center of Europe's network Nabucco weakens the bargaining power of all old suppliers, but in particular Russia (-2.5 points). The lion's share of the benefits, however, accrues to Turkey (+2.1 points) and Iraq (+0.5 points) while the impact on the regions within the EU is surprisingly small. Balkan and Center gain 0.2 points each. Nabucco and the Trans Caspian Pipeline also do little to improve the position of Central Asian producers (here represented by Turkmenistan). We attribute this to the fact, that the new supply route has three transit countries of which Azerbaijan is also a competing producer.

In our baseline scenario, these percentage points amount to a gain of 3.5 bn €/a for Turkey and 1.0 bn €/a for the European members of the consortium together, which cover the annualized investment cost of app. 2.7 bn €/a (incl. TC 3.0 bn €/a). In view of these results, the EU's support of the project makes little strategic sense since major gains from the project accrue to Turkey, instead of the European players. Nabucco appears oversized given the current gas flows in the system.

It is also instructive to consider the effect of the different sections separately. Suppose only the sections in the East are built (TC and ES), which connect Turkey to the producers in the Middle East and Central Asia (second column). As increased supply competition harms other producers, in particular Russia, it benefits Turkey and to a much lesser extend Balkan. The effects on other EU regions are negligible, which is not surprising in view of the bottleneck between Balkan and the rest of Europe. Taken altogether, the pipelines in the East appear to have little effect on the power of the various (potential) producers in the region, such as Azerbaijan (0.1 points), Iran (-0.1 points), Iraq (0.5 points) because they can be played off against each other.

Next, we consider only the western section (WS) connecting Balkan and Central Europe (column three). This pipeline with a capacity of 30 bcm/a will hardly be used. Nevertheless, the option to move gas from the Northwest to the Southeast intensifies competition for customers in the Southeast which benefits Turkey and Balkan as well as producers in Northwest at the cost of Russia and producers in the Middle East and Caspian region. Some regions in the EU, such as Center, Center-East and France are slightly harmed from increased demand competition since Norway and Netherlands will gain better access to other markets. Again the effect on the EU as a group is negligible. With a total gain of 2.0 bn €/a and cost of 0.5 bn €/a the section would be a viable option for producers in Northwest together

with Turkey and Balkan. But it is difficult to envisage how such diverse players can implement a project, which has little potential to generate direct revenues. The ‘returns of the investment’ come only indirectly with Turkey paying less for gas from Russia and Iran and Central Europe paying more for gas from Norway and Netherlands.

Finally, we return to the perception that South Stream and Nabucco are competing projects and the concern that the former might preempt investment into the latter. In the right panel of Table 4 we show the strategic impact of Nabucco in a situation where South Stream and Nord Stream will be fully operational. Comparing the fourth column of the left and the second column of the right panel, we find very little difference. Even if fully implemented South Stream has almost no impact on the strategic viability of Nabucco.

3.4 Evaluating Network Power with the Core & Nucleolus

In the previous sections we considered a number of cooperative games, one for each configuration of the gas network. All these games had a non-empty core, but none of the Shapley values used to measure the impact of new pipelines was in the core of the respective game. The same is also true for the games we analyzed for our robustness checks. This observation raises the question, whether we obtain very different results for the strategic value of pipelines if we solve the network game with the core or related concepts.

Adding a pipeline to the system will increase the value of some coalitions, other coalitions will remain unaffected, but their value will never be decreased. As a result, the core will be compressed. But will the pipelines change the core systematically to the favor of the same players as they do for the Shapley value? As the core is a set, the answer will depend on which point in the core we select. Here, we consider the nucleolus which is in the core and can be considered as the lexicographical center of the game.

We computed the equivalent of tables 2-4 for the nucleolus to find results, which differ drastically from the previous ones. If power is measured with the nucleolus, none of the three projects has any strategic value at all — essentially because they have no significant impact on bargaining power. We abstain from printing the equivalent of tables 2-4 here, as all but the few instances we discuss in the text below are “0.0”. The tables are available in the appendix.

We start again with Nord Stream. There is only one country, which is slightly af-

ected by this huge project: Russia. But surprisingly its power is *reduced* by 0.1 percentage points even though the project will (weakly) increase the value of coalitions which include this countries.²² For all other players the impact of Nord Stream is minute and lost when rounding to the first decimal. For South Stream we find no effect whatsoever, even if the project is considered as an alternative to Nord Stream. Nabucco has some minor effects, which go in the same direction as under the Shapley value, but are smaller by order of magnitude. Russia and Ukraine lose 0.2 and 0.1 percentage points, respectively, while Turkey gains 0.2 and Balkan gains 0.1. The remaining countries are not affected. Overall, the impacts of the pipelines on the the power structure are smaller by orders of magnitude than the cost of these projects. As a result, no project had any strategic value if the players would assess network power with the nucleolus.

We also computed the minimum and the maximum a player can obtain in the core. For most players these two values define a narrow range around nucleolus. In this sense the nucleolus gives a reasonably precise estimate of the possible effects of a pipeline to a players payoff in the core. We take Russia and Nord Stream as an example. The pipeline *decreases* both, Russia's minimal and maximal payoff in the core by a small amount — as it does for nucleolus. If we go to the extreme and pick the smallest possible value in the core without Nord Stream and the largest possible value with Nord Stream, the small loss would turn into a small gain. However this gain would still be only a tenth of what Russia gains under the Shapley value — not enough to make Nord Stream viable. Since similar claims can be made for all other important players, our results for the pipelines' impacts under nucleolus yield a good picture for any other possible solution in the core.

4 Concluding Remarks

We analyzed the strategic impact of three large pipeline projects, Nord Stream, South Stream and Nabucco. Starting with a dis-aggregated quantitative model of the Eurasian network for natural gas, consisting of its major producers, customers and trunk-pipelines, we calculate the value function to characterize the interdependencies among the main actors in the current system. We solve the game with the Shapley Value, and the nucleolus as alternative indexes for the power of the differ-

²²It is well known that the nucleolus is not monotone, i.e. a player's payoff can decrease even if his contributions to coalitions weakly increase. Our result for Nord Stream prove that this is not a theoretical oddity.

ent players. Adding a new pipeline changes the network, hence the value function and as a result the power index. We identified those players who are set to gain in bargaining power from a specific pipeline link and those who will be harmed. Moreover, we obtain quantitative estimates of the size of these effects, which can be compared to the cost of the link.

For the Shapley Value we obtained intuitive results, which help to make sense of major developments in the industry. If considered as an alternative, both South Stream and Nord Stream have very similar effects on the power structure in the Eurasian transport network for natural gas. The pipelines bypass the transit countries Belarus and Ukraine and allow Russia to compete more effectively with Norway and Netherlands. Nord Stream's strategic impact can hardly be overstated. For the initiators of Nord Stream, Russia and Germany, the gains in bargaining power clearly justify the cost of investment. Russia had a very rocky relationship with both transit countries throughout the nineties and several attempts for a long-term solution covering transit fees, prices for gas imports and control of trunk-pipes failed. In view of our results, it is not surprising that in 2005 more cost efficient pipeline projects such as Yamal II (through Belarus) or the modernization of the Ukrainian system, have been abandoned in favor of the expensive direct offshore link.

The main beneficiaries of South Stream are Russia, Germany and some Central European countries. However, once Nord Stream's large capacities become operational, South Stream's additional leverage is much reduced and the gain in power barely compensate for the high cost. Not surprisingly, the project has been repeatedly delayed and if realized at all, it will be a scaled down version of the original project.

Nabucco opens a southern corridor through Turkey connecting Europe to new suppliers in the Middle East and the Caspian region. It also offers a new option to the producers in Central Asia, which currently ship gas through Russia. Initiated in 2009 the EU made Nabucco a major strategic project under its Trans-European Energy Networks (TEN-E) and substantial public funds have been earmarked for the project. In view of our results, this policy is difficult to rationalize. The project has large potential to decrease Russia's power, but the benefits would accrue mainly to Turkey, which could diversify its gas imports and become a major potential hub. The gains for the players in the EU, in contrast, are negligible. Again, the empirical evidence supports this assessment. The original consortium has disintegrated because it failed to command enough support from private investors such as Austrian

OMV and German RWE.²³

If we solve the network game with the nucleolus, however, we obtain results which appear counterintuitive and are difficult to reconcile with the construction of Nord Stream: None of these pipelines has any strategic value at all. The reward in terms of increased bargaining power is by several orders of magnitude smaller than the investment cost.

A Appendix

A.1 Calibration

This section describes the functions and parameters used for the calculation of the value function (equation (1) in the main text). Let f_{ij}^* , $\{i, j\} \in L(N)$ denote the solution to the program in (1) when solved for the grand coalition, which has access to all resources. To calibrate the model, p_i and T_{ij} have to be determined such that f_{ij}^* are reasonably close to observed consumption and flows. As it is assumed that the players cooperate effectively, they will make efficient use of the existing network. Hence, for each player the marginal willingness to pay for gas, $p_i(q)$ will be equal to the local marginal cost of supplying gas, i.e., the nodal cost $c_i(q)$, which take into account the physical constraints of the system. This feature is used to calibrate first inverse demand and then supply cost using data on consumption and flows.

Demand

Transport costs within Europe are small compared to the cost of producing gas and transporting it to Europe's borders. As a first approximation, the small differences among local costs are neglected, and a common constant supply cost c is assumed. When the program is solved for the grand coalition, none of the links within Europe are capacity constrained. So, nodal costs differ only by the variable transportation cost between connected nodes which are small.

Each consumption node's willingness to pay for gas is represented with a linear inverse demand function. To reduce the number of parameters, for all consumption nodes the same intercept $a + c$ is assumed. Efficiency requires $p_i(q) = a + c - b_i q = c$ for each consumption node i . The slope parameters b_i are then calibrated as to replicate the consumption in 2009: $b_i = a/q_i$, where q_i is the consumption of gas in the consumption node i . As illus-

^bTo reduce the number of players, Central Asia (Cent.Asia) stands for Kazakhstan, Turkmenistan and Uzbekistan.

trated in Figure 2, the surplus, which a player obtains from participating in the trade of pipeline gas, depends on three parameters: the difference between the demand intercept and the common supply cost a , its consumption in the base year q_i , and its indigenous production q_i^o . The common supply cost c acts as a shift parameter, which does not affect the surplus.

A change of a , with b_i being adjusted, affects all players proportionally. Such a change has little impact on the *relative* Shapley value (measured in percent of the total), hence, will have little effect on the relative index for bargaining power. However, a determines the absolute size of the surplus and thus, the *absolute* Shapley value, which is of relevance if the changes in bargaining power are compared to the cost of a pipeline project. It is difficult to support any assumption for a by hard data. Obviously, it will depend a lot on how much time customers are given to substitute to other sources of energy. Making a bold assumption, in the baseline variant a is

set equal to 1500 mn €/bcm yielding a total surplus from consuming gas of 949.9 bn €/a. To check the robustness of the results, a 'low-surplus' scenario with $a = 500$ is considered as well. Table 5 presents the resulting values of the slope parameter b_i depending on a . All quantities are quoted in bcm/a. All prices or costs are quoted in mn €/bcm, giving the same figure as the more common €/tcm.

The parameter c acts as a shift parameter for the demand system and supposed to reflect the typical production and the transportation cost. Accordingly, it is decomposed as $c = c^P + \bar{c}^T$, where c^P reflects a common production cost parameter and \bar{c}^T an adjustment made for typical transportation cost. These values determine the patterns of production and transport which are presented next.

Production

Table 6 presents the players' production capacities, production volumes in 2009 as well as production costs. The production volumes in 2009 are collected from IEA (2010, 2011). For the players except Russia and Turkmenistan the production capacities are assumed equal to their production volumes in 2009.

The differences in the production cost of existing fields are small compared to differences in the cost of developing new fields. Since meaningful information on wellhead production cost is difficult to obtain, a common supply cost parameter c^P is introduced. In accordance with Table 13.6 in IEA (2009), Δ_i accounts for regional differences in wellhead production cost and adjusts c^P for each player. For the players, who are net importers, cost of using their indigenous production is ignored. Since it is more difficult to produce at maximal capacity k_{ij} , production cost is assumed to be piecewise linear : $T_{ij}(f) = (c^P + \Delta_i)(\min[f, 0.75 * k_{ij}] + 1.2 \max[f - 0.75 * k_{ij}, 0])$. These adjustments help to get more realistic flows for the network, but have only a negligible impact on the estimate of bargaining power. Since the demand system is adjusted to any choice of c^P , its absolute value is rather irrelevant and arbitrarily set as $c^P = 20$ mn €/bcm.

Transport

The total cost of transporting gas consists of, in principle, operating cost and capacity cost. Since capacity costs of existing pipelines are sunk, they are not taken into account. This simplification is based on the assumption that bargaining among rational players should not be influenced by sunk cost. The operating

^aThe global parameter c_p is set equal to 20. Production cost of the players, who are net importers, is set equal to zero. The unit cost is given for flows up to 75% of the capacity. For the remaining 25% of capacity the numbers are increased by 20%.

^bTo reduce the number of players, Central Asia (Cent.Asia) stands for Kazakhstan, Turkmenistan and Uzbekistan.

cost is composed by management & maintenance cost and energy cost, which are proportional to the length of the pipeline as well as to the quantity of gas transported. The operating cost is represented as a piecewise linear function: $T_{ij}(f) = c_{ij}^T * (\min[f, 0.75 * k_{ij}] + 1.2 * \max[f - 0.75 * k_{ij}, 0])$, where k_{ij} denotes maximal capacity. Per unit transportation costs are constant, but only up to three quarter of the pipe capacity and increased by 20% for the remaining quarter. Capacities of the pipelines linking the players' transit nodes are collected from ENTSOG (2010) and public sources. Flows in 2009 are compiled from IEA (2010, 2011). Capacities of the pipelines which are connected to areas outside of the regional scope are limited to flows through them in 2009. The pipeline capacities and the flows through them are presented in columns 1 and 2 of Table 7, respectively.

To calculate the link specific cost parameter c_{ij}^T , for onshore pipelines universal operating cost of 0.3 mn €/bcm/100km is assumed. For offshore pipelines operating cost is 50% higher to account for higher pressure and increased difficulties of maintenance. These coefficients are then multiplied with the distance between the nodes to obtain the link specific operating cost as shown in column 3 of Table 7.

Having specified the production cost by c^P and Δ_i , as well as the link specific transportation cost by c_{ij}^T , the only free parameter is the 'typical' transport cost \bar{c}^T . To determine a value, the optimization program (1) is run for the grand coalition to find that $\bar{c}^T = 19$ mn €/bcm yields a solution f_{ij}^* which closely replicates the empirical data on consumption and flows in the system.

LNG

In the model the LNG gas is considered as nonstrategic since a single LNG exporter's market share in the Eurasian gas trade is small relative to the market power of the suppliers of the pipeline gas. Incorporation of the global LNG market into a cooperative game would be challenging. Since the LNG gas is a common source so that actions of players outside of the considered coalition would have to be taken into account. They will form alternative coalitions which may tap the LNG market and change the availability of the LNG supplies. Since the focus of the paper is on pipeline gas, the LNG market is not modeled explicitly.

The LNG regasification plants, also called terminals, are represented as LNG links with flows limited to the figures in the year 2009. The LNG regasification capacities and imports through them are compiled from GIE (2010) and IEA (2010, 2011). Comparing Tables 13.5 and 13.6 in IEA (2009), the total cost (sum of production

and transportation costs) of gas which is imported through the LNG terminals is assumed as $2c^P$. Similar to the production and transportation costs, total cost of LNG is assumed to be piecewise linear : $T_{ij}(f) = 2c^P(\min[f, 0.75 * k_{ij}] + 1.2 \max[f - 0.75 * k_{ij}, 0])$. Parameters for the LNG links are given in Table 8.

New Projects

Information about the pipeline projects is obtained from various public sources. Cost estimates of the project consortia are supplemented by own estimates if figures are unavailable, outdated or subject to review. A rather high discount rate of 15% is used to translate capital expenditures into annualized capacity cost. This rate is a common hurdle rate in the gas industry and reflects the real option nature of the investment and depreciation. Table 9 collects the parameters for the new pipelines.

A.2 Robustness

The previous results depend on a number of parameter assumptions and we will briefly discuss, how robust they are.

The power index, as measured by the relative Shapley Value depends largely on architecture of the current network and access rights and is quite robust with respect to a proportional change of surplus in all regions or a uniform modification of production cost of all suppliers. Our conclusion about the strategic viability of

additional pipelines, however, compares absolute cost to absolute gains. To check robustness we reduced the surplus to its one third by uniformly decreasing the demand intercept for the customers while adjusting the slope to replicate consumption in the reference year. More pipelines and pipeline sections become strategically unviable, but the relative merits of the different projects do not change much. The benefit to cost ratio remains by far highest for Nord Stream, both from the perspective of the consortium and from the viewpoint of the EU. For the EU it is lowest for Nabucco and from the viewpoint of the respective consortium, South Stream remains the least attractive proposition.

The reduction in surplus does not change our conclusions derived by the absolute and relative nucleolus. Nord Stream and South Stream alter the power structure barely, and gains accruing from Nabucco to its consortium falls short to cover the project's large cost. However, impact of Nabucco measured by the relative nucleolus is not robust with respect to the reduction in surplus. While Turkey and Balkan gain more, Russia suffers a larger loss.

Next, we reconsider our assumption of free third party access within the European Union. When the European Commission started its policies to ensure a common market for natural gas in the late nineties, the situation was indeed very different. Most countries had a 'national champion' who monopolized the high pressure transportation grid, hence long distance transport, and one might argue that it is still a long way to overcome this fragmentation of the market. In a fragmented market, a region in the EU enjoys exclusive access to its trunk-pipes and can derive power by blocking gas shipments. As a rule, European regions, which neighbor a producer or a transit country, gain transit power, while importers without Non-European borders suffer in a fragmented market compared to an integrated one (see Hubert & Orlova (2012) for a detailed analysis).

The impact of a change of access rights on the relative bargaining power of the players is quite substantial. When measured by the Shapley value, the effect of additional pipelines in the new setting is similar and most of our conclusions regarding the strategic viability of the various projects remain valid. There is one minor exception. The incremental gain through the central and western sections of Nabucco are amplified. In an otherwise fragmented market, these sections of Nabucco, which will be open for access by third parties, have a stronger impact on the power structure.

When measured by the nucleolus, in the new setting Nord Stream alters the power of the European players substantially. However, the project is still strategically un-

viable for its consortium, and negative benefits accrue to Russia. Again, South Stream has negligible impact on the power structure.
