The Effects of Debt versus Equity Inflows on Savings and Growth in Developing Economies

By

Ulrich Lächler and Peter Nunnenkamp

I. Introduction

Since the onset of the international debt crisis, various new schemes and innovative financial arrangements have been proposed for the purpose of alleviating the external debt problems currently experienced by many developing countries [The World Bank, 1985]. Common to many of these proposals is the intent to alter the external capital structure of developing countries toward increasing the proportion of claims based on some form of risk and profit sharing (i.e., equity participation). This applies, for example, to recent measures designed to promote foreign direct investments (such as the Multilateral Investment Guarantee Agency), debt-equity swap arrangements (introduced in Chile), the promotion of mutual funds containing stocks of developing country industries (such as the Korean Fund), and contingency arrangements, such as commodity-linked bonds, with clauses that index their returns to the price of key commodities exported by the borrower (recent debt renegotiations involving Mexico and Venezuela included such clauses).

A shift in the external capital structure, as projected by these measures, yields the obvious benefit of reducing the extremely heavy debt-service burden of some developing countries. From a broader welfare perspective, however, can it be claimed that a developing country would be better off with a lower external debt-equity ratio? This question has recently been addressed in terms of a choice-theoretic model based on an agent-principal approach [Lächler, 1985]. That analysis arrived at the familiar result that both a first-best “cooperative” or a second-best “non-cooperative” equilibrium are possible outcomes of the capital transfer negotiations between foreign principals and the managing authorities of a developing country. It was then shown that if conditions conducive to a cooperative equilibrium pertain, a shift from debt financed to equity financed transfers, leaving the total capital inflow the same, would yield an unambiguous welfare improvement from the viewpoint of the capital importing nation. With a non-cooperative environ-
ment, however, the answer to the question posed above is less clear-cut. In that case, the choice between equity or debt financed inflows can be shown to involve a “risk-return” tradeoff between income stability and expected growth. That is, with a higher proportion of equity financed inflows, the variability of residual income generated and retained in the developing economy would decline, but the domestic savings incentives and hence the future growth prospects of that economy would also be reduced.

In view of these conclusions, it is of considerable interest for the purpose of formulating policy recommendations to determine whether the actual environment in which capital transfers to developing countries take place is more accurately characterized by a cooperative or non-cooperative process. This essay provides some evidence on this issue, using data from a sample of 36 developing countries over the period 1976–1979. Cross-country regression analyses are applied to test several competing hypotheses concerning the domestic savings and growth response of developing nations to alternative sources of capital inflows. These hypotheses are explicitly derived from the agent-principal model mentioned previously, and to be discussed next.

II. A Discussion of the Basic Model

The theoretical framework employed originates from the literature that focuses on agency relationships, or moral hazard problems, arising from the separation of ownership and control of the firm when monitoring costs are non-negligible [e.g., Jensen and Meckling, 1976; Ross, 1977; Stiglitz, 1974]. In contrast to the traditional profit-maximizing postulate, this literature builds on the assumption that the incentive structure governing the behaviour of decision-makers in a firm varies with the rules that determine how the proceeds from that firm are distributed. Since those rules are intimately connected to the firm’s financial structure, a change in the debt-equity ratio, for example, is likely to affect the firm’s performance. With this approach, the Modigliani-Miller Theorem holds only as a special case, when various market imperfections are removed.

Several authors have adopted a similar approach to explain different aspects of the international credit market, with an emphasis on the debt-related problems of developing countries [Eaton and Gersovitz, 1981; Folkerts-Landau, 1985; Sachs, 1982]. In this context, the decision-making authorities of a capital-recipient country can be visualized as agents in an economic enterprise vis-à-vis foreign principals. Lächer [1985] has extended this work by developing a choice-theoretic model that simultaneously incorporates both equity and debt instruments as alternative sources of foreign capital. The basic assumptions made in that model are:

(i) Aggregate future output of a small developing economy is a function of current investment and an exogenous random element, whose value is
realized after the investment decision has taken place.

(ii) The aggregate investment decision is made by a social planner, characterized as a risk-averse agent maximizing a well-behaved social expected utility function with domestic consumption as its argument.

(iii) Foreign capital owners supplying external funds are modelled as rational risk-neutral principals, who are indifferent to whether a capital transfer takes place in the form of debt or equity participation as long as the expected return on both claims is the same. From their viewpoint, the claims on this economy represent only one of many investment opportunities in a diversified asset portfolio.

(iv) Foreign capital inflows are perfectly "fungible", whether they appear in the form of debt, equity or foreign aid (treated here as an unrequited gift). In other words, once a transfer of capital has taken place, the agent obtains total control in disposing of these funds for current investment or consumption purposes.

In this stylized setting, a moral hazard situation arises once a transfer of capital has occurred. This situation is due to an informational asymmetry: The principal, unlike the agent, does not know how much is effectively invested after the capital transfer has taken place. All he observes is the level of output generated in the future, which is only partly a function of investment and in part stochastic. That rules out the possibility of setting up contingency contracts, that link the terms of transfer to the ex post level of investment undertaken [see, e.g. Haque and Mirakhor, 1986]. Consequently, the following disincentive problems emerge: If the transfer takes place in the form of equity participation, entitling the principal to a pre-negotiated share of future output, the agent has an ex post incentive to invest a smaller portion of the currently available funds (and hence consume more) than if the same transfer had been made as a gift. Alternatively, if the transfer is made in exchange for debt claims entitling the principal to a fixed sum in the future, then in making his investment decision, the agent has an ex post incentive to accept more risk than in the case of a gift-transfer, which translates into a greater intertemporal variability of domestic consumption. Both types of behaviour on the part of the agent would, ceteris paribus, reduce the expected value of claims held by the principal. Rational principals, however, would anticipate such behaviour before effecting the transfer, and demand commensurate adjustments in the terms and conditions at which the transfer is made.

A cooperative outcome of this transfer process is conceivable if the agent "cooperates" with the principals and complies with all previously negotiated commitments, including the amount of investment to be undertaken, in spite

---

1 The basic equations of the model that correspond to these assumptions are provided in the Appendix.
of the disincentives noted above. Perhaps more realistically, this outcome could be achieved if the principal had the ability to monitor the agent directly or to impose penalties on the agent for not responding in this cooperative manner. That would eliminate the moral hazard problem. However, if the costs of monitoring are sufficiently high, due to information barriers or limited legal enforcement capabilities, only a non-cooperative outcome may be feasible, which generally leaves the agent in a less favourable position relative to the hypothetical cooperative outcome.

Since it is difficult to say, a priori, whether the transfer negotiations are more likely to converge to a cooperative or non-cooperative equilibrium, both solutions were investigated, yielding the basic conclusions: in a cooperative environment the risk-averse agent would always prefer equity over debt financed inflows, while in a non-cooperative environment he would choose some optimal combination of both types of claims, corresponding to a preferred point on an implicit trade-off between domestic income variability and expected future consumption. On the basis of this conclusion alone one might infer that a non-cooperative equilibrium is more representative of actual transfer processes, since most countries usually receive foreign loans as well as direct investments. This outcome, however, could just as easily be due to the fact that those countries have faced supply-constraints in terms of the types of transfers made available by foreign principals.

A stronger and more interesting set of competing hypotheses emerges when both equilibria are subjected to a comparative statics analysis. This was done in Lächler [1985, Section 5] to derive the equilibrium investment response to a foreign capital inflow from alternative sources. The results reveal an important difference: In a non-cooperative environment, the equilibrium change in aggregate investment, \( I \), resulting from an increase in foreign transfers, \( T \), obeys the following pattern:

\[
(1) \quad \frac{dI}{dT} \bigg|_{\text{Equity}} \leq \frac{dI}{dT} \bigg|_{\text{Aid}} \leq \frac{dI}{dT} \bigg|_{\text{Debt}}
\]

and \( 0 \leq \frac{dI}{dT} \bigg|_{\text{Aid}} \leq 1 \). Aid, once again, is simply considered as a gift that raises the initial endowment of the capital recipient. Here it turns out that \( \frac{dI}{dT} \bigg|_{\text{Equity}} \) may be negative, while \( \frac{dI}{dT} \bigg|_{\text{Debt}} \) is always positive.

On the other hand, in a cooperative environment the following pattern results:

\[
(2) \quad \frac{dI}{dT} \bigg|_{\text{Aid}} \leq (\frac{dI}{dT} \bigg|_{\text{Equity}}, \frac{dI}{dT} \bigg|_{\text{Debt}})
\]

such that, also \( 0 \leq \frac{dI}{dT} \bigg|_{\text{Aid}} \leq 1 \). Expression (2) states that in a cooperative situation the agent would always invest more in response to transfers entailing future repayment obligations, be they in the form of equity or debt, than in response to a gift. In this case, it remains indeterminate whether \( \frac{dI}{dT} \bigg|_{\text{Equity}} \leq \frac{dI}{dT} \bigg|_{\text{Debt}} \), since that depends, among other things, on the initial
Debt versus Equity Inflows

A corollary of this result is that domestic savings and output growth should exhibit the same order of response behaviour in respective environments. That is because domestic savings, \( S \), are defined as total minus foreign savings, \( 1-T \), so that \( dS/dT = d(1-T)/dT = -1 \). The only necessary modification to be made in expressions (1) and (2) is that the expected response to an aid inflow would then be bounded by \( -1 \leq dS/dT_{\text{aid}} \leq 0 \). Similarly, on the assumption that a nation’s growth rate is positively related to the amount of investment, the same pattern of growth responses to foreign inflows as described by the preceding expressions should result. Our purpose next is to devise some tests that may help us to discriminate which of the two patterns given by expressions (1) and (2) best characterizes actual transfer processes.

III. Equation Specification and Statement of Hypotheses

The basic equation to be estimated below using cross-country data is of the form:

\[
X_i = a_0 + a_1(FDI/GDP)_i + a_2(AID/GDP)_i + a_3(DEBT/GDP)_i
\]

The exogenous variables on the right-hand side of this expression represent the net foreign capital inflows per annum received by country \( i \) in the form of foreign direct investment, aid, and through debt-related channels, each expressed as a share of GDP. The proxies used for these variables are discussed later. Suffice it to note here that FDI represents our measure of foreign capital introduced in the form of equity participation.

Three variables are used separately for the endogenous variable, \( X_i \). These are (i) the domestic savings rate, \( \text{DSR} \), also expressed in shares of GDP, (ii) the aggregate investment rate, \( \text{IR} \), and (iii) the annual per capita growth rate of GDP, denoted \( \text{GR} \).

Our hypothesis is that capital transfers to developing countries are best described by a non-cooperative process. From expression (1), we would therefore expect to obtain coefficient estimates in (3) that obey the following pattern:

\[
a_1 \leq a_2 \leq a_3
\]

Furthermore, with regard to the individual coefficient estimates, the theory states that these should satisfy the following constraints:

---

2 It also turns out that, for any given level of foreign debt or equity financed transfers, the equilibrium level of investment undertaken by the agent is always greater in a cooperative environment than in a non-cooperative one.

3 Additional regressions were also performed with the annual growth rate of GDP (unadjusted for population growth) instead of \( \text{GR} \) as the dependent variable. Since no significant difference in the estimation and hypothesis-test results emerged, we do not report those additional results.
(5) a) \(-1 \leq a_2 \leq 0\), when the endogenous variable is DSR,  
b) \(0 \leq a_2 \leq 1\), when the endogenous variable is IR,  
c) \(a_2 \geq 0\), when the endogenous variable is GR,  
d) \(a_3 \geq 0\), when the endogenous variable is IR or GR.

Our first step, then is to see whether any of these constraints can be statistically rejected.  
Our primary concern, however, is less with the absolute size of the individual coefficients. For purposes of theory validation, it is their relative size that is of main interest. With that focus in mind, we can set up the alternative hypothesis, proposing that there is no significant difference in the responses to the various forms of capital inflows. This alternative hypothesis may be supported or rejected by testing the simultaneous constraint:

\[ a_1 = a_2 = a_3 \]  

Continuing along these lines, we can proceed to make pair-wise comparisons, and examine whether the data permits us to reject the following restrictions:

(7) a) \(a_2 = a_3\)  
b) \(a_1 = a_3\)  
c) \(a_1 = a_2\)

It is important to note here that the crucial test for supporting or rejecting the assumption of a non-cooperative environment against the alternative, that a cooperative environment applies, concerns restriction (7.c). By comparing expressions (1) and (2), we observe that in both cases it would be predicted that \(a_3 \geq a_2\), and further, that it is left indeterminate whether \(a_3 \geq a_1\) in a cooperative environment. What is clear, however, is that in a cooperative environment we would observe that \(a_1 \geq a_3\), while in the non-cooperative environment, \(a_1 \leq a_3\).

Having performed these tests, two further issues are addressed below. Since the coefficient estimates are made by ordinary least square methods, it is necessary to discuss the simultaneity biases that might be involved in this procedure. The other issue concerns the sample homogeneity. Is it possible that in some developing countries a cooperative relationship with foreign principals has developed, but not in others? This question is examined by performing separate analyses for “problem” countries that encountered debt-servicing difficulties during, or shortly after, the relevant sample period, and for the remaining countries.

The impact of foreign inflows on domestic savings and growth has been a subject of controversy for many years in the development literature. This has led to a substantial body of empirical research (as surveyed, e.g., in Bhagwati
much of this work, however, is mainly concerned with the effectiveness of foreign aid. One major bone of contention is whether aid raises total domestic investment by an equal amount, as assumed in early applied development models [Chenery and Strout, 1966; Leontief, 1965]; or is fungible enough to be treated as a general increment to income [Mosley, 1980; Papanek, 1972; Weisskopf, 1974]; or it is downright deleterious, for various socio-political reasons, as argued in Griffin and Enos [1970]. While various attempts were also made to differentiate between alternative sources of foreign inflows, such as private versus official inflows [e.g., Papanek, 1973; Dowling and Hiemenz, 1983], none have addressed the central equity-versus-debt distinction emphasized in this essay. Another contrast with most earlier research emerges from the fact that the estimated coefficient values in (3) by themselves reveal little about whether a developing country is better off receiving one form of inflow or another. To arrive at such welfare conclusions it is necessary to place the regression estimates in a specific choice-theoretic context, such as we have described earlier. Previous related empirical studies have generally not provided such an explicit context.

IV. The Empirical Results

1. The Data Base – Some Explanatory Remarks

To perform our cross-country analysis, we began with an initial sample of about 50 developing economies, for which the required data was available. This sample was then reduced to 36 countries by eliminating those that reported net financial outflows of direct investment, debt or development aid for the entire period, 1976–1979. Since our study concerns the impact of foreign financial inflows on economic performance, this sample restriction seems appropriate; (see Weisskopf [1974], who employs a similar procedure). The data base for these 36 countries is presented in Table A1 of the Appendix, along with an explanation of the sources and definitions of the specific variables. We added all flows within each category over the period 1976–1979, so that the sample points reported in Table A1 represent period aggregates or averages. This sample, though considerably reduced, still covers a wide spectrum of developing economies in terms of income levels, economic performance, overall dependence on foreign resource inflows, and the structure of capital imports.

Before presenting the regression results, it is necessary to explain why the analysis is restricted to the period 1976–1979. To begin, comparable time series on the structure of net capital imports were not available until 1976. On the other hand, statistical information on most of our variables was available up to 1984, except for domestic savings. Nevertheless, we decided to concentrate on the second half of the 1970s because thereafter both the
volume and structure of international capital transfers to developing countries were significantly affected by severe economic shocks: At the turn of the decade, the second oil price shock induced a new round of enormous financial recycling of OPEC surpluses, which drastically altered the previous pattern of financial flows of the late 1970s. This was followed in the early 1980s by another shock to the international capital markets. With the eruption of severe repayment crises in some important debtor countries, Western commercial banks abruptly halted the provision of fresh money to the problem-ridden Latin American region. That also altered the flows to developing countries, both in terms of regional distribution and structural composition. To avoid statistical noise on this account, we chose 1979 as the endpoint date. To assess the robustness of our primary results, however, we repeated the main regressions extending the endpoint date to 1981 (i.e., after the oil shock occurred, but before Mexico suspended payments, triggering the debt crisis). It turns out that this modification has little impact on the pattern of estimated coefficients, but does affect their significance levels in some cases. These results are reported in a footnote.

Table 1 reports the correlation coefficients between all variables used in the subsequent regression analyses. In view of the fairly small correlation between the independent variables, we should not expect any serious multicollinearity problems to arise.

2. Estimation Results

The coefficient estimates obtained from the regressions described by (3) are presented in Table 2. The most remarkable feature of these results is that in all cases the estimated coefficient values clearly follow the characteristic pattern of a non-cooperative equilibrium, i.e., \( \hat{\alpha}_1 < \hat{\alpha}_2 < \hat{\alpha}_3 \). We also observe that none of the conditions implied by our hypothesis, and outlined earlier in
expressions (5.a)-(5.d), can be rejected with much confidence. Although the point estimates of \( \alpha_2 \) in regressions (2) and (3) of Table 2 violate conditions (5.b) and (5.c), this deviation from the predicted range is not significant at the 5 per cent level\(^4\). We can conclude from these results that the basic behavioural responses suggested by our model, along with the hypothesis that capital transfers take place in a non-cooperative environment, are not rejected by the empirical evidence\(^5\).

</table>

Note: Terms in parentheses are standard errors. See text for definitions. Eqs. (1) and (3) were estimated with a sample of 36 countries, (2) with a sample of 35 (data on IR was not available for Nepal). All estimations were made by OLS.

\(^4\) Notice that the regressions with DSR and IR in Table 2 exhibit a higher \( R^2 \) than that one with GR as dependent variable. This observation can also be given an interpretation which is consistent with our theoretical model: Recall that the basic theory concerns the determination of investment, while changes in output are necessarily a stochastic function of investment. Hence, even if our empirical model could perfectly explain all variations of IR (i.e., with an \( R^2 \) of 1), we should still expect a less than perfect fit in the case of GR. On the other hand, there could be measurement errors which may offset the statement just made. That is, the observed values of IR and DSR may not correspond to true investment, in the sense of foregone present consumption to raise future expected output. The empirical distinction between investment and consumption is largely a matter of convention. Thus, the label of investment gets attached to various consumption activities (perquisites) by management and to white elephant projects mainly designed to enhance the glory of some transient politicians, while other more productive expenditures (on cars, for example) are mislabeled consumption. This problem should not arise in the case of growth figures, since output changes presumably reflect true investment activities, independent of how they are labeled.

\(^5\) Performing the same OLS regressions shown in Table 2, but using data for the extended period 1976–1981, yields the following results (standard errors in parentheses):

\[
\begin{align*}
DSR = 15.43 - 1.31 \text{FDI/GDP} - 1.24 \text{AID/GDP} + 2.38 \text{DEBT/GDP} \\
& (1.87) (2.21) (0.29) (0.68) \\
& R^2 = 0.46 \quad F = 10.48 \quad SSR = 817 \quad 34 \text{ observations} \\
IR = 19.74 - 2.36 \text{FDI/GDP} - 0.66 \text{AID/GDP} + 2.49 \text{DEBT/GDP} \\
& (1.30) (1.52) (0.21) (0.45) \\
& R^2 = 0.53 \quad F = 12.84 \quad SSR = 359 \quad 32 \text{ observations}
\end{align*}
\]
The next logical step, in view of this outcome, is to examine whether any alternative hypotheses can be rejected. This is done by testing the parameter restrictions described in expressions (6) and (7.a)–(7.c). Toward that purpose, we use a standard F-test procedure of estimating the restricted form of regression equation (3) and comparing the resulting sum of squared residuals with those obtained from the unrestricted estimations, presented in Table 2. Table 3 reports these test results. From the first column of F-statistics we observe that the alternative hypothesis, which claims that all forms of external finance are alike in their impact on economic performance, is unanimously rejected. In other words, there does appear to be a significant difference in the savings and growth response to alternative sources of finance. With regard to the other (pair-wise) constraint tests, the results are not quite as convincing. We may note, however, that each of the restrictions, (7.a)–(7.c), is rejected at least once in the relevant series of tests.

As argued earlier, the test of restriction (7.c) is the decisive one in terms of pitting the non-cooperative hypothesis against the cooperative counterhypothesis. Given that the previous estimations yielded $\beta_1 < \beta_2$, a rejection of the

<td></td>
</tr>
</tbody>
</table>

Note: SSR denotes the sum of squared residuals obtained by estimating (3) with the respective constraints imposed. These values are then compared with the SSR of the unconstrained estimations, reported in Table 2, to derive the F-statistic values here. A* indicates that the parameter restriction can be rejected at the 5 per cent significance level.

| $GR = 3.11 - 1.85 \text{FDI/GDP} - 0.19 \text{AID/GDP} + 0.07 \text{DEBT/GDP}$ |
|-------------------|-------------------|-------------------|-------------------|
| (0.93)            | (1.10)            | (0.15)            | (0.32)            |
| $R^2 = 0.04$      | $F = 1.42$        | $SSR = 203$       | 34 observations   |

These coefficient estimates display the same qualitative pattern as those in Table 2. There are some differences, however, in terms of the statistical significance of the estimated values. Most notable is the decline in the explanatory power of the last equation, involving GR as the dependent variable ($R^2 = 0.04$). This decline may be attributed to the increased economic turbulence experienced in 1980–1981, when additional factors, ignored in this analysis, attain greater importance in determining growth patterns. The other major difference is that the AID/GDP coefficient in the second equation, involving IR as the dependent variable, now turns out to be significantly negative, contrary to what was hypothesized. This may be due to simultaneity bias, which we address later.
Debt versus Equity Inflows

constraint, \( a_1 = a_2 \), is sufficient for rejecting the cooperative hypothesis, which states that \( a_1 \geq a_2 \). From the last column of Table 3 we observe that while restriction (7.c) cannot be rejected when DSR and IR are used as dependent variables in the regression equations, it is rejected when GR is employed.

3. Simultaneous Equation Problems

By and large, the results obtained so far support our hypothesis. But since the estimation technique we used involves single-equation ordinary least squares, some doubt is bound to arise with regard to the unbiasedness of the estimated coefficients. Such doubt has been frequently voiced in criticism of similar studies addressing the effectiveness of foreign aid [e.g., Over, 1975; Papanek, 1972]. The main thrust of these critiques is that domestic savings and growth are not only determined by the amount of foreign aid inflows, but, in turn, they also determine how much aid flows in. Consequently, AID would not be fully exogenous in (3), which violates the orthogonality principle and leads to biased estimates.

With respect to the two-way causation argument between AID and domestic savings or growth, an underlying premise is that foreign assistance is largely given (for altruistic reasons) to countries in need. That by itself, however, is not enough to generate biased estimates. A further necessary assumption for that result is that “needy” countries are more likely to exhibit lower savings (or growth) rates. Should that assumption be valid, then the estimated relation between aid and savings or growth will reflect both the response of aid recipients and the motives of aid donors.

To account for the possibility of two-way causation in the case of AID, we reestimated (3) using a two stage, instrumental variable technique, such that DEBT/GDP, FDI/GDP and GDP/capita were specified as the exogenous instruments. In spite of this adjustment, all three regressions yielded the same basic results as were obtained by OLS. The 2SLS regression involving GR provides a representative example:

\[
(8) \quad GR = 3.79 - 2.81 (FDI/GDP) - 0.11 (AID/GDP) + 0.02 (DEBT/GDP)
\]

\[
(1.52) \quad (0.96) \quad (0.35) \quad (0.23)
\]

\[
SSR = 190 \quad \text{(standard errors in parentheses)}
\]

By comparing this result with the third regression in Table 2, we note that the relative order of the estimated coefficients is the same in both cases. That is, \( \hat{\alpha}_1 < \hat{\alpha}_2 < \hat{\alpha}_3 \), as hypothesized for a non-cooperative environment.

The two-way causality argument applied to AID is much less plausible in the case of FDI and DEBT inflows. Consequently, we did not attempt to explore this possibility further\(^6\). If the negative coefficients obtained for

\(^6\) Contrary to foreign aid, a convincing theoretical argument referring to the simultaneous equation problem in the case of FDI and DEBT does not exist to our knowledge. Therefore, the choice of instrumental variables would be entirely arbitrary.
(FDI/GDP) in our previous regressions are to be blamed on simultaneity bias, the logical corollary would have to be that FDI (but not DEBT) is systematically channelled to low-saving or slow-growing economies. It is difficult to find a persuasive argument to justify this type of behaviour among foreign capital owners.

4. Sample Homogeneity

When some firms, or countries, go bankrupt or encounter debt-servicing problems, and others do not, it is difficult to say, offhand, whether this outcome is simply due to random draws of fate or also to different patterns of conduct among the relevant decision-makers. One reason for supposing the latter is that some agents may have developed a cooperative relationship with their outside principals, while others remained in a non-cooperative relationship. One result to emerge from the earlier theoretical considerations was that the level of investment undertaken in response to a debt-financed transfer is always less in a non-cooperative equilibrium than in a cooperative one. At the same time, the terms of a transfer (e.g., interest rate) are always less favourable for the capital recipient in a non-cooperative environment relative to a cooperative environment. I.e., the agent bears the agency costs of finance. Consequently, the likelihood that a borrower would run into debt-servicing difficulties is always higher in a non-cooperative environment.

To investigate this issue, we separated our cross-country data into two subsamples on the basis of whether or not a country was engaged in multilateral debt renegotiations during the period 1975–1984, as stated in the World Development Report [1985, Fig. 2.4A]. Assuming that some countries developed a cooperative relationship while others did not, we would expect the former to be more highly concentrated among the countries that did not experience debt-servicing problems. Separate regressions of (3) were then performed over each subsample, to see if any difference in the pattern of responses emerged. When DSR and IR were used as dependent variables, the separate estimation results (not shown here) were both fairly close to those obtained from the combined sample regressions, shown in Table 2. This was also reflected in the F-tests, which compare the SSR's from both subsample regressions to the respective (constrained) SSR's in Table 2. In the case of DSR, $F(4,28) = 1.65$, and in the case of IR, $F(4,27) = 0.95$. Both are insignificant.

In the case of GR as the dependent variable, however, we obtain an F-statistic value of $F(4,28) = 3.22$, which is significant at the 5 per cent level. The subsample regressions that yield this result are (standard errors in parentheses):
(i) Countries that renegotiated \((n = 17)\)

\[
GR = 3.98 - 2.30 \text{ (FDI/GDP)} - 0.68 \text{ (AID/GDP)} + 0.06 \text{ (DEBT/GDP)}
\]

\[
(0.98) (0.84) (0.25) (0.37)
\]

\[
R^2 = 0.58 \quad \bar{R}^2 = 0.48 \quad SSR = 53 \quad F(3,13) = 6.0
\]

(ii) Countries that \textit{did not} renegotiate \((n = 19)\)

\[
GR = 4.08 + 3.46 \text{ (FDI/GDP)} - 0.18 \text{ (AID/GDP)} + 0.03 \text{ (DEBT/GDP)}
\]

\[
(1.20) (4.51) (0.14) (0.25)
\]

\[
R^2 = 0.18 \quad \bar{R}^2 = 0.01 \quad SSR = 74 \quad F(3,15) = 1.07
\]

From (9), we observe that the countries encountering debt-servicing difficulties exhibit the typical response pattern characteristic of a non-cooperative environment. Furthermore, the overall \(R^2\) of the regression is quite high. A noticeable contrast emerges in the case of countries that did not renegotiate. In (10), the estimated coefficient values obey a pattern that is more consistent with a cooperative environment, giving some support to the notion that a different transfer relationship, involving different response patterns, may have developed in some countries. With that interpretation, the low \(R^2\) of regression (10) is to be expected, since the data sample in question contains a more heterogenous group of countries, in terms of cooperative and non-cooperative behaviour, than the sample used for regression (9)\(^7\).

V. Conclusions

We propose that our preceding estimation results be interpreted within a specific choice-theoretic context. That context was provided by an agent-principal model of capital transfers, where both a cooperative and a non-cooperative equilibrium are possible. A central prediction of that model is that the aggregate savings and investment responses to alternative forms of capital inflows are systematically different, depending on whether a cooperative or non-cooperative setting applies. The purpose of this analysis has been to determine which of the two response patterns best describes the observed behaviour among developing countries. Our empirical estimations and hypothesis test results suggest that, with some possible exceptions, most

\(^7\) It may be useful to make a small analytical observation at this point. Throughout the paper we have implicitly assumed that each capital recipient country is engaged in either a cooperative or a non-cooperative relationship with foreign principals, but not both. To model a situation where the capital recipient is simultaneously involved in cooperative relations with some principals and non-cooperative ones with others would require various modifications to the original model, e.g., that foreign inflows are not perfectly fungible and that foreign principals cannot communicate with each other. In the present analytical framework, a partly cooperative, partly non-cooperative transfer solution would not constitute a stable equilibrium.
developing countries were engaged in a non-cooperative relationship with foreign suppliers of capital during the period analysed.

The consequence of a non-cooperative equilibrium is that capital recipients face a trade-off between less income variation and faster growth, when confronted by the alternative of receiving equity or debt-financed inflows. Whereas debt-financed transfers exert a relatively stronger positive influence on domestic savings and growth, equity-financed transfers provide the benefit of lower fluctuations in domestic consumption. This means that neither form of capital inflow can be judged unambiguously superior to the other, and thus recommended for all countries, independent of social attitudes towards risks.

An unambiguous welfare improvement can only result from a shift of this trade-off toward less risk and more growth. How to bring such shifts about is beyond the scope of this essay. Broadly speaking, this would require some fundamental institutional changes (e.g., improved information channels, a better defined and uniform allocation of legal rights, and effective legal enforcement), especially within many developing countries, to reduce monitoring costs and thereby provide a more conducive setting for attaining cooperative equilibria. Our previous sample homogeneity test gives a partial indication that some countries may have evolved further in this regard than others. Those countries, once identified, can provide suitable examples for further study and possible emulation.

Appendix
Definition of Variables

The data for the explanatory variables, aid, debt, and direct investment, is taken from OECD, Geographical Distribution of Financial Flows to Developing Countries.

- Aid consists of grants and net official development assistance (ODA) loans provided by the member countries of the OECD Development Assistance Committee (DAC), multilateral agencies, and OPEC member countries. The figures do not include financial flows from the IMF (except loans by the IMF Trust Fund), member countries of the Council for Mutual Economic Assistance, other developing countries, and grants by private voluntary agencies. Grants cover gifts, in money or in kind, for which no repayment is required as well as grant-like flows, i.e., loans repayable in the recipients' currencies. ODA loans carry maturities of over one year and contain a grant element (a measure of the concessionality of a loan) of at least 25 per cent. Official loans with a grant element of less than 25 per cent appear under the heading "other official flows (OOF)" and are classified in our study as debt-creating financial flows.

- In addition to net OOF, our debt figures include net private sector flows in

Debt versus Equity Inflows

the form of export credits and portfolio investment (as defined in the OECD source) from DAC members. Portfolio investment largely corresponds to transactions by the private monetary sector (bank sector loans). Loans by branches in offshore centres of banks resident in DAC countries are omitted. The portfolio investment figure is a direct measurement of new bank transactions with more than one year maturities, less repayments of principal, converted to U.S. $ at the average annual exchange rate.

- The data on direct investment is from the OECD figures on net private sector flows from DAC member countries to developing countries.

Table A1 presents aid, debt, and direct investment (FDI) both in absolute amounts for 1976–1979 and as a percentage share of the recipient country's GDP over this period. To calculate the latter figures, the developing countries' nominal GDP (published in IMF, *International Financial Statistics*) is converted to U.S.$ by applying annual average exchange rates. Data on the economic performance variables (apart from domestic savings which are not reported there) are also from International Financial Statistics. Average annual economic growth rates in 1976–1979 are given by GDP per capita in constant prices, while investment ratios refer to the average share of gross fixed capital formation in GDP. Information on gross national savings (excluding net current transfers from abroad) is from World Bank, *World Tables*, and is expressed as a share of GDP, as reported in the same source. It should be remembered that, within the system of national accounts statistics, gross national savings are calculated as a residual, i.e., gross domestic capital formation minus the current account deficit. However, since our figures for DSR and IR originate from different sources, they may not be exactly related in this indicated manner.

A Mathematical Outline of the Underlying Theoretical Model

A two-period Fisherian consumption model is considered, where future output is a stochastic function of current investment.

(B.1) \[ Q_{t+1} = x_{t+1} F(I_t) \]

Q = aggregate output, I = investment, x = a stochastic variable with mean 1, distributed according to the probability density function, g(x), over the non-negative interval (0,\( \bar{x} \)).

The expected social utility function to be maximized by the agent is:

(B.2) \[ S = U(C_t) + \beta \frac{1}{\delta} \int U(C_{t+1})g(x)dx \]

where \( U' > 0, U'' \leq 0 \) and \( U(0) = 0 \). We also have that, \( C_t = \bar{y} + T - I_t; \ C_{t+1} = \text{Max} (\gamma [x_{t+1} F(I_t) - B], 0) \)

* The subsequent paragraphs draw heavily on Lächler [1985].
\( \bar{y} \) = initial endowment of the agent,
\( \beta \) = discount term,
\( T \) = capital transfer from abroad,
\( B \) = the amount owed to the foreign principal in period 2, in return for a debt transfer in period 1,
\( \gamma \) = domestic equity share (= 1 minus the equity share of net output accruing to the foreign principal in return for an equity transfer in period 1).

The present expected value of a combined claim (held by the foreign principal), involving an amount, \( B \), of debt and \((1-\gamma)\) in foreign equity participation, can be expressed, for any given level of investment by the agent, as

\[
T = F(I)\left(1 - \gamma \int_b^{\bar{y}} (x-b)g(x)dx\right)
\]

where \( b = B/F(I) \). In this simplified version of the model, the absence of "sovereign risk" is assumed.

For a given transfer of size \( \bar{T} \), the cooperative equilibrium solution is derived by maximizing \( S \) w.r.t. \((I,\gamma)\) or \((I,B)\) subject to (B.3). The non-cooperative equilibrium solution is derived by maximizing \( S \) only w.r.t. \( I \), given \( \gamma \) and \( B \). The resulting first-order condition, together with (B.3) is then used to solve for the equilibrium values of \((I,\gamma)\) or \((I,B)\).

A transfer in the form of foreign aid (gifts) can be simply treated as an increase in \( \bar{y} \).

* 

Résumé: Les effets de l'influx de la dette et du capital propre sur l’épargne et la croissance en économies développantes. – L’élément commun des beaucoup de propositions données pour faciliter les problèmes de la dette extérieure des pays développants est l’intention de changer la structure des importations de capital vers l’augmentation du rapport des créances qui basent sur quelque forme de partager les risques, p.e. la participation en capital propre. Cependant, le choix entre le capital propre ou des influx des capitaux financés par des dettes peut induire un conflit de «rendement-risque» entre la stabilité de revenu et la croissance attendue. Cette hypothèse est dérivée d’un modèle choix-théorique basé sur l’approche agent-principal et testée empiriquement en appliquant l’analyse de régression trans-pays. Les auteurs démontrent que, dans un cadre non-coopératif des relations débiteur-créditeur, des transferts financés par des dettes ont une influence plus positive sur l’épargne et la croissance économique. La participation en capital propre ne peut pas être évaluée supérieure sans ambiguïté et c’est pourquoi elle ne peut pas être recommandée pour tous les pays, indépendant des attitudes sociales envers le risque.

* 

Resumen: El efecto del endeudamiento sobre el ahorro y el crecimiento en economías en desarrollo comparado con el de las inversiones directas. – En varias propuestas para aliviar el problema de la deuda externa de los países en desarrollo se sugiere alterar la composición de las importaciones de capital en el sentido de aumentar la proporción de derechos con participación en el riesgo económico, es decir, la participación de la inversión directa. La elección entre inversión directa y deuda considera la relación inversa riesgo-beneficio que existe entre la estabilidad del ingreso y el crecimiento esperado. Esta tesis se deriva de un modelo teórico de elección basado en el enfoque agente-principal, que es sometido a un test empírico de regresión sobre una muestra de países. Se muestra que en el marco de relaciones deudor-acreedor de tipo no cooperativas las transferencias de financiamiento por deuda ejercen una influencia positiva relativamente superior sobre el ahorro y el crecimiento económico. La participación directa en el capital no resulta superior en todos casos y por ello no puede ser recomendada para todos los países, independientemente de las actitudes frente al riesgo que prevalezcan.
