Abstract

The production of ethanol and sugar from sugar cane has sharply increased for the last 20 years. If there are overall incentives to substitute the consumption of fossil fuels by biofuels, the increase of production and the expansion of new cultivated areas of sugar cane have eventually an impact on human health and employment mainly at regional levels. To harvest the crop—mostly manually done by low-skill workers—the practice of burning to clean dry grasses and poisonous insects has been executed for years during the dry season, what increase the productivity of workers. However, the burning generates a massive quantity of smoke that spread in the region reaching cities and becoming a potential threat to the human health. The main objective of this paper is to investigate the impact of the burning prohibition of sugar cane on respiratory problems of children, teenagers and elderly people. This analysis proposes a spatial difference-in-difference technique, to control the effect of treatment (the sugarcane culture) over the untreated regions, closest to producing regions. We consider also other control variables such as workforce, income, proportion of woman, elderly and young people in the population, and a time trend variable, to control institutional changes. The data used in this study corresponds to a balanced panel of 644 municipalities from 2002 to 2011.

Key-Words: Sugar Cane Burning, Health Condition, Spatial Econometrics

Jel Classification: C14, C21, Q18

1 Introduction

The production of ethanol and sugar from sugar cane has sharply increased over the last 20 years in Brazil. The culture is one of the most important in Brazilian agricultural, representing about 10% of agricultural area in Brazil, and more or less 1% of GDP. The ethanol industry is about 3.5% of Brazilian industrial GDP, and the sector employs more than 6 million of people.

The increase in ethanol production is explained by the incentives to substitute fossil fuels for biofuels. The planted area of sugarcane doubled in the last twenty years. It is the largest increase in production in entire world. In the early nineties, Brazilian production represented 25% percent more than the second producer, India. Now, the difference is more than double.

On the other hand, the increase in sugarcane production and the expansion of new cultivated areas of sugarcane might have an impact on human health and employment, mainly at regional levels. There exist doubts about the impact of sugarcane production, for example, concerning the quality of employment, the environmental impacts (soil contamination, atmospheric pollution from burning fields, water use, etc.) and dislocation of other crops to native forests, among others Noronha (2006).

Some studies have shown that the balance of costs and benefits is positive from the standpoint of the entire country BNDES and CGEE (2008), but the benefits for the cane growing regions may not be as evident, once the producing regions may disproportionately bear the negative impacts of the sector's presence. The most studied aspect in this respect is the labor market. Many authors encountered negative impacts to manual harvesting Alves (2006, 2007); Baccarin et al. (2008).

It is recognized that sugarcane is significantly more valuable by tilled area than many other crops, such as soybeans and corn. As for employment, (Toneto-Jr and Liboni, 2008) observe that sugarcane cultivation generates more jobs than soybean, and only slightly fewer than corn. Thus, because it generates more value per hectare and more jobs as well, cane growing generates more income per area planted than other staple crops. Given the importance of transportation costs in relation to the value of sugar cane, processing plants (sugar mills and/or ethanol distilleries) are located near the growing fields. This tends to increase local employment even more, because of the need for industrial workers and services - transportation, maintenance, etc. - increasing the sector's indirect effects on the producing region.

(Chagas et al., 2011) evaluates the impact of sugarcane on social regional indicators,

like HDI (Human Development Index) by a spatial propensity score matching, which control the fact that the sugarcane production in one specific region is not aleatory. The results suggest that the presence of sugarcane growing in these areas is not relevant to determine their social conditions, whether for better or worse. It is thus likely that public policies, especially those focused directly on improving education, health and income generation/distribution, have much more noticeable effects on the municipal HDI.

The increasing importance of sugarcane production in the country tends to raise more and more arguments about its consequences. This paper provides a contribution to the discussion, by assessing the effects of sugarcane on the respiratory problems of children and adults. We propose a spatial difference-in-difference technique, to control the effect of treatment (the sugarcane culture) on the untreated regions, closest to producing regions. Then, we compare municipalities where burning occurs with others where it does not occur, over the time.

The burning is meant to increase the productivity of workers. It facilitates the harvest, easing access to the plants and reducing work hazards (dry leaves are harmful, there might be poisonous insects). It takes place in the beginning of harvest, which coincides with the dry season. Many works relates sugarcane burning and increase of fine particulate matter , coarse particulate matter and black carbon concentration, especially in burning hours Lara et al. (2005), and alter positively the air concentration of substances as nitrite, sulfite, oxide of carbon and others Allen et al. (2004). The sugarcane is harvested by unskilled workers, mostly manually. The literature also relate that short- and long-term exposition to classical pollutants (matter, sulfite, nitrite, oxide carbon, etc.) can affect negatively human health capital Sicard et al. (2010) specially for young, elderly and woman people Braga et al. (1999); Roseiro (2002); Gonçalves et al. (2005).

The burning of sugarcane generates a massive quantity of smoke that spreads in the region, reaching cities and becoming a potential threat to the human health. Few studies have linked the burning of sugarcane straws with respiratory diseases in the producing regions. Although the pollution from sugarcane pre-harvest burning may be as harmful as the pollution from traffic and industries Mazzoli-Rocha et al. (2008), many studies relate the impact of of pre-harvest burning of sugar-cane on health, for specific municipalities or a larger region Arbex et al. (2000, 2004); Cançado et al. (2006); Arbex et al. (2007); Ribeiro (2008); Uriarte et al. (2009); Carneseca et al. (2012) . This studies, in general, based in closest effects of burning, considering only the local events of both, burning and respiratory health. They fail, for example, to capture the interactions among the burning events to another place.

This article is organized in four sections, including this introduction. The next section presents the methodology used to identify the possible impacts of growing sugarcane on the social conditions of producing regions, and the data utilized. The fourth section presents the results, and the fifth section contains the final remarks.

2 Methodology and data

2.1 The model

As usual in spatial studies, we consider the region interrelated together. Then, we consider a possibility of propagation in the treatment effect, that is, after the treatment, the effect of sugarcane production acts on both region, treated and non-treated. To be clear, consider y_{it} as a variable of interest, \mathbf{x} a vector of observable characteristic, \mathbf{w}_i a $n \times 1$ vector that associate a region to all other, and d_{it} a $n \times 1$ vector in that, such $d_{it} = 1$ if the region 1 is treated in time t and zero, in contrary. Additionally, consider two situation for each region: before and after the treatment. Then, for the before treatment situation, we have

$$\begin{aligned} y_{it,0}^b &= \mu(\mathbf{x}) + u_{it} \\ y_{it,1}^b &= y_{it,0}^b \end{aligned}$$

where, $y_{it,0}^b$ represents the dependent variable in non-treated region, before the treatment, and $y_{it,1}^b$ the same, for the treated region. Now, after the treatment, we have two impacts - one on treated region e other in non-treated region. But, the impact on non-treated region depends of the proximity of this region to treated one. For clarity, we consider both regions after the treatment in follow

$$\begin{aligned} y_{it,0}^a &= \mu(\mathbf{x}) + \mathbf{w}_i d_{it} \beta + u_{it} \\ y_{it,1}^a &= y_{it,0}^a + \alpha \end{aligned}$$

In this way, α capture the direct effect of treatment on treated region, and β the indirect effect of treatment over all region, treated and non-treated, conditioned to the neighbor treated, which is captured by $\mathbf{w}_i d_{it}$. Defining D_{it} a region- i specific indicator of

treatment in time t , we can define

$$y_{it} = (1 - D_{it})y_{it,0} + D_{it}y_{it,1} \quad (1)$$

Using “before” and “after” definitions, we can compute three effects: ATE (Average Treatment Effect), ATET (Average Treatment Effect on the treated), and ATENT (Average Treatment Effect on the non-treated), as follow

$$\begin{aligned} \text{ATE} &= E[y_{it,1}^a - y_{it,1}^b] - E[y_{it,0}^a - y_{it,0}^b] \\ &= \alpha \\ \text{ATET} &= E[y_{it,1}^a - y_{it,1}^b] \\ &= \alpha + \mathbf{w}_i d_{it} \beta \\ \text{ATENT} &= E[y_{it,0}^a - y_{it,0}^b] \\ &= \mathbf{w}_i d_{it} \beta \end{aligned}$$

In matrix notation, as common in Spatial Econometrics literature, we have

$$Y = \mu(\mathbf{X}) + (\alpha + \mathbf{I}_t \otimes \mathbf{W}\beta)D + U \quad (2)$$

where Y is a matrix $nt \times 1$ of observations, \mathbf{X} is a $nt \times k$ matrix of covariates, D is a *dummy* variable that indicate treated regions in each time, \mathbf{I}_t is a square identity matrix of $t \times t$ dimension, \mathbf{W} is a $n \times n$ weight matrix of neighborhood and U is a vector of errors of $nt \times 1$ dimension. μ , α and β are parameters to estimate.

In this perspective, $\mathbf{I}_t \otimes \mathbf{W}D\beta$ represents the indirect effect of treatment on both region, treated and non-treated. This is a additional effect, not estimated in general ¹. This effect, however, is an average effect. It is possible that the indirect effect is different in treated and non-treated regions. For example, if the treatment in treated region is tiny, because the direct effect is more important, and, in the same time, the indirect effect on non-treated region is profound, because is the only effect to impact this region, then,

¹The exception are, for example, (Angelucci and De Giorgi, 2009; Kaboski and Townsend., 2012; Berniell et al., 2013). The difference of our work for these is that with the spatial econometrics it is possible to control for different structures of neighborhood, not captured by these studies

when estimating β as an average to all region, we can underestimate the real effect of the treatment, because β will be estimate as an average of indirect effect on treated and indirect effect on the non-treated.

Consider, for clarity, the follow decomposition in \mathbf{W} matrix,

$$\mathbf{I}_t \otimes \mathbf{W} = \mathbf{W}_{11} + \mathbf{W}_{12} + \mathbf{W}_{21} + \mathbf{W}_{22}$$

where

$$\begin{aligned} \mathbf{W}_{11} &= \text{diag}(D) \times (\mathbf{I}_t \otimes \mathbf{W}) \times \text{diag}(D) \\ \mathbf{W}_{12} &= \text{diag}(D) \times (\mathbf{I}_t \otimes \mathbf{W}) \times \text{diag}(1 - D) \\ \mathbf{W}_{21} &= \text{diag}(1 - D) \times (\mathbf{I}_t \otimes \mathbf{W}) \times \text{diag}(D), \text{ and} \\ \mathbf{W}_{22} &= \text{diag}(1 - D) \times (\mathbf{I}_t \otimes \mathbf{W}) \times \text{diag}(1 - D) \end{aligned}$$

As D is a *dummy* variable associated to treatment information, and $\text{diag}(D)$ represent a $nt \times 1$ matrix with D in the principal diagonal and zero, out. Then \mathbf{W}_{ij} represent the neighborhood effects of the j -region on i -region . Substituting in (2), result

$$Y = \mu(\mathbf{X}) + [\alpha + (\mathbf{W}_{11} + \mathbf{W}_{12} + \mathbf{W}_{21} + \mathbf{W}_{22})\beta]D + U$$

Then, it is clear that β represents an average effect, as we mentioned above. A more realistic model consider different effect for dissimilar \mathbf{W} matrix. As, by construction, $\mathbf{W}_{12}D$ and $\mathbf{W}_{22}D$ are a $\mathbf{0}$ -vector, the unrestricted model is

$$Y = \mu(\mathbf{X}) + [\alpha + (\mathbf{W}_{11}\beta_1 + \mathbf{W}_{21}\beta_2)]D + U \quad (3)$$

The models in (2) and (3) represent a spatial dif-in-dif model (SDID model). It is important to register that this model does not contains a traditional spatial interaction effect, like SAR and SEM models Anselin (1988); LeSage and Pace (2009). But, we can

model the control effects, $\mu(\mathbf{X})$, including an auto-regressive spatial term, or the error as a spatial error model,

$$\mu(\mathbf{X}) = \rho(\mathbf{I}_t \otimes \mathbf{W})Y + \mathbf{X}\gamma'$$

and/or

$$E = \lambda(\mathbf{I}_t \otimes \mathbf{W})U$$

where, in the first equation \mathbf{X} is a $n \times k$ vector of observable characteristics, \mathbf{W} is a spatial weight matrix of $n \times n$ dimension, γ is a $1 \times k$ parameter vector to be estimated, and ρ is the spatial auto-regressive parameter. And, in the second one, E is an error vector, does not spatial associated, λ is the spatial error parameter to be estimated.

In this way, a complete version of 2 and 3 models is

$$Y = [\mathbf{I}_{nt} - \rho(\mathbf{I}_t \otimes \mathbf{W})]^{-1}\{\mathbf{X}\gamma' + [\alpha + (\mathbf{W}_{11}\beta_1 + \mathbf{W}_{21}\beta_2)]D + [\mathbf{I}_{nt} - \lambda(\mathbf{I}_t \otimes \mathbf{W})]^{-1}U\} \quad (4)$$

2.2 Data

The data used corresponds to an balanced panel of 644 municipalities, from 2002 to 2011. We have information of sugarcane production, year by year, for each locality, provided for IBGE (Statistical and Geography Brazilian Institute), and the Brazilian official department to statistical research. This department makes annually a survey about Brazilian agricultural production, that includes information relates to production, planted area, and harvested area.

In São Paulo state, the planted area with sugarcane represents nearly 50%. The expanding area in the last years given over to cane has prompted a series of questions on the possible conflict between lands used to produce food versus energy. At the national level, of the over 800 million hectares of landmass in Brazil, over 300 million are suitable for farming and ranching activities. Of these, about 60 million are used to grow permanent and temporary crops and some 200 million for animal husbandry. This means there is an ample amount of land available for cane and other crops, and this can benefit from recovery of former pasturage and productivity gains in stock breeding that can release lands. Hence, on closer study this conflict is not borne out on a national scale Chagas

et al. (2008).

In the figure 1 we mapping the evolution of sugarcane production in São Paulo state, by municipalities, in the period 2002-2011². It is clear the increase in the production in Northwest region of the state, since the initial year until current year. It is evident too the production sprawl to the west of the state, area until recently occupied by pasture.

[FIGURE 1 HERE]

The production of sugarcane is important to define our treatment variable. We consider as treated al region in that the sugarcane area represents at least 6.7% of total agricultural area. This number represents the median in production area distribution. In the table 1 we report the number of treated area in each year, in the panel. Over time, the treatment increase from 38.4% of the areas until 62.4%, in the end of the period.

[TABLE 1 HERE]

We consider as our interested variable of interest the hospitalization for respiratory problems per one thousand habitants. This data is provided by the computer department of the public health system (DATASUS)³. This department collects and systematizes administrative information about the health system, not only of the public health system, but of the private system too. This information is very disaggregated, in spatial terms. For our interest, we take the data in county level. In the figure 2 we can see the evolution of the hospitalization in São Paulo state, by region, from 2002 until 2011. It is evident the reduction in the cases of hospitalization over the time.

[FIGURE 2 HERE]

This result can be due to reduce on burning sugarcane. Nowadays, the legislation prohibits certain types of fires in certain areas and times. The controlled burning of sugarcane is regulated by the federal act (Act 2661/98) and in the State of São Paulo has a specific law more restrictive (State Law 11.241/02). The actual trend is that this practice be ended in a few years, both by regulatory pressures to reduce the emission of pollutants and their harmful effects as by the economic stimulus resulting from full use of the cane (juice, straw, leaves and bagasse), or even issues related to the labor market, formalization of the labor and enhancement of workforce. In São Paulo state, the Environmental

²We select some years in this periods, but the evolution is evident.

³<http://www2.datasus.gov.br/DATASUS/index.php>.

Protocol signed between the plants, sugarcane producers and the government establishes the end of the burning in the mechanized areas until 2014, and in all areas, in 2017. For this, it is possible that the trend in hospitalization accompanies the end of the burning. The table 2 makes this fact more evident.

[TABLE 2 HERE]

Then, we consider a trend variable as a control, to adjust for this empirical evidence. Additionally, we can consider other control variables, such proportion of workers in the population, mean income, proportion of elderly and young people, and proportion of woman in the population. The first two variables control to socio-economic conditions, which makes possible that people prevent health problems. The remain variables control the groups more susceptible to respiratory health problems, as pointed in literature Braga et al. (1999); Roseiro (2002); Gonçalves et al. (2005). Table 3 reports statistical descriptive about the variables considered, and the table 4 reports the linear correlation matrix.

[TABLE 3 HERE]

[TABLE 4 HERE]

3 Preliminary results

This section presents preliminaries results. We test two set of model, based on 2 and 3, as follow. In the first one, we consider only the average indirect treatment effect, and test the pooled specification, spatial fixed effect and pooled spatial error model. We based on Elhorst routine for panel data models (Elhorst, 2010a,b, 2011). Elhorst consider a ML estimation. The main, because the number of studies considering IV/GMM estimators of spatial panel data models is still relatively sparse ⁴.

(Elhorst, 2010b) provides a Matlab routines to estimate spatial panel data models, including the bias correction procedure proposed by (Lee and 2010, 2010) if the spatial panel data model contain spatial and/or time-period fixed effects, the direct and indirect effects estimates of the explanatory variables proposed by (LeSage and Pace, 2009), and a selection framework to determine which spatial panel data model best describes the data.

⁴One exception is (Kelejian et al., 2006), who considered IV estimation of a spatial lag model with time-period fixed effects. They point out that this model cannot be combined with a spatial weights matrix whose non-diagonal elements are all equal to $1/(N-1)$. In this situation, the spatially lagged dependent is asymptotically proportional and thus collinear with the time-period fixed effects as N goes to infinity.

We consider a k -nearest distance matrix of neighbor. To choose the order of the k -nearest neighbor we estimate a pooled model, without spatial effects, and compute the Moran I on the residual of this regression. We replicate this procedure to k between 3 and 20, and choose the order that maximizes the Moran I, so we choose the matrix for which there are the greatest spatial auto correlation.

Then, we compute three models, as follow

pooled model

$$y_{it} = \mathbf{x}_{it}\gamma' + \alpha D_{it} + \beta \mathbf{w}'_i d_t + u_{it}$$

sar model

$$y_{it} = \rho \mathbf{w}'_i y_t + \mathbf{x}_{it}\gamma' + \alpha D_{it} + \beta \mathbf{w}'_i d_t + u_{it}$$

sem model

$$y_{it} = \mathbf{x}_{it}\gamma' + \alpha D_{it} + \beta \mathbf{w}'_i d_t + u_{it} + \lambda \mathbf{w}'_i u_t$$

where y_{it} is a hospitalizations per thousand in habitants, in region i in time t , \mathbf{X}_{it} represents a vector of control variables, including a constant term, \mathbf{w}_i is a vector of neighbor weights, u_{it} is a error term, D_{it} is a indicator of treatment and d_t is vector of all indicators in t , y_t and u_t are vectors for all region, i time t . The parameters ρ , α , γ , and β will be estimate. This set of model estimate a indirect effect of the treatment as an average effect between all region, treated and non-treated.

A less restrictive set of model is

pooled model

$$y_{it} = \mathbf{x}_{it}\gamma' + \alpha D_{it} + \beta_1 \mathbf{w}'_{\mathbf{NT}} d_t + \beta_2 \mathbf{w}'_{\mathbf{TT}} d_t + u_{it}$$

sar model

$$y_{it} = \rho \mathbf{w}'_i y_t + \mathbf{x}_{it}\gamma' + \alpha D_{it} + \beta_1 \mathbf{w}'_{\mathbf{NT}} d_t + \beta_2 \mathbf{w}'_{\mathbf{TT}} d_t + u_{it}$$

sem model

$$y_{it} = \mathbf{x}_{it}\gamma' + \alpha D_{it} + \beta_1 \mathbf{w}'_{\mathbf{NT}} d_t + \beta_2 \mathbf{w}'_{\mathbf{TT}} d_t + u_{it} + \lambda \mathbf{w}'_i u_t$$

where $\mathbf{w}_{\mathbf{NT}}$ is a vector with only weight of neighbor treated related to neighbor non-treated, and $\mathbf{w}_{\mathbf{TT}}$ is a vector with weight of neighbor treated related to neighbour treated

too. To choose between the models, we use a Lagrange Multiplier (LM) test for a spatially lagged dependent variable, for spatial error correlation, and their counterparts robustified against the alternative of the other form ⁵ (Anselin et al., 1996). These tests have become very popular in empirical research. Recently, (Anselin L, 2006) also specified the first two LM tests for a spatial panel

$$LM_\rho = \frac{[\mathbf{e}'(\mathbf{I}_t \otimes \mathbf{W})\mathbf{Y}/\hat{\sigma}^2]^2}{J} \quad \text{and} \quad LM_\lambda = \frac{[\mathbf{e}'(\mathbf{I}_t \otimes \mathbf{W})\mathbf{e}/\hat{\sigma}^2]^2}{T \times T_W}$$

where \mathbf{e} denotes the residual vector of a pooled regression model without any spatial or time-specific effects or of a panel data model with spatial and/or time period fixed effects. Finally, J and T_W defined by

$$\begin{aligned} J &= \frac{1}{\hat{\sigma}^2} [(\mathbf{I}_T \otimes \mathbf{W})\mathbf{X}\hat{\beta}]'(\mathbf{I}_{NT} - \mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}')(\mathbf{I}_T \otimes \mathbf{W})\mathbf{X}\hat{\beta} + TT_W\hat{\sigma}^2], \\ T_W &= tr(\mathbf{W}\mathbf{W} + \mathbf{W}'\mathbf{W}) \end{aligned}$$

and “tr” denotes the trace of a matrix. In view of these formulas, the robust counterparts of these LM tests for a spatial panel will take the form

$$\begin{aligned} \text{robust}LM_\rho &= \frac{[\mathbf{e}'(\mathbf{I}_t \otimes \mathbf{W})\mathbf{Y}/\hat{\sigma}^2]^2 - [\mathbf{e}'(\mathbf{I}_t \otimes \mathbf{W})\mathbf{e}/\hat{\sigma}^2]^2}{J - TT_W}, \\ \text{robust}LM_\lambda &= \frac{[\mathbf{e}'(\mathbf{I}_t \otimes \mathbf{W})\mathbf{e}/\hat{\sigma}^2 - TT_W/J \times \mathbf{e}'(\mathbf{I}_T \otimes \mathbf{W})\mathbf{Y}/\hat{\sigma}^2]^2}{T \times T_W} \end{aligned}$$

(Elhorst, 2010a) call attention for these tests in panel data model, when a model includes spatially lagged independent variables must still be investigated.

The result are reported in table 5. The first three models relate to average indirect effect of treatment, and the last one, to the less restricted model with different impacts for different groups of region.

For pooled models (model 1 and 4), the results are intuitive, in general. The only one is the result to proportion of children in the population, for the both pooled models, which

⁵Software programs have built-in routines that automatically report the results of these tests. Matlab routines have been made available by Donald Lacombe at <http://oak.cats.ohiou.edu/~lacombe/research.html>. Elhorst provided the routines for the panel data case.

are negative and significant values. In the pooled model still, all control variables are very significant, unless the proportion of woman in the population - which is not significant in all models. In both models, the treatment seems a strong impact, much higher than in the other models, and the indirect effect is negative and non-significant (in the model 1).

Hold up in this result a little more. It is the result that a research will have, applying the conventional techniques. And this can justified the fact that the researches not explore more the interrelation between regions, because a result not significant is not a incentive result. But, if we compare the difference between the model 1 and the model 4, we can see a provocative result. The separation in the indirect effects on treated and non-treated regions increase the direct effect on treated regions. And give us a counterintuitive result relate to indirect effect on treated region, which is negative. This result, in particularly, can be due a omitted relevant variables, despite a high significant level. In fact, when we include spatial controls, this result does not remain.

But, for the non-treated region, the effect is very interesting. The signal is very significant and positive. Then, the indirect effect on non-treated is about half of the effect on treated regions.

We improve this investigation, including spatial controls. The LM tests, computed over the residuals of pooled model, are very conclusive to inclusion of this control, and the robust LM test can suggest that model with lag in dependent variable is more significant than in the error. Nevertheless, we report both results.

The conclusion does not change in relation to the pooled models. The controls appearance very weak controls now. Only proportion of workers in the population remains significant and negative, as expected. For the treatment effect, the magnitude of impact decreasing in all situation, compared to the pooled model. Is this can due to the fact that a part of this respiratory problem is consequence of the other regional factors than the sugarcane culture, like climatic conditions and seasonal effects. But, the impact of sugarcane culture appearance to be positive and significant in treated regions.

About the indirect effect, the difference in results remains, when we compare the average indirect effect to the separated effect. The impact on the non-treated regions seems very important and very different than indirect impact on the treat one. In the SAR model (model 5), the indirect effect on non-treated (0.78) is circa 80% of the direct effect of treatment (0.97). If we estimate to the mean, the indirect effect in the model 2 (0.44) is only 66% of the direct effect (0.65), and both are smaller.

These are preliminary results only and other test need to make until the final paper.

A counterintuitive result relate to the SAR model to overcome the SEM model. It is not reasonable assume that hospitalization due respiratory diseases cause more hospitalization on neighbour. It would be more intuitive that the error in the region was impacted to the neighbours error. It is possible that some omitted relevant variable remain in this case.

4 Final remarks

The increase in ethanol in the last years provoked many debates. In this paper we try to address on of this, more specifically, the impact on human health due to burning sugarcane.

We proposed a new methodology to evaluate impact, using aggregate data in regional level and information about the neighbors. More specifically, we consider the indirect effect of treatment on treated and non-treated region.

Our results suggest the correction on our assumption. In fact, the results suggest that our method makes it possible to identify better the impact, not only in the treated regions, but on non treated too.

The research is in beginning, but the results look promising.
