## **Abstract**

At the Institute for Employment Research (Institut für Arbeitsmarkt- und Berufsforschung (IAB)) a classification system of regional labour market conditions at the level of districts ('*Kreise*' and '*kreisfreie Städte*' or NUTS3 regions) was developed. The resulting division into a total of 18 groups constitutes an important aid for active labour market policy and is used in an adapted form at the Federal Employment Services (Bundesagentur für Arbeit – BA) and the Federal Ministry for Labour and Social Affairs (Bundesministerium für Arbeit und Soziales – BMAS) for diverse tasks in the field of benchmarking and management accounting. In addition to this the classification fulfils scientific criteria and therefore permits diverse analyses because the complexity of empirical labour markets is reduced to a manageable dimension.

The methodology selected follows to a certain extent an approach developed by Blien and Hirschenauer et al. 2004. The idea behind this approach is based on the fact that the variables used for the clustering are not chosen "arbitrarily" but are determined on the basis of causal relationships using regression analyses.

## **1 Introduction**

The classification of regions is a scientific procedure in which the empirical complexity of regional development is reduced to a manageable number of types (or groups). This makes regions comparable and therefore accessible for analysis. In the management of labour market policy, too, it is often useful to compare the labour market situations of different regions. Only in this way is it possible to conduct budgeting, to evaluate performance and to select optimal strategies in the best possible way. The comparison in turn assumes a preferential selection of criteria. In this paper a concept for this is presented which is demonstrated using the example of the management of labour market policy in the Federal Republic of Germany. In two steps types are formed which can also be used for diverse purposes in scientific analyses of regions.

The classification presented in this paper became necessary because social assistance and unemployment assistance were combined in Germany as of the beginning of 2005. The administrative districts at NUTS3<sup>1</sup> level are responsible for the newly created assistance and set up new institutions for the task.

In order to permit a differentiated performance assessment and management of these regional institutions, it was necessary to form types comprising labour markets that are as similar as possible and therefore comparable, whilst the types were to be as dissimilar as possible to one another.

Behind this concept was the fundamental consideration that the basic conditions of the regional labour market already predetermine to a substantial extent the success of these institutions, in the sense of a “handicap”. The problems prevailing in the different regions can vary considerably. Thus for example some regions in Germany are characterised by severe labour market crises, whereas other areas have almost full employment. The success of active labour market policy does not depend solely on the performance of the local institutions responsible for this task, but must be seen in the light of the objective labour market situation. It is possible that individual measures or strategies that can be implemented with great success in a certain environment may show little effect in other regions.

The exogenous determinants which already restrict the efficiency of the institutions responsible can generally not be influenced directly in the short term by the local actors. In order nonetheless to make adequate comparisons possible, districts with a similar structure are

---

<sup>1</sup> NUTS = Nomenclature of Territorial Units for Statistics.

to be grouped together. For this purpose a cluster analysis is carried out, which is explained in section 2.3. The factors included in the cluster analysis are first identified using a regression analysis (section 2.1).

## 2 Methodology

The core of the chosen procedure is a combination of regression and cluster analyses. This follows an approach developed by Blien and Hirschenauer et al. (2004) and constitutes an innovation in labour market research.

For this the variables that later go into the cluster analysis are not determined solely on the basis of experts' opinions, as is usually the case, but are identified using causal analyses.

By means of multivariate (regression) analyses it is possible to investigate which exogenous determinants have an influence on the success of regional labour market policy, and to what extent. The analyses are based on a data basis for the 439 districts in Germany from 2000 to 2004. The data on unemployment and employment are process data from the statistics of the Federal Employment Services (BA). The data on economic development and regional characteristics are from the Federal Statistical Office. The territories covered by the newly founded institutions generally coincide with those of the districts.

### 2.1 Regression analysis

The success of regional labour market policy is examined using the indicator of the integration rate. This rate is calculated as integrations of unemployment assistance recipients into regular employment in proportion to all the recipients of unemployment assistance in a region at the point in time t. It represents the target variable of the regression analysis.

The (model) specification used assumes a non-linear relationship between the independent variables and the integration rate. The estimates are based on the Ordinary Least Squares (OLS) method with robust standard errors:

$$\ln y = \beta_0 + \sum \beta_i \ln x_i + \varepsilon_i$$

The included exogenous variables  $x_i$  are listed in Table 1 and are described in more detail below. They show a time lag of one year since the individual factors do not have an immediate effect. One exception is the development of employment subject to social security, which represents a rate of change from 2000 to 2004.

The determinants of the labour market which are taken into consideration here are seen to be significant in the estimates and already explain over 75% of the variation in the integration rates:

**Table 1: Results of the regression**

Independent variables	Coefficient	Robust standard error	t-value
<b>GDP per capita</b>	0.1153 ***	0.0267	4.33
<b>Social assistance rate</b>	-0.0396 **	0.0154	-2.57
<b>Population density</b>	-0.0363 ***	0.0099	-3.69
<b>New empl. subj. to soc. security</b>	0.5275 ***	0.0863	6.12
<b>Seasonal span</b>	0.0748 ***	0.0196	3.83
<b>Dev. of empl. subj. to soc. security</b>	0.6580 ***	0.2095	3.14
<b>Underemployment rate</b>	-0.3059 ***	0.0450	-6.80
<b>Environment variable</b>	-0.1579 ***	0.0444	-3.56

Dependent variable: integrations into employment of recipients of unemployment assistance in relation to all unemployment assistance recipients in 2004

\*\* = significant at the 5% level; \*\*\* = significant at the 1% level;  $R^2=0.7548$

Data basis: statistics from the Federal Employment Services and the Federal Statistical Office

Gross domestic product (GDP) per capita as a measure of a region's economic power has a positively significant influence on the number of integrations. This study uses data in which recipients of unemployment assistance and social assistance are still examined separately. Nevertheless the social assistance recipients for their part exert pressure on the labour market. This becomes clear from the significantly negative effect that the social assistance rate is seen to have on the integrations. The higher this rate is in a region, the more difficult it is to get recipients of unemployment assistance into employment. The reason for taking into account the population density is based on the hypothesis that the labour market situation in towns generally differs from that in rural districts. The negatively significant effect of this variable on the number of integrations confirms the consideration. The newly begun employment relationships covered by social security in the place of residence constitute an indicator of the stability of the employment relationships in the locality. The more unstable or the more dynamic a region shows itself to be, the more integrations there are among the recipients of unemployment assistance. As the labour market in some districts is characterised by strong seasonal influences, a seasonal span was calculated from the monthly values of the respective unemployment rates. This shows a positively significant correlation with the integrations.

Changes in the structures of the regional labour market take place only slowly – if at all. By using the rate of change of employment covered by social security in the place of residence between 2001 and 2004 not only a region's current situation is included but also the trend of the last few years. A person's opportunities for labour market participation are generally not restricted to the boundaries of the particular district (or the territory of the institution responsible). For this reason the employment relationships covered by social security are recorded according to the principle of location of residence. The variable has a positively significant effect on the integrations.

The underemployment rate describes the situation on the labour market more comprehensively than the unemployment rate since it also covers participants in employment and training schemes. It therefore gives a better picture of the true extent of the problem of unemployment. It is easy to understand that this variable makes the largest contribution to explaining the variation in the integration rates. It is negatively correlated with the integrations. If only the underemployment rate is included in the regression, the result is already an  $R^2$  of 0.57.

In order to model the spatial interconnections between the districts, an environment variable is also included. This is calculated as the mean underemployment rate of the districts with which there are commuter interconnections, weighted in each case with the proportions of the commuters. The environment variable also shows a negatively significant influence on the number of integrations.

## **2.2 *The weighting***

The high explanatory power with an  $R^2$  of over 0.75 confirms that the determinants identified using the regression analysis depict the decisive basic conditions for the integrations in the regions. Therefore the group formation is carried out using these variables with the aid of cluster-analysis procedures.

Since using the original values of the respective variables would result in those variables with a high scaling dominating the cluster formation entirely, these first have to be transformed. For this all the variables are standardised using a so-called z-transformation. Here the respective mean is deducted from each variable and the result is then divided by the standard deviation so that the final result is a mean of zero and a standard deviation of one. Pure scale effects are eliminated in this way.

In order to be able to use as much as possible of the information obtained from the regression

analysis, these standardised variables are then weighted. The t-values of the regression provide the weights for this. These are listed in Table 1. Experiments with other weights, e.g. with standardised coefficients, lead to similar results with regard to the final group compositions. The t-values are used because they represent an indicator of how reliably a variable has a detectable influence on the target variable. The variables multiplied by the t-values are the classification variables of the actual cluster analysis.

### **2.3 The cluster analysis**

The k-means procedure is used in the cluster analysis. This is preceded by Ward's method in order firstly to obtain initial values for the k-means procedure and secondly to determine the number of types. Cluster analysis techniques have the characteristic of forming groups of objects that are as similar as possible whilst at the same time the objects in different groups are as dissimilar as possible.

Before the cluster analyses are conducted, a distance measure must first be selected in order to be able to determine the similarity or dissimilarity between two entities, in this case districts. The squared Euclidean distance is used for this:

$$d(i, j) = \sum_{f=1}^p (x_{if} - x_{jf})^2$$

The distance  $d$  between two objects  $i$  and  $j$  is therefore the sum of the squared differences of all the classification variables  $p$ .

#### **2.3.1 Ward's method**

Ward's method, as a hierarchical-agglomerative procedure, joins clusters (or objects) together gradually. At the beginning of the procedure the finest partition exists, in which each study unit represents a cluster of its own. At the end of the procedure only one cluster remains, which contains all of the objects. Each time that clusters are joined together the variance within the newly formed cluster increases<sup>2</sup>. Each time Ward's method combines two clusters (objects) which cause the smallest increase in the variance (cf. Bacher 1994, Chapter 3). One of the intermediate steps in this algorithm represents the sought result of the Ward procedure. For this a dendrogram is usually used to determine the cluster-fusing step in which the

---

<sup>2</sup> Unless objects are combined which are perfectly identical as regards the variables taken into account.

greatest increase in variance occurs. The strong increase in variance occurs when very dissimilar clusters are combined.

For each cluster the means of the classification variables are calculated. These means are also called (cluster) centroids and constitute the result of the Ward procedure. A classification conducted using Ward's method has the disadvantage, however, that objects which have been grouped together can no longer be separated in the subsequent steps. In the course of the fusing stages, the centroids shift their position. As a consequence of this shifting it can happen that at the end of the process individual districts are further away from the centroid of their own cluster than from the centroids of other clusters. This is where the k-means procedure comes in, since it permits objects to be reallocated to different clusters later on and can be used in a way that is compatible with Ward's method.

### 2.3.2 *The k-means procedure*

The k-means procedure is a method of cluster centre analysis. In an iterative process, individual objects (in this case districts) are repeatedly reallocated to different clusters in order to minimise the variance. The target criterion pursued, to minimise the variance as far as possible, can be described as follows. For each cluster it is possible to calculate the similarity of the objects using the error sum of squares (ESS). For this the sum is formed of all the squared distances between the objects of a cluster  $v$  (with  $v=1, \dots, k$ ) and their centroids (cf. e.g. Kaufman and Rousseeuw 1990, p.111 ff).

$$ESS(C_v) = \sum_{i \in C_v} \sum_{f=1}^p (x_{if} - \bar{x}_f(v))^2$$

The k-means procedure thus attempts to minimise the error sum of squares across all k clusters.

$$ESS = \sum_{v=1}^k ESS(C_v) \rightarrow \min$$

During the process, every time that an object changes cluster the centroids for its old and its new cluster are re-calculated. The centroids calculated during the Ward procedure are taken as initial values for the iteration process.

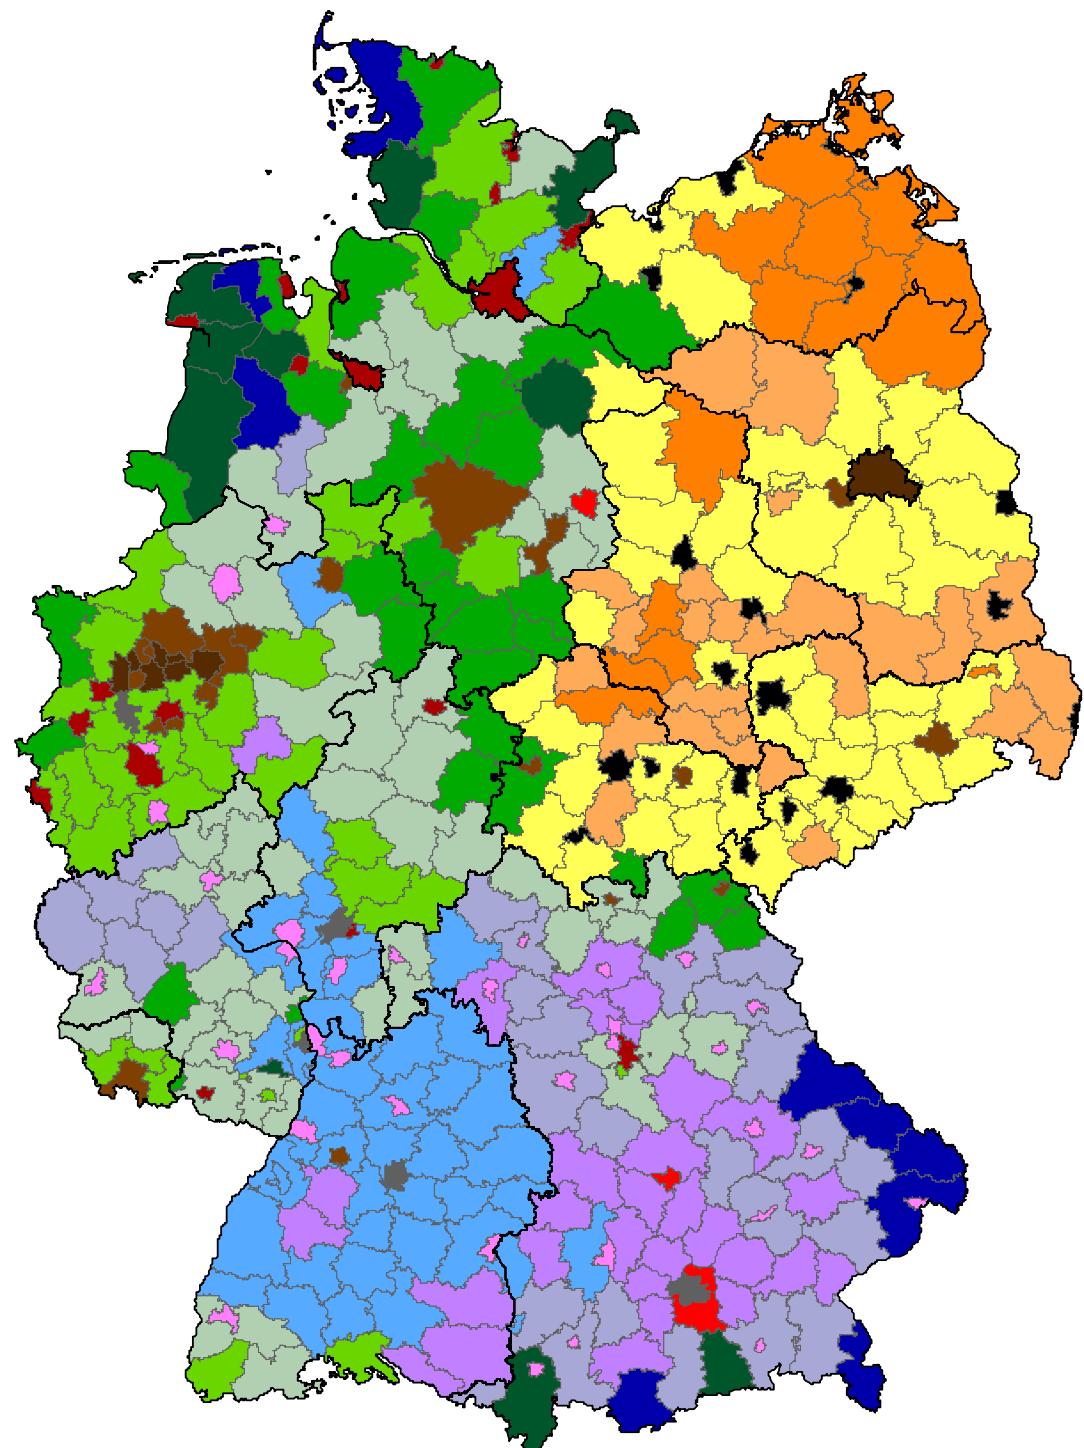

## 3 The result

In the case presented here of a classification of regional labour markets, the decision as to the

number of groups can not be made adequately using a dendrogram. The greatest increase in variance occurs when five groups are aggregated to four. However, the number of types has to be manageable for the subsequent use in management accounting and benchmarking tasks. On examination of the different results using differing numbers of clusters, a good compromise between group size (and thus manageability) and information gain is found in the structure of the groups obtained when there are 17 types. Here one type contains a total of 90 districts. For this group a complete cluster analysis is conducted again. In this way this large group can be divided into two manageable ones. The group concerned is type 8, which becomes 8a and 8b after re-clustering. Figure 1 shows the result of the classification of Germany's regional labour markets. In the appendix boxplots of the classification variables are shown separately according to types, which provide information as to how the variables vary in the individual groups. It emerges here that in particular the underemployment rate already differentiates well between the groups. This variable alone, however, does not lead to the structure that was found in the end. If this variable is examined alone, clear overlaps can still be detected for example for types 9 to 11 and for 13 and 14. All eight dimensions are necessary in order for these groups, too, to be revealed in the cluster analysis. The information about the group-specific values of the classification variables are particularly useful in selecting the right labour market policy measures. Thus for instance adequate measures should always take into consideration the high seasonal dynamics of types 11 and 13.

The resulting picture of the classification (Figure 1) shows similarities to classifications of other regional units which were conducted prior to this study (see on this subject Blien and Hirschenauer et al. 2004), which suggests that the results are robust. The rough structure indicates considerable differences between the labour market situations prevailing in eastern and western Germany. It also becomes clear that towns have special labour market conditions. There are disparities between the north and the south of western Germany.

**Figure 1: Classification of districts in Germany**

[Grey]	type 1 [ I ] (5)	[Red]	type 6 [ I ] (3)	[Dark Green]	type 10 [ II ] (10)	[Yellow]	type 15 [ IV ] (46)
[Pink]	type 2 [ I ] (34)	[Brown]	type 7 [ I ] (21)	[Dark Blue]	type 11 [ III ] (9)	[Orange]	type 16 [ IV ] (25)
[Dark Red]	type 3 [ I ] (19)	[Light Grey]	type 8a [ II ] (53)	[Purple]	type 12 [ III ] (29)	[Dark Orange]	type 17 [ IV ] (16)
[Dark Brown]	type 4 [ I ] (8)	[Light Green]	type 8b [ II ] (37)	[Light Purple]	type 13 [ III ] (29)		
[Black]	type 5 [ I ] (19)	[Green]	type 9 [ II ] (31)	[Medium Purple]	type 14 [ III ] (45)		

For rapid orientation the 18 types have been divided into four groups. The groups are denoted by Roman numerals. The types can be described more precisely on the basis of their key characteristics:

#### Group I: Mainly municipal districts ('*kreisfreie Städte*')

Type 1	Mainly large cities with a good labour market situation and high GDP per capita
Type 2	Medium-sized cities with a good labour market situation and high GDP per capita
Type 3	Towns with a poor labour market situation
Type 4	Towns mainly in the Ruhr area with a poor labour market situation
Type 5	Eastern German towns with a very poor labour market situation
Type 6	Urban areas with a good labour market situation and the highest GDP per capita
Type 7	Urban areas in western and eastern Germany with a poor labour market situation

#### Group II: Districts with an average labour market situation

Type 8a	Areas of mainly rural character with an average labour market situation
Type 8b	Fairly densely populated areas with an average labour market situation and slightly above-average rate of social assistance recipients
Type 9	Areas of mainly rural character with an average labour market situation and slightly above-average rate of social assistance recipients
Type 10	Areas of mainly rural character with an average labour market situation and high seasonal dynamics

#### Group III: Districts with a good labour market situation

Type 11	Very thinly populated areas with an average labour market situation and the highest seasonal dynamics
Type 12	Rural areas with a very good labour market situation and seasonal dynamics
Type 13	Thinly populated areas of mainly rural character with a good labour market situation and strong seasonal dynamics
Type 14	Fairly densely populated areas with a good labour market situation and low seasonal dynamics

#### Group IV: Districts with a poor labour market situation

Type 15	Districts in eastern Germany (with the exception of Lüchow-Dannenberg) with a poor labour market situation
Type 16	Rural areas in eastern Germany with a poor labour market situation and low seasonal dynamics
Type 17	Very rural areas (exceptions: Greifswald and Hoyerswerda) with extremely poor labour market situation and very strong decline in employment covered by social security

In the appendix the individual values of the variables used for the classification are also listed for each district and structured by type membership.

## 4 Limits of the classification and the concept of the nearest neighbours

Germany's labour market appears to vary greatly. The classification of regional labour markets presented in this paper shows the essential structures.

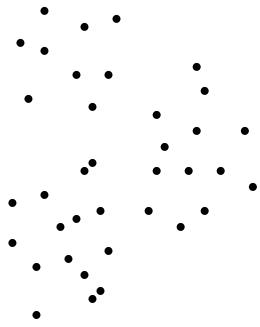

Here districts within the types have a greater similarity to one another with regard to the variables examined than if all the districts were compared with each other.

Generally, however, problems always arise when forming groups of entities that possess multidimensional characteristics. These problems are now examined briefly.

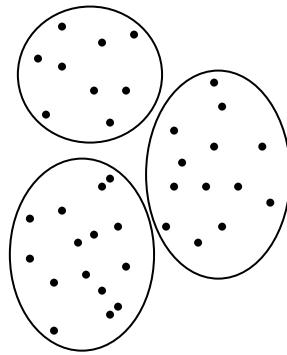

Firstly, important differences still remain between the individual objects (districts) within the groups. As the districts within a group are not absolutely identical, it is inevitable that a certain amount of inner heterogeneity remains in the types.

In addition to this, in some cases the phenomenon occurs that for individual districts the most closely comparable districts are not in the same group as that particular district but in a different one. This peculiarity of dividing into groups can be explained easily using the following example with only two dimensions. The pre-determined set of objects (Figure 2) is to be divided into **three** groups. A possible grouping could then be made as shown in Figure 3.

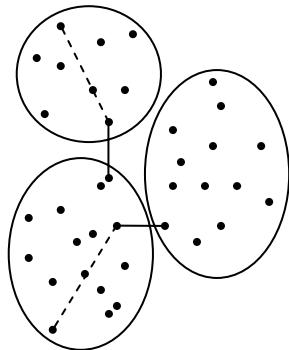

**Figure 2: Grouping objects into three groups**

**Figure 3: Example of a possible grouping**

**Figure 4: “Nearest neighbours“ not in an object’s group**

Ultimately it makes no difference how the three groups are formed; usually some members of a group are more comparable with objects in another group (Figure 4). The lines show the relationship. The distance between objects in the same group may be greater (dashed line) than the distance from objects in a different group (unbroken line). This phenomenon is also known as the peripheral location problem. It occurs in particular when the boundaries of groups are close together.

It is however possible to quantify the similarity between the individual objects. In this way the respectively most similar units can be compared with each other without paying attention to the group membership. By means of a distance measure (here the squared Euclidean distance, see above) the similarity between the districts can be determined on the basis of a so-called distance matrix. This is also known as the nearest neighbours matrix. The greater the value revealed is, the greater is the distance between two districts. By means of an appropriate sorting it is now possible to draw up for each district separately an order of the degree of similarity to all the other districts according to the similarity of the characteristics. The first nearest neighbours are generally members of the same type as the districts under examination. In the case of districts located on the periphery of a cluster (see diagram above), districts from other groups are often among the first nearest neighbours.

## 5 Conclusion

The classification of Germany's regional labour markets at NUTS3 level presented in this paper forms the basis for a classification of the newly established institutions responsible for active labour market policy. The management of these newly created institutions by means of the targeted use of measures and funds is of particular importance both in financial and social terms in view of the far-reaching consequences of the problem of unemployment.

The classification of districts presented here is, however, also of scientific interest in itself. Those working in labour market research have long been aware of the importance and the persistence of regional disparities on the labour market. Nonetheless not many studies on the regional contexts in Germany have been conducted so far.

The regional disparities even seem to be becoming more persistent over time. This result is also reached by a national research project conducted by the IAB which examined the differences in the development of employment (VALA 2005).

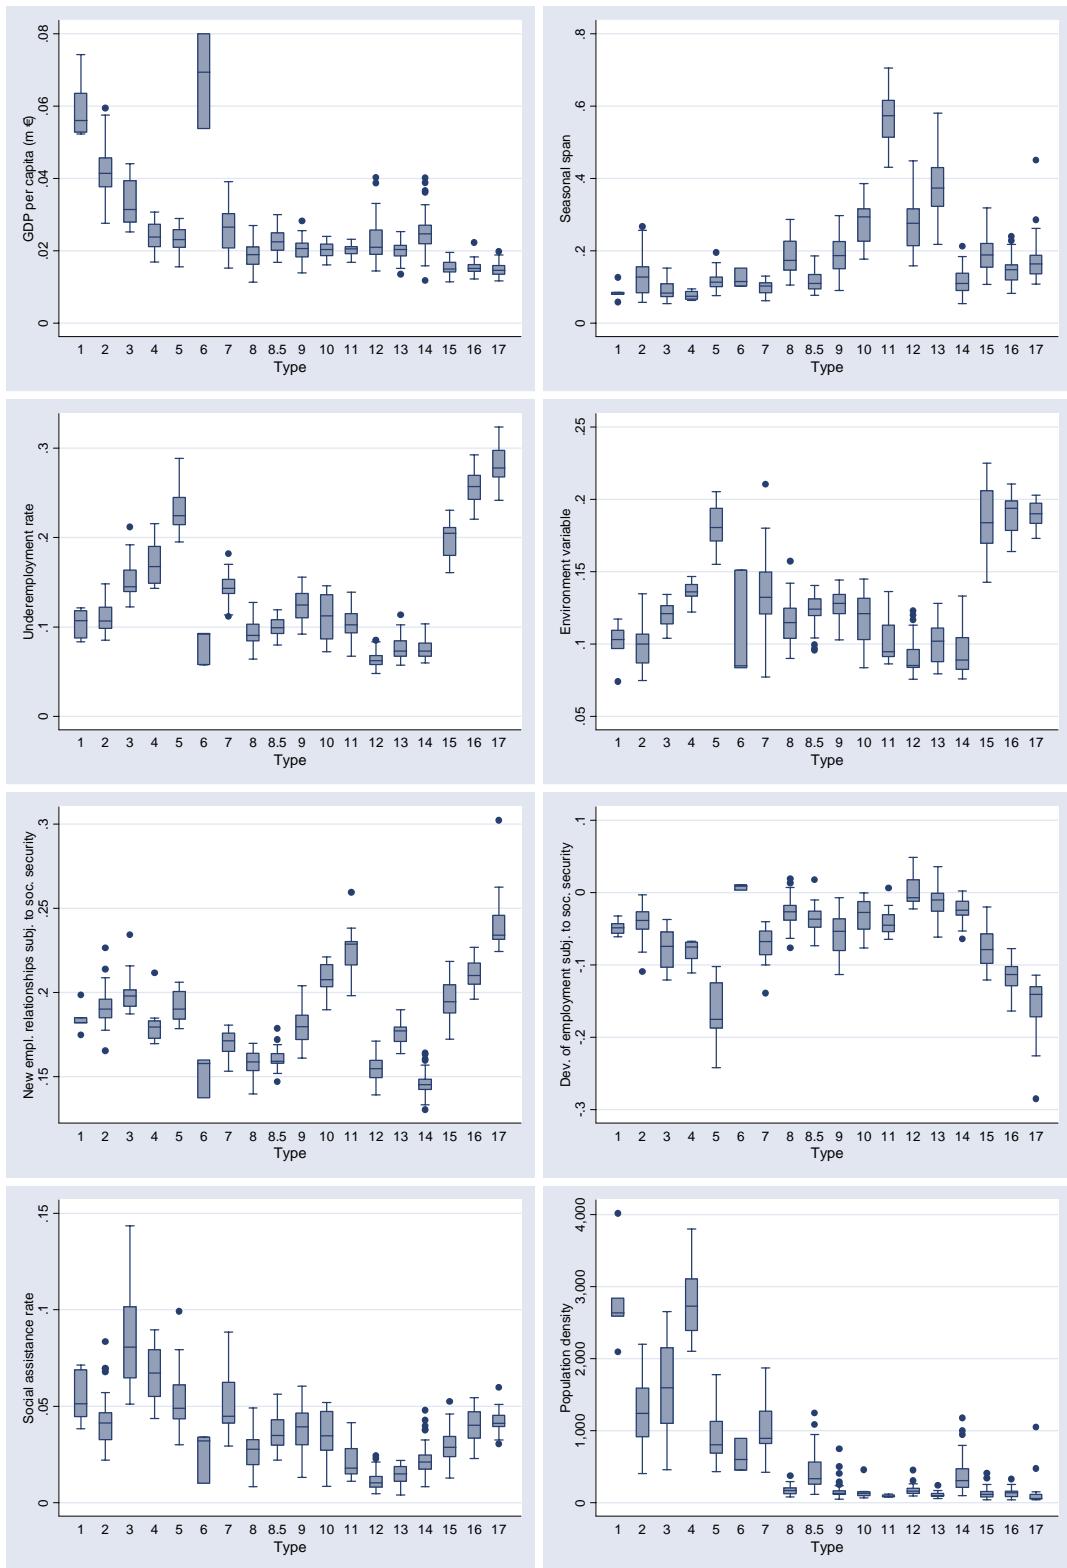

In order to be able to combat specifically the causes of the regional unemployment rates it is necessary to know the actual contexts.

This classification of districts can make a first contribution to this as it facilitates a firm overview of the structure of the different regional labour market situations in Germany.

The statistical methods used for this can also be transferred to other classification problems, in particular in regional research. The innovative procedure, the linking of causal and cluster analyses, has proved here to be useful for cases in which the criteria to be used for forming the groups are not exactly known or defined beforehand.
