THE INFORMATION CONTENT OF MONEY AND CREDIT FOR US ACTIVITY*

Bruno Albuquerque[§], Ursel Baumann[‡] & Franz Seitz[†]

February 2015

Abstract

We analyse the forecasting power of different monetary aggregates and credit variables for US GDP. Special attention is paid to the influence of the recent financial market crisis. For that purpose, in the first step we use a three-variable single-equation framework with real GDP, an interest rate spread and a monetary or credit variable, in forecasting horizons of one to eight quarters. This first stage thus serves to pre-select the variables with the highest forecasting content. In a second step, we use the selected monetary and credit variables within different VAR models, and compare their forecasting properties against a benchmark VAR model with GDP and the term spread. Our findings suggest that narrow monetary aggregates, as well as different credit variables, comprise useful predictive information for economic dynamics beyond that contained in the term spread. However, this finding only holds true in a sample that includes the most recent financial crisis. Looking forward, an open question is whether this change in the relationship between money, credit, the term spread and economic activity has been the result of a permanent structural break or whether we might go back to the previous relationships.

Non-technical summary

Economists and forecasters alike were widely surprised by the sudden onset and the depth of the Great Recession of 2007-09. While the unprecedented scale of the recession was arguably quite challenging to be foreseen, the commonly held view is that most economic models failed to predict the financial crisis mainly because they were not taking sufficiently into account the interaction between financial variables and real activity. Against this background, our aim is to revisit and explore the informational content of money and credit, in order to draw conclusions as to whether stronger attention should be set on such variables to improve the forecasting of US activity.

In this paper we analyse the role of a large set of money and credit variables to forecast real activity in the United States, given the information content of interest rate spreads. Selection of the preferred money and credit variables is done via a single-equation forecasting procedure using a sample covering the period 1985Q1-2012Q4. The performance of these variables is then assessed within different small-scale VAR models relative to a benchmark VAR model with GDP growth and the term spread. In this forecasting exercise, we also account for the 2007-09 international financial crisis, which might have created a structural break and changed the relationship between some of the variables.

Our preferred money variables are M1 plus sweeps into money market deposit accounts and currency in circulation. The credit variables selected are credit to the private non-financial sector and total mortgages of the private non-financial sector, as well as tightening standards on residential mortgages. These credit variables have become particularly relevant when including the recent business cycle, where the housing and thus the mortgage market played an important role.

The key findings of the paper support the view that in most cases, and for all forecasting horizons considered (up to 2 years), our small-scale VAR models with money or credit variables are able to outperform the benchmark in rolling (but not in recursive) forecasting exercises over a sample that includes the most recent crisis period. In the pre-crisis sample, however, most of our selected VAR models with money or credit seem not to have additional information content for predicting GDP growth beyond that contained already in the term spread.

Our main findings suggest that money and credit variables together with the term spread should be taken into account when forecasting real activity in the United States. Nevertheless, these findings are mainly the result of a change in the relationship between money, credit, the term spread and GDP growth since the 2007-09 financial crisis. Looking forward, an open question is thus whether the change in this relationship is permanent or whether we might go back to the previous trends.

1. Introduction

Economists and forecasters alike were widely surprised by the sudden onset and the depth of the Great Recession of 2007-09. While the unprecedented scale of the recession was arguably quite challenging to be foreseen, the commonly held view is that most economic models failed to predict the financial crisis mainly because they were not taking sufficiently into account the interaction between financial variables and real activity. Moreover, against the background of modern monetary policy frameworks that have a substantial emphasis on inflation targeting, the analysis of monetary variables has lost some of its previous relevance.¹ Against this background, our aim is to revisit and explore the informational content of money and credit, in order to draw conclusions as to whether stronger attention should be set on such variables to improve the forecasting of US activity.

The analysis of the role of money and credit for output has a long history. Empirical evidence on the money-output nexus for the United States is mixed.² On the one hand, Amato and Swanson (2001), Berger and Österholm (2009), Estrella and Mishkin (1997), Feldstein and Stock (1997) and Friedman and Kuttner (1992) tend to cast doubt on the role of money for predicting economic activity. In contrast, Aksoy and Piskorski (2005; 2006), Darrat et al. (2005), Favara and Giordani (2009), Hafer et al. (2007), Nelson (2002), Swanson (1998) and Vilasuso (2000) find that there is information in money for predicting output. The latter authors often exclude certain monetary assets from the official aggregates or re-define money. For example, Darrat et al. (2005) emphasise that the forecasting power of money depends heavily on whether simple sum or Divisia measures of money are used, with positive results for money only holding for Divisia money; Aksoy and Piskorski (2005; 2006) exclude foreign holdings of cash in their analysis. In contrast, the older literature on the US economy usually found that official monetary aggregates play a causal role in output (see, e.g., Sims, 1972, 1980).

A large empirical literature has established statistically significant positive effects of credit growth to the non-financial sectors in the United States on (national and international) output growth (see, e.g. Gambetti and Musso, 2012; Lown and Morgan, 2006; and Xu, 2012). Additionally, Schularick and Taylor (2012) demonstrate that credit growth is a powerful predictor of financial crises which, in turn, produce large output costs. Interestingly, and in contrast to the findings for the money-output relationship, the results for the United States with credit variables are not too different from those for the euro area (see, e.g., Gambetti and Musso, 2012). Den Haan et al. (2007) highlight the importance of distinguishing between different kinds of loans, especially between commercial and industrial loans on the one hand and real estate and consumer loans on the other.

¹ See for example Carlstrom and Fuerst (2004).

² The evidence in the euro area seems to suggest that especially narrow monetary aggregates, such as M1, outperform the yield spread in terms of its predictive content for cyclical movements in GDP (see Brand et al., 2004).

Many authors have shown that interest rate spreads contain useful information for future real developments in the United States (see, e.g. Adrian and Estrella, 2009; Ang et al., 2006; Estrella and Trubin, 2006; Hamilton and Kim, 2002; and Rudebusch and Williams, 2009).³ This is especially true for the term spread – the difference between long-term and short-term rates. Many studies attribute the forecasting content of the term spread for activity to the impact that monetary policy has on both short- and long-term interest rates and thereby on output growth. A tightening of monetary policy undertaken to bring down inflation and stabilise the deviation of output growth around its potential value likely causes short term interest rates to rise by more than long term rates, leading to a flattening of the yield curve or a decline in the term spread. Adrian and Estrella (2010) put forward another link between the term spread and economic activity, suggesting that when the term spread narrows, and since banks borrow short but lend long, the marginal loan becomes less profitable for the banks, leading to lower credit supply in the economy and consequently lower economic activity (the so-called risk-taking channel). However, the link between the term spread and activity seems to have become weaker or even disappeared since the mid-2000s (see de Pace and Weber, 2013, and the survey of Wheelock and Wohar, 2009).

In this paper, we use a comprehensive set of monetary and credit variables to investigate whether any of these helps to predict US GDP developments beyond the influence of interest rate spreads. Our results suggest that particularly narrow monetary aggregates as well as different credit variables do a good job in forecasting US GDP growth. In particular, our paper supports the view that for all forecasting horizons considered (up to 2 years), our small-scale VAR models with money or credit variables are able to outperform a benchmark VAR with GDP growth and a term spread in rolling forecasting exercises over a sample that includes the most recent crisis period. In the pre-crisis sample, however, most of our selected VAR models with money or credit seem not to have additional information content for predicting GDP growth beyond the information contained already in the term spread.

Overall, our main findings suggest that money and credit variables together with the term spread should be taken into account when forecasting real activity in the United States. Nevertheless, these findings are mainly the result of the change in the relationship between money, credit, the term spread and economic activity since the 2007-09 financial crisis. Looking forward, an open question is thus whether the change in this relationship is permanent or whether we might go back to the previous trends.

The remainder of the paper is organised as follows. In the next section, we describe briefly the data used in the paper, whereas in Section 3, we introduce a single-equation approach to help select the

³ This holds also for many other countries (see, e.g., Ivanova et al., 2000 and Buchmann, 2011). Nevertheless, Ratcliff (2013) finds that while the term spread is useful in predicting whether there will be a recession or not, it does a poor job in capturing the probability of a recession.

money and credit variables to be used in the following forecasting exercises. In Section 4, we first describe the benchmark model, which will be used as a reference when assessing the relative forecast accuracy of different VAR models and, subsequently, the forecast results stemming from these VAR specifications. Section 5 concludes.

2. Data

We use seasonally-adjusted quarterly data for the sample 1985Q1-2012Q4. US activity is measured by chain-linked real Gross Domestic Product (at 2009 prices). As the yield curve, and especially the term spread, has proven to be a good leading indicator in the United States, we always include a spread variable in our regressions. The different spreads tested are term spreads, bond spreads, lending spreads and the external finance premium (see Appendix A for details).

The models below with real GDP and one of the spread variables are augmented with one money or credit variable at a time, to yield a 3-variable regression framework. In total, we consider 30 monetary aggregates and 15 credit variables (see Appendix A). To calculate real variables, we deflate nominal variables with the personal consumption expenditures (PCE) deflator provided by the Bureau of Economic Analysis.⁴ All variables have been transformed into logarithms, with the exception of the spread and the data from the Federal Reserve Board's Senior Loan Officer Opinion Survey (SLOOS), for which a level specification was taken into account.

We do not use real-time vintages of the data, but the revised and latest available figures because we are interested in what actually happens to the economy, not in an assessment of preliminary announcements of economic growth (see Ang et al., 2006). Charts of the main variables used are shown in Appendix B.

3. Single-equation approach

3.1. Econometric framework

Hamilton and Kim (2002) establish the importance of the yield spread for forecasting real output growth in the United States for the period 1953Q2 to 1998Q2. They use the following equation:

$$(1) \quad \Delta y_t^h = \alpha_0 + \alpha_1 spread_t + \alpha_2 x_t + \varepsilon_t,$$

where $\Delta y_t^h = \frac{400}{h}(\ln Y_{t+h} - \ln Y_t)$ is the annualised real GDP growth over the next h quarters (and Δ is the difference operator), $spread_t$ is the term spread (the 10-year Treasury Note yield minus the 3-month Treasury Bill yield), x_t is a vector of alternative explanatory variables (e.g. growth rates of M1,

⁴ Bullard (2013) presents some reasons why the PCE should be preferred over the Consumer Price Index (CPI).

M2 and lagged growth rates of GDP) and ε_t is a white noise error term. Their general conclusion is that the term spread is especially useful in predicting real GDP growth up to two-years ahead. Whereas the coefficient on M1 is generally not statistically different from zero (and sometimes has the wrong negative sign), M2 exhibits statistically significant results with a positive sign for up to $h = 16$ quarters.

In order to present some preliminary evidence on the role of money and credit for real GDP and, at the same time, to pre-select variables, we update the results by Hamilton and Kim (2002) by using an analogous single equation approach with the term spread as a starting point. For x_t , we take the different monetary or credit variables in real terms mentioned above. We estimate (1) with OLS with the Newey and West correction for heteroscedasticity and autocorrelation. Our forecasting horizon ranges from $h = 1, \dots, 8$ quarters. In order to control for the 2007-09 international financial crisis, which might have created a structural break and changed the relationship between some of the variables, making it more challenging to forecast economic activity (see Ng and Wright, 2013), we distinguish between two different samples: the full sample goes from 1985Q1 to 2012Q4, while the shorter sample stops in 2007Q4. This procedure should help to identify to which degree the results are distorted by the crisis period. Money and credit are judged to be helpful in forecasting GDP if α_2 is statistically significant (at least at the 10 % level of significance).

3.2. Results

3.2.1. Monetary aggregates

Money (m) enters Equation (1) in annual growth rates. Irrespective of the sample considered – including or excluding the crisis period – the results are generally promising, i.e. statistically significant, for all leads of M1 plus sweeps into money market deposit accounts, and currency in circulation, both with or without adjusting for currency abroad (see for the latter, Aksoy and Piskorski, 2005, 2006), as well as the Monetary Service Index M1 (see Table B1 in Appendix B with the R-squared of all equations for all forecast horizons and for the full sample). These are all transactions-oriented narrow monetary aggregates which highlight money's unique role for transactions purposes. Therefore, they should in principle have the closest relation to expenditures and real GDP, which turns out to be the case. The results for the narrow Divisia Index are in line with Gogas et al. (2014), but in contrast to Schunk (2001) who presents evidence supporting the broad Divisia monetary aggregates as the dominant predictors of real GDP.⁵ Some of the money variables are distorted by the crisis period, in the sense that they are only statistically significant up to 2007, such as currency plus demand deposits and the monetary base (adjusted or unadjusted). The latter result is not surprising, given the unprecedented large increase in banks' reserves at the Federal

⁵ Belongia and Ireland (2012) show that the relative forecasting performance of different Divisia money depends on the real variable considered.

Reserve since the outbreak of the crisis, which has not pushed up US GDP growth as much as suggested by historical norms. For all other monetary aggregates, especially official simple-sum M1, M2 and MZM, the estimates are not statistically significant.

The results of the two best performing models, both in terms of the R-squared and statistical significance (for the full and the restricted sample), are shown in Table 1. They refer to M1 plus sweeps into money market deposit accounts (*m1*) and currency in circulation (*cu*). These are the monetary aggregates which we include in the Vector Autoregressive Models (VAR) analysis in Section 4. The term spread (*Spread*) is generally not significant when taking money additionally into account. However, there is some (weak) evidence that the term spread is statistically significant in the longer leads ($h=4, \dots, 8$) when excluding the crisis period. This is surprising as most studies find that the term spread is a good predictor for output growth up to one year in advance (see Wheelock and Wohar, 2009). Using a comparable single-equation exercise, Hamilton and Kim (2002) find that official M1 (however with the wrong sign) and M2 are significant together with the term spread for short and long leads in a sample from 1959 to 1998.

Notes: OLS estimates with the Newey-West correction for heteroscedasticity and autocorrelation. The dependent variable is annualised real GDP growth. Standard errors are shown in parentheses. Asterisks, *, **, ***, denote, respectively, statistical significance at the 10, 5 and 1% levels.

The fact that the term spread appears to be statistically more powerful in the sample that excludes the crisis period might be related to the nature of the 2007-09 financial crisis which appears to have made credit/corporate spreads more important than the term spread. Ng and Wright (2013) argue that, although the forecasting performance of the term and credit spread is somewhat episodic, the forecasting accuracy of credit spreads over the term spread has improved since the early-2000s due to two fundamental reasons. First, credit spreads are more useful in forecasting economic activity in the presence of a more highly leveraged economy, where developments in financial markets imply that credit spreads provide more information than before. Second, the Great Recession was rooted in excess leverage and the housing and credit market bubble, which have made credit spread developments central in trying to forecast economic activity. Our results for the term spread are also consistent with the literature, as several recent studies summarised in Wheelock and Wohar (2009) find that the term spread's forecasting power for US output has diminished in recent years.

3.2.2. Credit variables

Like with monetary aggregates, the credit variables are in annual growth rates. In contrast, the SLOOS survey data enter Equation (1) in levels, and the sample begins in 1990Q3 due to data availability. Within credit variables, we distinguish between three main groups: credit growth, credit impulse, and credit standards. As regards the first group, in general all credit growth variables yield statistically significant results for all leads, with the exception of unadjusted real estate loans. Interestingly, the predictive power of credit to the private non-financial sector (particularly mortgage credit), and break-adjusted real estate loans before the crisis do not pass the conventional statistical significance levels, implying that the forecasting power of these variables is only due to the crisis period. The term spread is usually highly statistically significant regardless of the sample period, contrasting with the results for money variables. This implies that the term spread contains information beyond that inherent in credit aggregates, whereas this information seems to be incorporated already in monetary aggregates. As with money, we select from Table B1 in Appendix B the two preferred credit growth variables to be included later in the VARs (Table 2). These are credit to the private non-financial sector (*cr_pr*) and total mortgages of the private non-financial sector (*mo_pr*).⁶

⁶ Based on economic reasoning, we choose these two variables over break-adjusted real estate loans in bank credit, and break-adjusted bank credit. While the R-squared is broadly the same, credit to the private non-financial sector and total mortgages of the private non-financial are broader, enabling us to capture a wider and a more important fraction of the credit segment in the United States.

Notes: OLS estimates with the Newey-West correction for heteroscedasticity and autocorrelation. The dependent variable is annualised real GDP growth. Standard errors are shown in parentheses. Asterisks, *, **, ***, denote, respectively, statistical significance at the 10, 5 and 1% levels.

As alternative to credit growth, we also analyse credit impulse variables (ci_t), which might contain useful signals. These are based on the *change* in flow of credit, and defined as follows:

$$(2) \quad ci_t = 100 \left(\frac{cr_t - cr_{t-1}}{Y_{t-1}^n} - \frac{cr_{t-4} - cr_{t-5}}{Y_{t-5}^n} \right),$$

where cr_t is the stock of nominal credit and Y^n refers to nominal GDP. The choice of this variable is motivated by Biggs et al. (2009) who argue that, to the extent that spending is credit financed, GDP is

a function of *new* borrowing, i.e. the flow of credit. If this is true, GDP growth should be related to changes in the flow of credit (or the second derivative of the stock) rather than changes in the stock. However, since this theory is subject to some controversy, where the literature has not yet reached a consensus on its appropriateness and validity, we present the results only in Appendix B as a side check and as additional information. The results of the selected credit impulse variables (consistent with the credit growth variables considered above, i.e. *ci_cr_pr* and *ci_mo_pr*) are shown in Table B2 in Appendix B.

Finally, all credit standard variables also reveal forecasting properties for GDP growth, in line with the findings by Cunningham (2006), Lown and Morgan (2006) and Kishor & Koenig (2014). Cunningham (2006) has shown that the SLOOS's ability to predict GDP (especially the C&I series) does not extend beyond the simple prediction of one of its components (private investment). In our results, the financial crisis distorted the predictive power of the tightening standards on consumer credit cards, which only have forecasting power when excluding the crisis period. Conversely, and interestingly, the statistical significance of banks' willingness to lend to consumers and tightening standards on consumer loans excluding credit cards in the full sample is driven solely by the crisis period. These results are in line with Cunningham (2006), who finds that survey results directed specifically at consumer lending market conditions never significantly foreshadow changes in personal consumption expenditures.⁷ The term spread is generally not significant, again in line with Cunningham's (2006) results, which reveal that the term spread loses predictive power once variables from the SLOOS are included. The best performing credit standard variable that we have chosen to feed into the VARs in the next section is also shown in Table 2. It refers to tightening standards on residential mortgages (*tight*).

4. VAR analysis

We now analyse the predictive content of the five monetary and credit variables, which were selected before, with the help of VARs. The variables are: M1 plus sweeps into money market deposit accounts (*m1*), currency in circulation (*cu*), credit to the private non-financial sector (*cr_pr*), total mortgages of the private non-financial sector (*mo_pr*), and tightening standards on residential mortgages (*tight*). Results for the credit impulse variables are shown in the appendix. We restrict ourselves to a 3-dimensional system in which we add to one of these five variables real GDP and a spread. Our choice of small, parsimonious VARs stems from the fact that it has been found in the literature that these types of models with a limited number of variables perform fairly well in forecasting exercises, especially during periods characterised by structural breaks, which are known to make VARs with a large number of variables fairly sensitive to changes in the specification (see for

⁷ Kishor & Koenig (2014) establish that banks' willingness to lend is especially helpful in real-time forecasting.

instance Clark and McCracken, 2007 and Elbourne and Teulings, 2011). Moreover, by choosing small-scale VARs we avoid losing too many degrees of freedom.⁸

4.1. Benchmark model

The performance of the VAR models will be assessed against a benchmark model. As benchmark, we use a VAR model with GDP growth and the term spread over the period 1985Q1 to 2012Q4. The selection of the lag order h is based on the Akaike (AIC) and Schwarz (SC) information criteria (see Lütkepohl, 1993), with a maximum of eight lags considered. We then make sure that no residual autocorrelation remains present by conducting VAR residual Portmanteau tests for autocorrelation up to lag h and serial correlation Lagrange-Multiplier tests at lag order h . We end up selecting 2 lags, which are sufficient to ensure white noise residuals. In addition, we have tested two alternative benchmark models, but find that their predictive power is worse than the main VAR benchmark specification (see Appendix C for more details on the alternative benchmarks).⁹

4.2. Difference VARs

We focus on VAR models in first differences (except for the spread, credit standards and credit impulse variables) as in the presence of large structural breaks – in our sample represented by the recent financial crisis – such models may be particularly promising because the break has less of a persistent impact than in VARs in levels or in VECMs (see Clements and Hendry, 1998, chs. 6 and 7). Similarly to the single-equation exercise reported in Section 3, we always include a money or credit variable in the VARs, a spread term and real GDP. As regards the spread, we use the term spread in our baseline models, but experiment with alternative spreads in Section 4.2.3.

As with the benchmark, the selection of the lag order is based on the AIC and SC information criteria, with a maximum of eight lags considered. The resulting lag choices of our preferred models are reported in Table B3 in Appendix B. It is evident that in most cases up to 2 lags are enough to ensure white noise residuals. Only credit variables sometimes require richer dynamics.

⁸ An alternative approach is proposed by Alessandri & Mumtaz (2014), who use a Financial Conditions Index (FCI) constructed using dynamic factor analysis from a set of over 100 series describing money, debt, equity markets and the leverage of financial intermediaries. With monthly data from 1983 until 2012 they find that the FCI significantly improves the accuracy of Bayesian predictive distributions for output growth measured by industrial production.

⁹ In addition, we compared the forecast errors of our models to the errors obtained by using the median forecasts from the Survey of Professional Forecasters (SPF) up to four quarters ahead. Although we are not able to beat the SPF over these horizons, the forecasting performance of our models is not very different from the SPF. Moreover, the VAR models have the advantage of being timelier, as we are able to produce a 1-step ahead forecast already one month after the end of a quarter, whereas the SPF is released only two weeks after this date.

4.2.1. Recursive out-of-sample forecasts

We *recursively* estimate the different VAR specifications including the best-performing money and credit variables selected via the single-equation exercise in Section 3. The initial sample covers the period 1985Q1 to 2005Q4, to which we add an additional quarter at a time and recursively conduct out of sample forecasts for up to eight quarters ahead.¹⁰

The recent financial crisis that started in late 2007 may have led to a structural break in the relationship between money, credit and economic activity. Going forward, it is an open question whether this change is a permanent structural break or whether we might go back to the previous relationships. To investigate whether the forecasting performance of the alternative variables has changed since the financial crisis we distinguish between two different forecasting samples: one that ends in 2007Q4 (with estimation until 2000Q4), so as to avoid the crisis period and subsequent recovery, and a second sample that includes the full period, ending in 2012Q4 (estimation period until 2005Q4).

Table 3 presents the root mean squared forecast errors (RMSFEs) of the different VAR specifications relative to the benchmark model. The results suggest that money and credit variables contain valuable information for forecasting GDP growth, thus confirming the single equation exercises. Almost all models for the full sample presented in Table 3 beat the benchmark model at all $h=1$ to 8 forecasting horizons, as indicated by a relative RMSFE smaller than one. But in most cases, this difference is not statistically significant at conventional levels, based on the Newey-West corrected Diebold-Mariano test statistics (see Diebold, 2012). Nevertheless, some of the models do a good job at longer horizons: notably the two money variables and the model with total mortgages outperform the benchmark in a statistically significant way.

However, excluding the period covering the financial crisis and subsequent recovery changes the results substantially. Information from the pre-crisis sample suggest that before the crisis, the VAR with money or credit variables does not contain additional information content for predicting GDP growth beyond that contained already in the term spread and past GDP growth. This is in line with the findings from the literature that the term spread had been a good predictor of activity in the past but that this link may have been become weaker or even disappeared more recently (de Pace and Weber, 2013; Wheelock and Wohar, 2009).¹¹ Using as a different benchmark a simple autoregressive model of GDP growth (thus leaving out the term spread from the regressions), the VARs with money or credit still beat the benchmark in a statistically significant way, as their predictive power likely comes from the term spread (see Appendix C).

¹⁰ The estimation sample for the VAR with credit standards begins in 1990Q3 due to a lack of data availability.

¹¹ The loss in the predictive power of the term spread can, for example, be seen in the substantial increase in the RMSFE from the pre-crisis sample to the full sample (RMSFEs in the pre-crisis sample are on average around 58% smaller).

Table 3: Relative RMSFE of recursive out-of-sample forecasts for different

	Forecast horizon							
	1	2	3	4	5	6	7	8
<i>Full sample</i>								
Benchmark model	0.007	0.014	0.021	0.027	0.034	0.040	0.045	0.051
<i>ml</i>	0.95	0.94	0.91	0.90	0.89*	0.89**	0.91**	0.93**
<i>cu</i>	0.91	0.84	0.76	0.71*	0.70*	0.71**	0.74**	0.77**
<i>cr_pr</i>	1.03	1.02	1.00	0.98	0.97	0.96	0.97	0.97
<i>mo_pr</i>	1.01	0.92	0.87	0.84	0.81	0.79*	0.79*	0.80*
<i>tight</i>	0.83	0.82	0.77	0.79	0.83	0.87	0.90	0.94
<i>Pre-crisis</i>								
Benchmark model	0.004	0.007	0.010	0.011	0.012	0.014	0.015	0.017
<i>ml</i>	1.00	0.99	0.99	1.00	1.01	0.99	0.97	0.94*
<i>cu</i>	1.00	1.01	1.03	1.04	1.04	1.02	1.00	0.99
<i>cr_pr</i>	1.04	1.03	1.04	1.06	1.08	1.08	1.07	1.05
<i>mo_pr</i>	1.09	1.06	1.05	1.05	1.06	1.06	1.06	1.06
<i>tight</i>	1.06	1.07	1.1	1.11	1.13	1.11	1.08	1.08

Notes: The 1- to 8-quarter ahead out-of-sample forecasts have been estimated recursively, using 1985Q1 to 2005Q4 as the starting sample (1985Q1 to 2000Q4 for the pre-crisis sample), and then adding one more quarter at a time. The full sample goes up to 2012Q4, whereas the pre-crisis sample stops at 2007Q4. The variable *ml* is M1 plus sweeps into money market deposit accounts, *cu* is currency in circulation, *cr_pr* is credit to the private non-financial sector, *mo_pr* is total mortgages of the private non-financial sector, and *tight* refers to tightening standards on residential mortgages. The reported RMSFE is the ratio between the RMSFE of the several VAR specifications and the one from the benchmark model, implying that values below 1 indicate that the VAR model outperforms the benchmark. The absolute RMSFE for the benchmark model is also reported. Significance levels are based on the Newey-West corrected Diebold-Mariano test statistics (see Diebold, 2012). Using the standard Diebold-Mariano statistic improves somewhat the significance of the results shown in the table (available upon request). Asterisks, *, **, ***, denote, respectively, statistical significance at the 10, 5 and 1% levels.

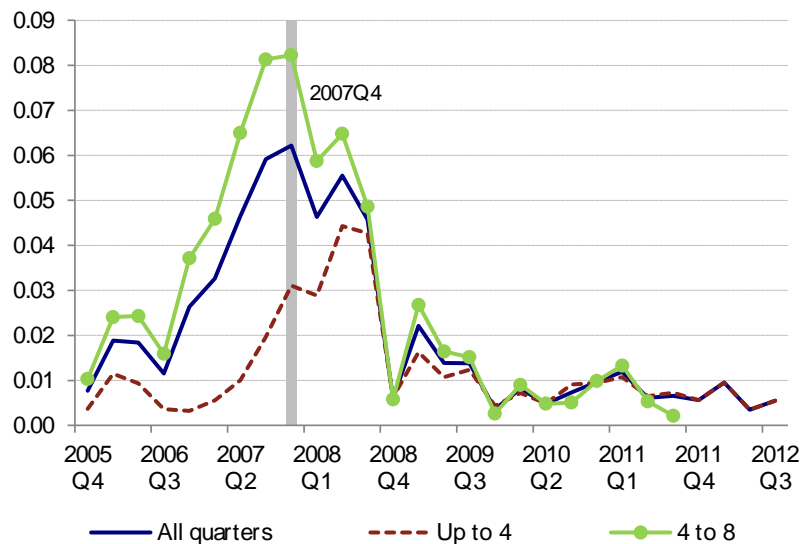

As regards credit impulse variables, the forecasting performance of the model with the narrower measure referring only to mortgages performs significantly better than in the pre-crisis sample (see Table B4 in Appendix B). This finding may be explained by the fact that the housing boom and subsequent bust, and therefore mortgage credit, were at the epicentre of the 2008-09 financial crisis in the United States. Furthermore, the finding that credit impulse variables add generally information content for predicting GDP growth is in line with the proposition by Biggs et al (2009) that *changes* in the flow of credit matter most for GDP growth. Moreover, the authors' conclusion that the credit impulse measure should be based on the broadest possible credit aggregate to the non-financial private sector is also in line with our findings.

Further evidence on how the recent financial crisis has impacted the forecasting performance of our models is provided in Chart 1, which shows the RMSFEs over time around the crisis period, averaging the forecast errors for up to four quarters, four to eight quarters and all horizons. The chart refers to the VAR with currency, but the results for the models with other money and credit variables are broadly similar. The RMSFE started increasing as the quarter corresponding to the start of the US recession (2007Q4), as defined by the National Bureau of Economic and Social Research (NBER),

approached. This is not surprising, as the forecasting performance of all (linear) models deteriorated around that time. As more of the observations from the crisis period were included and as the sharp declines in GDP growth moderated, the accuracy of the model started to improve again, reflected in a gradually declining RMSFE.

Chart 1: Forecasting accuracy over time around the financial crisis

(RMSFE)

Notes: RMSFE over time for the VAR with GDP growth, the term spread and currency. Up to 4 (4 to 8) refers to an average RMSFE for horizons 1 to 4 (4 to 8).

4.2.2. Accounting for structural breaks: constant rolling window

Both the recursive forecasting exercises as well as the selection of the variables within the single-equation procedure advise us to be careful when estimating and forecasting over a period which includes the financial turbulences that struck the US economy in late 2007. Giacomini and White (2006) offer a solution to this problem of data heterogeneity and structural shifts, by proposing a rolling-window forecasting scheme to supplement or replace the recursive procedure. They argue that in such environments, the use of an expanding estimation window is not appropriate, as observations from the distant past start losing at some point their predictive relevance. Therefore, they suggest that it is better to base the forecasts on a moving window of the data that discards gradually older observations.

In what follows, we combine a constant estimation window of 64 quarters with our $h=1, \dots, 8$ forecast horizons having 41 forecasts each. The full sample ends once again in 2012Q4, while the pre-crisis sample stops in 2007Q4. To be specific, our first estimation sample starts in 1985Q1 and ends in 2000Q4. After having done our up to 8 quarter-ahead forecasts, we proceed to the next estimation sample which runs from 1985Q2 to 2001Q1, and do again the forecasts for up to 8 quarters, and so on

and so forth until the last observation where it is possible to forecast eight quarters ahead is reached. The results of these rolling regression exercises in the form of relative RMSFEs are shown in Table 4. The five different models all outperform the benchmark model in a statistically significant way in the full sample. Compared to the recursive forecasts (Table 3), and in line with the suggestions by Giacomini and White (2006), the significance of the rolling out-of-sample forecasts is considerably higher.¹² The best model for the shortest horizon is the money model that refers to M1 plus sweeps into money market deposit accounts. For the remaining horizons, the models with currency in circulation and with total mortgages to the private non-financial sector are consistently the best ones, with a statistically significant large improvement from the VAR benchmark model. This result is broadly in line with the findings from the recursive forecasts. Another common feature shared with the recursive approach is that in the pre-crisis sample the VAR models with money or credit seem not to have additional information content for predicting GDP growth beyond that contained already in the term spread, with the exception of currency in circulation at longer horizons.

Table 4: Relative RMSFE of constant rolling out-of-sample forecasts for different VARs

	Forecast horizon							
	1	2	3	4	5	6	7	8
<i>Full sample</i>

tight	0.82	0.83	0.81*	0.82**	0.83**	0.84**	0.86**	0.88***
<i>Pre-crisis</i>								
Benchmark model	0.004	0.007	0.009	0.010	0.010	0.012	0.013	0.015
ml	1.00	0.97	1.00	1.04	1.11	1.11	1.06	1.00
cu	1.03	1.01	0.94	0.90*	0.80**	0.74*	0.69**	0.72**
cr_pr	1.00	1.01	1.00	1.03	1.06	1.06	1.06	1.06
mo_pr	0.88	0.91	0.93	0.93	0.93	0.91	0.90	0.90
tight	1.03	1.01	1.05	1.07	1.10	1.11	1.10	1.09

Notes: The 1- to 8-quarter ahead out-of-sample forecasts have been estimated with a constant number of observations, using 1985Q1 to 2000Q4 as the starting window, and then rolling the window one quarter at a time. The full sample goes up to 2012Q4, whereas the pre-crisis sample stops in 2007Q4. The variable *ml* is M1 plus sweeps into money market deposit accounts, *cu* is currency in circulation, *cr_pr* is credit to the private non-financial sector, *mo_pr* is total mortgages of the private non-financial sector, and *tight* refers to tightening standards on residential mortgages. The reported RMSFE is the ratio between the RMSFE of the several VAR specifications and the one from the benchmark model, implying that values below 1 indicate that the VAR model outperforms the benchmark. The absolute RMSFE for the benchmark model is also reported. Significance levels are based on the Newey-West corrected Diebold-Mariano statistic tests. Using the standard Diebold-Mariano statistic improves somewhat the significance of the results shown in the table (available upon request). Asterisks, *, **, ***, denote, respectively, statistical significance at the 10, 5 and 1% levels.

¹² Although the ratio of the RMSFEs are comparable between the recursive and rolling methods, the fact that the statistical significance increases dramatically is related to the properties of the rolling approach. This technique produces far less volatile out-of-sample forecasts with credit or money variables.

4.2.3. The forecast power of different interest rate spreads

As mentioned before, evidence from the literature suggests that the link between activity and the term spread may have weakened over time (see Wheelock and Wohar, 2009), although there is no consensus as to the causes of this decline.¹³ This has led some authors to study the role of other spreads in forecasting real economic activity (see for example, Barnett, 2012; or Pace and Weber, 2013). Against this background, in this section we investigate whether alternative term and yield spreads improve the forecasting accuracy of our models. For that purpose, we focus on the VAR with currency, which has been found to perform best in many cases in both the recursive and the rolling regressions. We consider ten alternative spreads, including not only other term spreads but also bond spreads, lending spreads and the external finance premium.

Table 5 shows the RMSFEs of the rolling out-of-sample forecasts. The first takeaway from this table is that, in general and in the full sample, the VAR with currency in circulation is able to consistently outperform the benchmark in a statistically significant way over all horizons, irrespective of the interest rate spread used. The second key finding is related to the quality of our VAR with currency and the standard term spread in terms of its forecasting accuracy, which again shows up when we compare it with specifications that employ alternative spreads: for the full sample, it is among the best ones for $h=2$ to 3, and it is *the* best model, beating the benchmark by the strongest margin over longer horizons ($h=4$ to 8). The model with the mortgage term spread (*mortgage_10y*) defined as the rate on 30-year mortgages less the ten-year Treasury yield is the second best. The predictive role of the mortgage term spread is perhaps not that surprising given the role of the housing cycle in the most recent recession, but also as housing activity tends to lead the overall US business cycle more generally (see Leamer, 2007). The results for the pre-crisis period point to a rather different picture, highlighting again the role of the term spread for predicting GDP growth. The benchmark VAR model that only includes GDP growth and the term spread outperforms all other VAR models that additionally include money or credit, with the exception of currency in circulation with the term spread at longer horizons (in line with the results of Table 4).¹⁴

¹³ Wheelock and Wohar (2009) note that the strength of the relationship between the yield curve and economic activity depends on the responsiveness of the monetary authority to output and inflation, and on the extent of inflation persistence.

¹⁴ We also explored the forecasting power of two other VARs that had performed well, notably the VAR with mortgage credit to the non-financial sector (*mo_pr*) or credit standards on mortgages (*tight*) and alternative spreads. These results (available upon request) tentatively suggest that the mortgage spread is somewhat less powerful in models where a mortgage-related variable is already included. Overall, in these VARs, which spread performed best depends strongly on the forecast horizon and the sample.

Table 5: Relative RMSFE of rolling out-of-sample forecasts for VARs with alternative spreads

Notes: The 1- to 8-quarter ahead out-of-sample forecasts have been estimated recursively, using 1985Q2 to 2005Q4 as the starting sample (1985Q1 to 2000Q4 for the pre-crisis sample), and then adding one more quarter at a time. The full sample goes up to 2012Q4, whereas the pre-crisis sample stops at 2007Q4. The variable *term spread* is the 10-year Treasury Note yield minus the 3-month Treasury Bill yield (our benchmark), *mortgage_3m* and *mortgage_10y* are respectively the 30-year mortgage rate minus the 3-month Treasury Bill or minus the 10-year Treasury Note yield, *Aaacorp_10y* and *Baacorp_10y* are the Aaa or the Baa corporate bond yield minus the 10-year Treasury Note yield, *10y_fundrate* and *3m_fundrate* are the 10-year Treasury Note yield or the 3-month Treasury Bill yield minus the effective Federal Funds Rate, *primebank_3m* and *c&i_3m* are the bank prime loan rate or the commercial and industrial (C&I) loan rate minus the 3-month Treasury Bill yield, *efp_financial* and *efp_nonfinancial* are the AA 3-month commercial paper rate (respectively, financial and nonfinancial) minus the 3-month Treasury Bill yield. The reported RMSFE is the ratio between the RMSFE of the several VAR with currency in circulation and alternative spreads and the one from the benchmark model, implying that values below 1 indicate that the VAR model outperforms the benchmark. The absolute RMSFE for the benchmark model is also reported. Significance levels are based on the Newey-West corrected Diebold-Mariano statistic tests (see Diebold, 2012). Asterisks, *, **, ***, denote, respectively, statistical significance at the 10, 5 and 1% levels.

After having analysed the predictive power of money and credit variables for GDP growth, we also look at the quantitative importance of changes in selected money and credit variables for developments in activity. We do this through the analysis of impulse response functions, which are followed by the variance error decomposition for GDP growth (see Appendix D). The overall

conclusion is that impulse response functions and the forecast error variance decomposition analysis are helpful in tracing the effects of a money and credit innovation to GDP growth. Nevertheless, this interpretation should be made with caution as our models have not been selected for structural interpretation but rather for forecasting. A fully-fledged structural analysis would ideally be based on more complex models (Elbourne and Teulings, 2011).

5. Summary and Conclusion

In this paper we have analysed the role of a large set of money and credit variables to forecast real activity in the United States, given the information content of interest rate spreads. Selection of the preferred money and credit variables is done via a single-equation forecasting procedure. The performance of these variables is then assessed within different VAR models, where we distinguish between pre-crisis and post-crisis results.

In the single-equation exercise to pre-select the variables, our preferred money variables turn out to be M1 plus sweeps into money market deposit accounts and currency in circulation. The selected credit variables are credit to the private non-financial sector and total mortgages of the private non-financial sector, as well as tightening standards on residential mortgages. When we assess the performance of the aforementioned five preferred variables with small-scale VAR models, we find that in most cases, and for all forecasting horizons considered (up to 2 years), our models are able to outperform a benchmark VAR with GDP growth and the term spread in rolling forecasting exercises over a sample that includes the most recent crisis period. In the pre-crisis sample, however, the VAR models with money or credit seem not to have additional information content for predicting GDP growth beyond that contained already in the term spread, with the exception of currency in circulation at longer horizons.

Against this background, our results suggest that the 2007-09 financial crisis has given a role to money and credit variables for predicting GDP growth, a role which may have been played by the term spread before that period. A decisive and open question is whether this change in the relationship between money, credit, the term spread and economic activity has been the result of a permanent structural break or whether we might eventually go back to the previous relationships. However, as a general conclusion, since the small-scale VAR models with the narrow monetary aggregates and with total mortgages to the private non-financial sector deliver good results, it seems wise not to disregard the information inherent in money and credit when forecasting GDP growth in the United States.

Appendix A: Variable definitions

The data are taken from Haver Analytics, Bloomberg, the Center for Financial Stability, the Federal Reserve Board and the Fed St. Louis.

The spreads used in the paper are defined as follows:

(1) Term spreads

- the 10-year Treasury Note yield minus the 3-month Treasury Bill yield
- the rate on 30-year mortgages minus the 3-month Treasury Bill yield
- the rate on 30-year mortgages minus the 10-year Treasury Note yield
- the 10-year Treasury Note yield minus the effective Federal Funds Rate
- the 3-month Treasury Bill yield minus the effective Federal Funds Rate

(2) Bond spreads

- the Aaa corporate bond yield minus the 10-year Treasury Note yield
- the BAA corporate bond yield minus the 10-year Treasury Note yield

(3) Lending spreads

- the bank prime loan rate minus the 3-month Treasury Bill yield
- the commercial and industrial (C&I) loan rate minus the 3-month Treasury Bill yield

(4) External finance premium

- the AA 3-month commercial paper rate (nonfinancial) minus the 3-month Treasury Bill yield
- the AA 3-month commercial paper rate (financial) minus the 3-month Treasury Bill yield

As monetary aggregates, we consider:

- The monetary base (non-adjusted and adjusted by the Federal Reserve Board (FRB) or the Federal Reserve Bank of St. Louis)¹⁵
- The official aggregates MZM, M1 and M2
- M1 without foreign currency holdings; M1 plus sweeps into money market deposit accounts (with and without foreign currency holdings)¹⁶
- M2 without foreign currency holdings; M2 less small time deposits (time deposits of less than USD 100,000); M2 adjusted for FDIC regulation; transactions and non-transactions components in M2

¹⁵ The St. Louis Fed adjusts the monetary base for the effects of changes in statutory reserve requirements on the quantity of base money held by depositories. The FRB also adjusts the base for discontinuities (breaks) associated with regulatory changes in reserve requirements.

¹⁶ Foreign currency holdings are either from the official flow-of-funds statistics (Z.1 release, table L106) or from Judson (2012).

- Subcategories: currency (with and without foreign currency holdings); savings deposits, including MMDAs; small denomination time deposits; total checkable deposits; demand deposits at commercial banks; currency component of M1 (with and without foreign currency holdings) plus demand deposits
- Weighted monetary aggregates: monetary services index (MSI) from the Fed St. Louis (all assets¹⁷, M1, M2 with and without small time deposits, MZM); Divisia money from W. Barnett (M3, M4 with and without Treasuries)¹⁸

The credit variables we evaluate are the following:

- Bank credit of commercial banks (total and break-adjusted)
- Credit to private Depository Institutions
- Credit to the private domestic non-financial sectors
- Real estate loans (total and break adjusted)
- Total mortgages to the private non-financial sector
- Federal Reserve Board's Senior Loan Officer Opinion Survey (SLOOS) on banks' credit conditions: a quarterly survey of major banks in the United States (tightening: C&I loans to large and small firms, commercial real estate, residential mortgages, consumer credit cards and consumer loans excluding credit cards; willingness to lend to consumers)¹⁹
- Credit impulse which is based on the change in the flow of credit of different credit aggregates

¹⁷ MSI (all assets) corresponds to the assets in M2 plus institutional money market mutual funds.

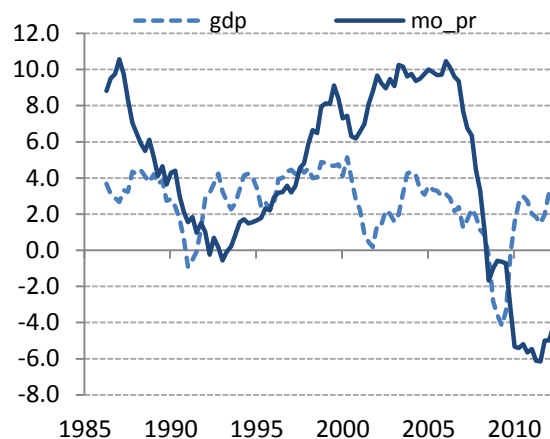

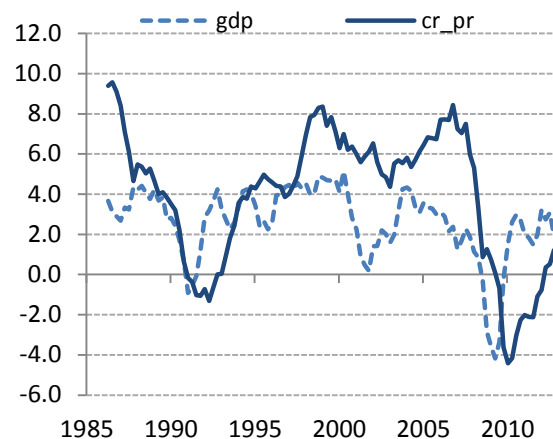

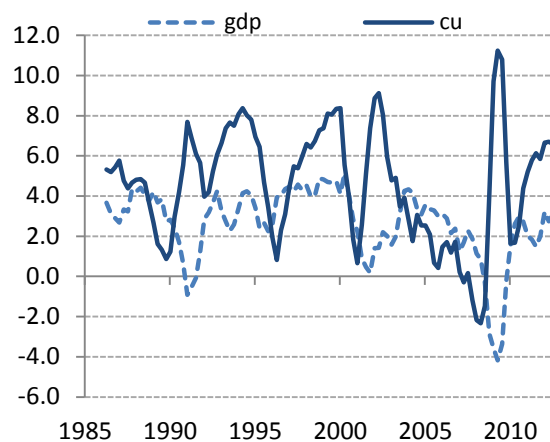

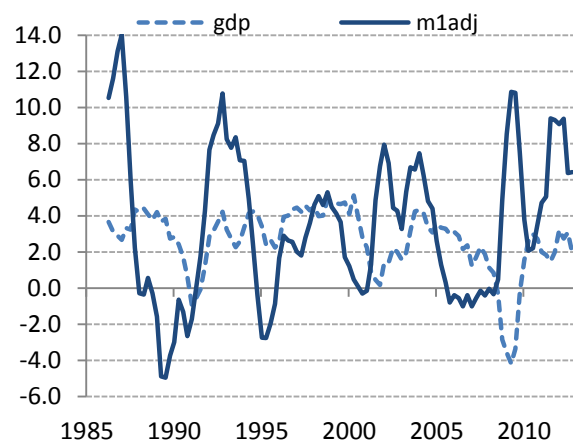

¹⁸ See www.centerforfinancialstability.org. Divisia (M3) includes the assets in M2 plus institutional money market funds, large time deposits and repurchase agreements. Divisia (M4) additionally covers commercial paper and Treasury Bills. See Serletis et al. (2013) for a comparison among the simple-sum, MSI and CFS Divisia monetary aggregates. An application to the relationship between nominal and real macroeconomic variables is provided by Serletis and Gogas (2014).

¹⁹ The survey (starting in 1967) is currently undertaken at approximately 60 large domestic banks and 24 branches of foreign banks. In aggregate, participating banks account for about 60% of all loans by US banks and about 70% of all US bank business loans (Dufrénot et al., 2012). For a recent analysis of the (real-time) forecasting properties of banks' willingness to lend for US GDP see Kishor & Koenig (2014).

Appendix B: Additional charts and tables

Charts B1 to B4: US GDP, money and credit growth

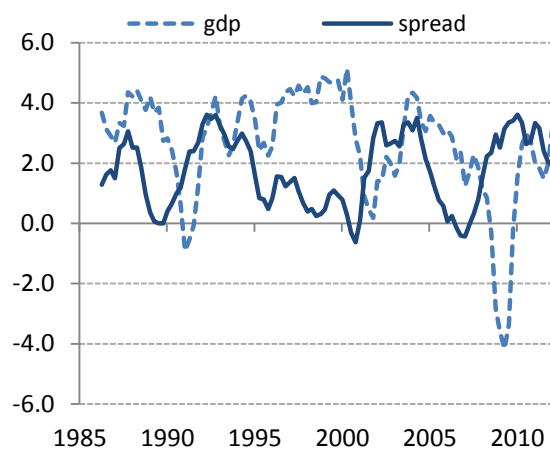

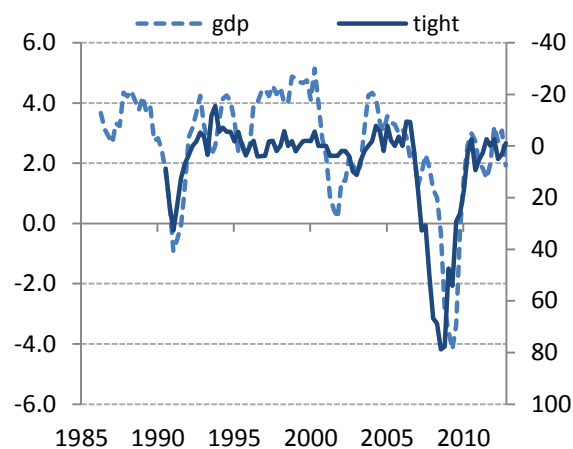

(year-on-year percentage change)

Charts B5 to B6: US GDP, credit standards and term spread

(year-on-year percentage change for gdp (lhs); net percentage of respondents for tight (rhs))

(year-on-year percentage change for gdp; percentage points for spread)

Note: (*gdp*) refers to real GDP, (*m1_adj*) to M1 plus sweeps into money market deposit accounts less currency abroad, (*cu*) to currency in circulation, (*cr_pr*) to credit to the private non-financial sector and (*mo_pr*) to total mortgages of the private non-financial sector. (*tight*) refers to standards on residential mortgages and (*spread*) refers to the term spread.

Rolling								
Benchmark model	0.004	0.007	0.009	0.010	0.010	0.012	0.013	0.015
ci_cr_pr	1.00	0.98	0.98	0.98	0.98	0.98	0.96*	0.95*
ci_mo_pr	0.97	0.97	0.95	0.94	0.95	0.96	0.97	0.97

Notes: For the recursive approach, the 1- to 8-quarter ahead out-of-sample forecasts use the 1985Q1 to 2005Q4 as the starting sample (1985Q1 to 2000Q4 for the pre-crisis sample), and then adding one more quarter at a time. The rolling approach employs a constant number of observations, using 1985Q1 to 2000Q4 as the starting window, and then rolling the window one quarter at a time. The full sample goes up to 2012Q4, whereas the pre-crisis sample stops at 2007Q4. The variable *ci_cr_pr* is the credit impulse of the credit to the private non-financial sector, and *ci_mo_pr* is the credit impulse of total mortgages of the private non-financial sector. The reported RMSFE is the ratio between the RMSFE of the several VAR specifications and the one from the benchmark model, implying that values below 1 indicate that the VAR model outperforms the benchmark. The absolute RMSFE for the benchmark model is also reported. Significance levels are based on the Newey-West corrected Diebold-Mariano statistic tests (see Diebold, 2012). Using the standard Diebold-Mariano statistic improves somewhat the significance of the results shown in the table (available upon request). Asterisks, *, **, ***, denote, respectively, statistical significance at the 10, 5 and 1% levels.

Appendix C: Alternative benchmarks

As first alternative benchmark model, we use a simple autoregressive model for year-on-year GDP growth over the period 1985Q1 to 2012Q4. First, following a general-to-specific approach, the model is estimated with eight lags and insignificant coefficients are successively eliminated. We end up with the following benchmark specification, where y_t is the log level of GDP and Δ is the difference operator:²⁰

$$(2) \quad \Delta_4 y_t = \underset{(1.98)}{0.0027} + \underset{(19.50)}{1.20\Delta_4 y_{t-1}} - \underset{(-5.70)}{0.48\Delta_4 y_{t-3}} + \underset{(2.89)}{0.17\Delta_4 y_{t-5}}$$

t-statistics in parenthesis; adjusted R^2 : 0.86; Portmanteau $\chi^2(6)=6.06$ (0.109); normality $\chi^2(2)=11.40$ (0.002); serial correlation $\chi^2(5)=0.006$ (0.940).

Overall, the diagnostic statistics do not suggest evidence of model misspecification. In particular, there is no evidence of residual autocorrelation, according to the Ljung Box test of autocorrelation for the first 6 lags (Portmanteau). Although the Jarque-Bera test of normality based on skewness and kurtosis of the residuals suggest some evidence of kurtosis, this result could be due to the inclusion of the 2007-09 financial crisis. As we are mainly interested in forecasting, this result does not pose a major problem. As regards serial correlation, the Lagrange Multiplier test fails to reject the null hypothesis of no serial correlation for the first five lags.

The second autoregressive benchmark model assumes instead a fixed number of lags (5 lags):

$$(2) \quad \Delta_4 y_t = \underset{(1.91)}{0.0026} + \underset{(12.34)}{1.21\Delta_4 y_{t-1}} - \underset{(-0.46)}{0.07\Delta_4 y_{t-2}} - \underset{(-1.73)}{0.27\Delta_4 y_{t-3}} - \underset{(-1.71)}{0.27\Delta_4 y_{t-4}} + \underset{(3.02)}{0.30\Delta_4 y_{t-5}}$$

t-statistics in parenthesis; adjusted R^2 : 0.87; Portmanteau $\chi^2(6)=19.46$ (0.245); normality $\chi^2(2)=50.34$ (0.000); serial correlation $\chi^2(5)=10.28$ (0.036).

Table C1 shows that the RMSFE of the alternative benchmarks presented above are considerably larger than those from a VAR with GDP growth and the term spread (used as the benchmark in the main text). On average, the RMSFE are around 8% to 9% larger for the autoregressive benchmarks. The difference increases when only the pre-crisis period is taken into account.

²⁰ In the pre-crisis model, there are minor differences with lag 5 only marginally significant.

Notes: The *Benchmark VAR* includes GDP growth and the term spread (displaying the absolute RMSFE from recursive out-of-sample forecasts), while the *Refined AR* is an autoregressive process of GDP growth with lags 1, 3 and 5, and the *AR - 5 lags* is also an autoregressive process of GDP growth but with 5 lags. The two last columns on the right show the % worsening of the RMSFE from the *Benchmark VAR* over the full and pre-crisis samples.

Appendix D: Impulse responses and variance decomposition for selected VARs

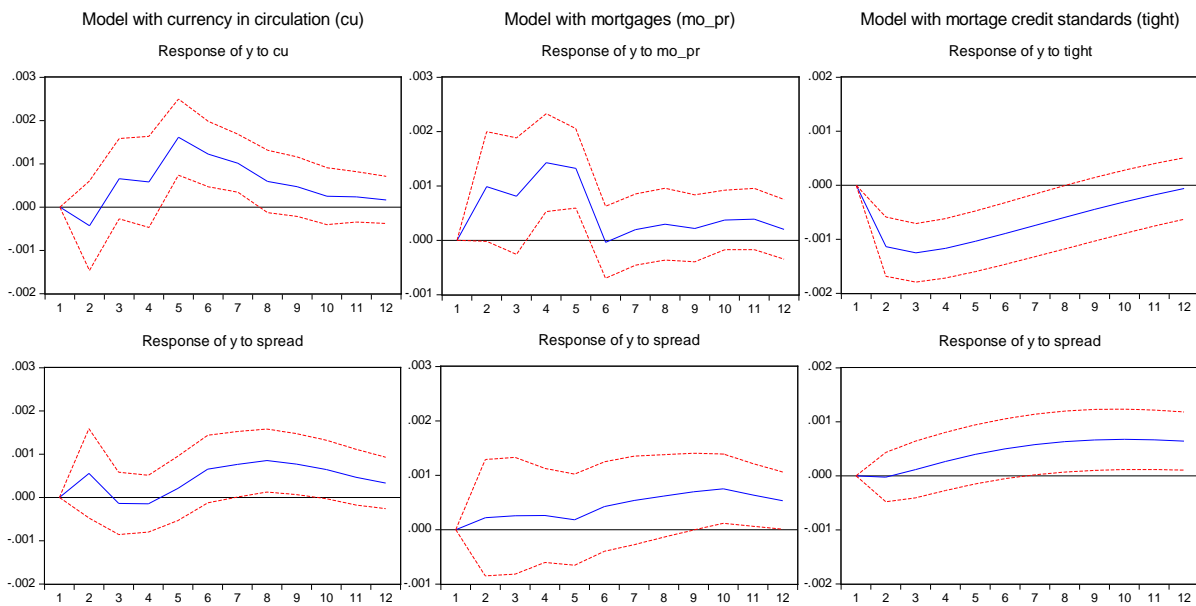

After having analysed in the main text the predictive power of money and credit variables for GDP growth in the United States, in this section, we look at the quantitative importance of money and credit variables for developments in activity by analysing typical impulse response functions of 3 selected VARs, followed by the variance error decomposition for GDP growth. The criterion for selecting these three models relies on choosing those that performed best in Table 4, while at the same time trying to capture the 3 different dimensions, i.e. money, credit and credit standards. The chosen models are those that employ currency in circulation (*cu*), mortgage credit to the non-financial sector (*mo_pr*) and credit standards on mortgages (*tight*).

For the identification of the VAR we apply a Cholesky decomposition of the following contemporaneous ordering of the variables: GDP growth before the term spread, and with the money or credit variable as the last one, as is usually done in the literature (see for instance, Lown and Morgan, 2006). In Chart D1 we show selected impulse responses of GDP growth (with standard error bands) over 12 quarters, following a shock to either the credit or money variable and to the term spread for each of the three models.

First, the left-hand panel shows the response of output growth to a one-standard deviation shock to *cu* (amounting roughly to a 0.8% quarterly increase in currency in circulation), which remains significantly above zero for around three quarters. This expansion of money leads to a statistically significant increase in GDP growth of just below 0.2% after five quarters, remaining statistically significantly above zero for three more quarters. As we have seen before, GDP growth does not respond in a statistically significant manner to shocks to the term spread if money is included in the model. Second, the middle panel shows innovations in *mo_pr* (corresponding to a 0.6% quarterly increase in mortgage lending) which decrease over time, although remaining significantly above zero for three years. A positive credit shock stimulates GDP, as expected, with the expansion in economic activity being statistically different from zero after three quarters (and up to 6 quarters). In this specification, GDP also appears not to react significantly to a term spread shock. Finally, the right-hand panel of shows selected impulse responses based on a shock to credit standards (*tight*), with the one-standard deviation innovation amounting to roughly a 7% net tightening lasting about two years. Following this shock, output growth declines immediately, remaining significantly below zero for the duration of the shock, in line with the findings in Lown and Morgan (2006), while a positive term spread shock, reflecting a lower short-term interest rate, boosts permanently GDP growth.

As a robustness check, we find that the results above remain broadly unchanged when altering the ordering of the VAR and also when restricting the estimation of the VAR to the pre-crisis sample.

Chart D1: Impulse responses to Cholesky one S.D. innovations ± 2 S.E.

Notes: Impulse responses for GDP growth (y) following innovations in the term spread, the growth of currency in circulation (cu ; first panel), growth of mortgage credit (mo_pr ; middle panel) and credit standards on mortgages ($tight$; right panel) over 12 quarters. Cholesky decomposition applied to the VAR, with GDP growth ordered first and with the money or credit variable ordered last. The solid blue line refers to the point estimates, with the associated ± 2 standard error bands shown by the dashed red line.

While impulse response functions are helpful in tracing the effects of a money or credit shock to GDP growth, an investigation of the forecast error variance decomposition complements this analysis, as it provides information about the relative contribution of each innovation to the variance of the error made in forecasting h -step ahead GDP growth. In this context, Table D1 shows whether unexpected swings in the money and credit variables have accounted for a large share of the overall variability in GDP growth over the full sample (1985Q1-2012Q4) and the pre-crisis sample (1985Q1-2007Q4) for different time horizons, and using the same three above-mentioned VAR specifications. Overall, the importance of innovations in growth of currency in circulation, mortgage credit growth and credit standards on mortgages in explaining the error variance of GDP growth increases over the forecast horizon. Interestingly, innovations in the credit and money variables are significantly more important in explaining the variance of GDP growth when including the crisis period. However, and not surprisingly due to our focus on forecasting, they still remain relatively small. Focusing on the full sample, innovations in currency in circulation account for around 16% of the error variance in GDP growth after two years; the second VAR shows mortgage credit growth accounting for roughly 14%; and the last specification indicates that credit standards on mortgages explain a little more than 18% in the error variance of output growth. The shocks to the term spread account for a much smaller share of the errors in GDP growth across the three models.

Table D1: Variance decomposition of GDP growth for selected VARs

Full sample				Pre-crisis sample			
Model with <i>cu</i>				Model with <i>cu</i>			
Horizon	GDP growth	Spread	cu	Horizon	GDP growth	Spread	cu
1	100.0	0.0	0.0	1	100.0	0.0	0.0
4	95.9	1.1	3.0	4	96.8	2.4	0.9
8	78.5	5.4	16.1	8	89.8	4.9	5.2
12	75.4	8.3	16.3	12	87.9	6.4	5.6
Model with <i>mo_pr</i>				Model with <i>mo_pr</i>			
Horizon	GDP growth	Spread	mo_pr	Horizon	GDP growth	Spread	mo_pr
1	100.0	0.0	0.0	1	100.0	0.0	0.0
4	89.4	0.5	10.1	4	92.7	2.4	4.9
8	83.3	2.7	14.0	8	89.3	4.7	6.1
12	79.2	6.7	14.1	12	88.2	5.8	6.0
Model with <i>tight</i>				Model with <i>tight</i>			
Horizon	GDP growth	Spread	Tight	Horizon	GDP growth	Spread	Tight
1	100.0	0.0	0.0	1	100.0	0.0	0.0
4	87.4	0.3	12.4	4	98.2	0.5	1.3
8	78.4	3.2	18.3	8	96.9	1.5	1.6
12	74.4	7.4	18.2	12	95.9	2.2	1.9

Notes: The table shows the percentage contribution of each shock to the forecast error variance of GDP growth at different horizons, conditional on data for both the full sample (1985Q1-2012Q4) and the pre-crisis sample (1985Q1-2007Q4).

When interpreting the results from the impulse response analysis and the variance decomposition, one needs to bear in mind that our models have not been selected for structural interpretation but rather for forecasting, and the “selection of an empirical model by its forecast performance may be a good way to select a forecasting model, but it is not so to select a model for evaluating economic theory or a policy model” (see e.g. Clements and Hendry, 1998). The choice of limiting ourselves to small parsimonious VAR models stems from the findings in the literature that these types of models perform fairly well in forecasting exercises, while for structural analysis more complex models may be more appropriate (see for instance Elbourne and Teulings, 2011).
