Abstract

This paper proposes methods for estimation and inference in multivariate, multi-quantile models. The theory can simultaneously accommodate models with multiple random variables, multiple confidence levels, and multiple lags of the associated quantiles. The proposed framework can be conveniently thought of as a vector autoregressive (VAR) extension to quantile models. We estimate a simple version of the model using market equity returns data to analyse spillovers in the values at risk (VaR) between a market index and financial institutions. We construct impulse-response functions for the quantiles of a sample of 230 financial institutions around the world and study how financial institution-specific and system-wide shocks are absorbed by the system. We show how the long-run risk of the largest and most leveraged financial institutions is very sensitive to market wide shocks in situations of financial distress, suggesting that our methodology can prove a valuable addition to the traditional toolkit of policy makers and supervisors.

Keywords: Quantile impulse-responses, spillover, codependence, CAViaR

JEL classification: C13, C14, C32.

Non-technical summary

The financial crisis which started in 2007 has had a deep impact on the conceptual thinking of systemic risk among both academics and policy makers. There has been a recognition of the shortcomings of the measures that are tailored to dealing with institution-level risks. In particular, institution level Value at Risk (VaR) measures miss important externalities associated with the need to bail out systemically important banks: government and supervisory authorities may find themselves compelled to save ex post systemically important financial institutions, while these ignore ex ante any negative externalities associated with their behaviour. As a consequence, in the current policy debate, great emphasis has been put on how to measure the additional capital needed by financial institutions in a situation of generalized market distress.

One necessary input for the implementation of these measures is an estimate of the sensitivity of risk of financial institutions to shocks to the whole financial system. Since risks are intimately linked to the tails of the distribution of a random variable, this requires an econometric analysis of the interdependence between the tails of the distributions of different random variables. One popular econometric technique which can be used to study the behaviour of the tails is regression quantiles. While univariate quantile regression models have been increasingly used in many different academic disciplines (such as finance, labor economics, and macroeconomics), it is not obvious how to extend them to analyse tail interdependence. This paper develops a multivariate regression quantile model to directly study the degree of tail interdependence among different random variables, therefore contributing to the extension regression quantiles into the time series area in finance. Our theoretical framework allows the quantiles of several random variables to depend on (lagged) quantiles, as well as past innovations and other covariates of interest. The proposed framework can be conveniently thought of as a vector autoregressive (VAR) extension to quantile models. We estimate a simple version of the model using market equity returns data to analyse spillovers in the VaR between a market index and financial institutions. This modelling strategy has at least three advantages over the more traditional approaches that rely on the parameterization of the entire multivariate distribution. First, regression quantile estimates are known to be robust to outliers, a desirable feature in general and for applications to financial data in particular. Second, regression quantile is a semi-parametric technique and as such imposes minimal distributional assumptions on the underlying data generating process (DGP). Third, our multivariate framework allows researchers to directly measure the tail dependence among the random variables of interest, rather than recovering it indirectly via models of time-varying first and second moments.

In the empirical section of this paper, the model is estimated on a sample

of 230 financial institutions from around the world. For each of these equity return series, we estimate a bivariate VAR for VaR where one variable is the return on a portfolio of financial institutions and the other variable is the return on the single financial institution. We find evidence of significant tail codependence for a large fraction of the financial institutions in our sample. When aggregating the impulse response functions at the sectorial and geographic level no striking differences are revealed. We, however, find significant cross-sectional differences. By aggregating the 30 stocks with the largest and smallest market value (thus, forming two portfolios), we find that, in tranquil times, the two portfolios have comparable risk. In times of severe financial distress, however, the risk of the first portfolio increases disproportionately relative to the second. Similar conclusions are obtained when aggregation is done according to the most and least leveraged institutions. These results hold for both in-sample and out-of-sample.

1 Introduction

Since the seminal work of Koenker and Bassett (1978), quantile regression models have been increasingly used in many different academic disciplines such as finance, labor economics, and macroeconomics due to their flexibility to allow researchers to investigate the relationship between economic variables not only at the center but also over the entire conditional distribution of the dependent variable. In the early stage, the main development in both theory and application has taken place mainly in the context of cross-section data. However, the application of quantile regression has subsequently moved into the areas of time-series as well as panel data.¹ The whole literature is too vast to be easily summarized, but an excellent and extensive review on many important topics on quantile regression can be found in Koenker (2005).

This paper suggests a multivariate regression quantile model to directly study the degree of tail interdependence among different random variables, therefore contributing to the quantile extension into the time series area in finance. Our theoretical framework allows the quantiles of several random variables to depend on (lagged) quantiles, as well as past innovations and other covariates of interest. This modeling strategy has at least three advantages over the more traditional approaches that rely on the parameterization of the entire multivariate distribution. First, regression quantile estimates are known to be robust to outliers, a desirable feature in general and for applications to financial data in particular. Second, regression quantile is a semi-parametric technique and as such imposes minimal distributional assumptions on the underlying data generating process (DGP). Third, our multivariate framework allows researchers to directly measure the tail dependence among the random variables of interest, rather than recovering it indirectly via models of time-varying first and second moments.

To illustrate our approach and its usefulness, consider a simple set-up with two random variables, Y_{1t} and Y_{2t} . All information available at time t is represented by the information set \mathcal{F}_{t-1} . For a given level of confidence $\theta \in (0, 1)$, the quantile q_{it} at time t for random variables Y_{it} $i = 1, 2$ conditional on \mathcal{F}_{t-1} is

$$\Pr[Y_{it} \leq q_{it} | \mathcal{F}_{t-1}] = \theta, \quad i = 1, 2. \quad (1)$$

A simple version of our proposed structure relates the conditional quantiles of the two random variables according to a vector autoregressive (VAR) structure:

$$\begin{aligned} q_{1t} &= X_t' \beta_1 + b_{11} q_{1t-1} + b_{12} q_{2t-1}, \\ q_{2t} &= X_t' \beta_2 + b_{21} q_{1t-1} + b_{22} q_{2t-1}, \end{aligned}$$

¹Some relevant and important papers are Koenker and Xiao (2004, 2006), Xiao (2009) in the time-series domain and Abrevaya and Dahl (2008), Lamarche (2010), Galvao (2011) in the panel data setting.

where X_t represents predictors belonging to \mathcal{F}_{t-1} and typically includes lagged values of Y_{it} . If $b_{12} = b_{21} = 0$, the above model reduces to the univariate CAViaR model of Engle and Manganelli (2004), and the two specifications can be estimated independently from each other. If, however, b_{12} and/or b_{21} are different from zero, the model requires the joint estimation of all of the parameters in the system. The off-diagonal coefficients b_{12} and b_{21} represent the measure of tail codependence between the two random variables, thus the hypothesis of no tail codependence can be assessed by testing $H_0 : b_{12} = b_{21} = 0$.

The first part of this paper develops the consistency and asymptotic theory for the multivariate regression quantile model. Our fully general model is much richer than the above example, as we can accommodate: (i) more than two random variables; (ii) multiple lags of q_{it} ; and (iii) multiple confidence levels, say $(\theta_1, \dots, \theta_p)$.

In the second part of this paper, as an empirical illustration of the model, we estimate a series of bivariate VAR models for the conditional quantiles of the return distributions of individual financial institutions from around the world. Since quantiles represent one of the key inputs for the computation of the Value at Risk (VaR)² for financial assets, we call this model VAR for VaR, that is, a vector autoregressive (VAR) model where the dependent variables are the VaR of the financial institutions, which are dependent on (lagged) VaR and past shocks.

Our modeling framework appears particularly suitable to develop sound measures of financial spillover, the importance of which has been brought to the forefront by the recent financial crisis. In the current policy debate, great emphasis has been put on how to measure the additional capital needed by financial institutions in a situation of generalized market distress. The logic is that if the negative externality associated with the spillover of risks within the system is not properly internalized, banks may find themselves in need of additional capital at exactly the worst time, such as when it is most difficult and expensive to raise fresh new capital. If the stability of the whole system is threatened, taxpayer money has to be used to backstop the financial system, to avoid systemic bank failures that may bring the whole economic system to a collapse.³

Adrian and Brunnermeier (2009) and Acharya et al. (2009) have recently proposed to classify financial institutions according to the sensitivity of their VaR to shocks to the whole financial system. The empirical sec-

²An extensive discussion on how to properly use quantile regression to estimate VaR can be found in Chernozhukov and Umantsev (2001) in which they also emphasize the importance of using extremal or near-extremal quantile regression.

³It should be emphasized that the proposed method measures the degree of tail dependence between variables in a predictive manner, as in a GARCH framework. Since the tail risk metric of a given variable is affected only by lagged or past tail-risk metrics of other variables, the contemporaneous tail dependence cannot be measured in our framework.

tion of this paper illustrates how the multivariate regression quantile model provides an ideal framework to estimate directly the sensitivity of VaR of a given financial institution to system-wide shocks. A useful by-product of our modeling strategy is the ability to compute quantile impulse-response functions. Using the quantile impulse-response functions, we can assess the resilience of financial institutions to shocks to the overall index, as well as their persistence.

The model is estimated on a sample of 230 financial institutions from around the world. For each of these equity return series, we estimate a bivariate VAR for VaR where one variable is the return on a portfolio of financial institutions and the other variable is the return on the single financial institution. We find strong evidence of significant tail codependence for a large fraction of the financial institutions in our sample. When aggregating the impulse response functions at the sectorial and geographic level no striking differences are revealed. We, however, find significant cross-sectional differences. By aggregating the 30 stocks with the largest and smallest market value (thus, forming two portfolios), we find that, in tranquil times, the two portfolios have comparable risk. In times of severe financial distress, however, the risk of the first portfolio increases disproportionately relative to the second. Similar conclusions are obtained when aggregation is done according to the most and least leveraged institutions. These results hold for both in-sample and out-of-sample.

The plan of this paper is as follows. In Section 2, we set forth the multivariate and multi-quantile CAViaR framework, a generalization of Engle and Manganelli's original CAViaR (2004) model. Section 3 provides conditions ensuring the consistency and asymptotic normality of the estimator, as well as the results which provide a consistent asymptotic covariance matrix estimator. Section 4 contains an example of a data generating process which is consistent with the proposed multivariate quantile model, while Section 5 introduces the long run quantile impulse-response functions and derives the associated standard errors. Section 6 contains the empirical application. Section 7 provides a summary and some concluding remarks. The appendix contains all of the technical proofs of the theorems in the text.

2 The Multivariate and Multi-Quantile Process and Its Model

We consider a sequence of random variables denoted by $\{(Y_t', X_t') : t = 1, 2, \dots, T\}$ where Y_t is a finitely dimensioned $n \times 1$ vector and X_t is also a countably dimensioned vector whose first element is one. To fix ideas, Y_t can be considered as the dependent variables and X_t as the explanatory variables in a typical regression framework. In this sense, the proposed model which will be developed below is sufficiently general enough to handle multiple

dependent variables. We specify the data generating process as follows.

Assumption 1 The sequence $\{(Y'_t, X'_t)\}$ is a stationary and ergodic stochastic process on the complete probability space $(\Omega, \mathcal{F}, P_0)$, where Ω is the sample space, \mathcal{F} is a suitably chosen σ -field, and P_0 is the probability measure providing a complete description of the stochastic behavior of the sequence of $\{(Y'_t, X'_t)\}$.

We define \mathcal{F}_{t-1} to be the σ -algebra generated by $Z^{t-1} := \{X_t, (Y_{t-1}, X_{t-1}), (Y_{t-2}, X_{t-2}), \dots\}$, i.e. $\mathcal{F}_{t-1} := \sigma(Z^{t-1})$. For $i = 1, \dots, n$, we also define $F_{it}(y) := P_0[Y_{it} < y \mid \mathcal{F}_{t-1}]$ which is the cumulative distribution function (CDF) of Y_{it} conditional on \mathcal{F}_{t-1} . In the quantile regression literature, it is typical to focus on a specific quantile index; for example, $\theta \in (0, 1)$. In this paper, we will develop a more general quantile model where multiple quantile indexes can be accounted for jointly. To be more specific, we consider p quantile indexes denoted by $\theta_{i1}, \theta_{i2}, \dots, \theta_{ip}$ for the i^{th} element (denoted by Y_{it}) of Y_t . The p quantile indexes do not need to be the same for all of the elements of Y_t , which explains the double indexing of θ_{ij} . Moreover, we note that we specify the same number (p) of quantile indexes for each $i = 1, \dots, n$. However, this is just for notational simplicity. Our theory easily applies to the case in which the number of quantile indexes differs with i ; i.e., p can be replaced with p_i .

To formalize our argument, we assume that the quantile indexes are ordered such that $0 < \theta_{i1} < \dots < \theta_{ip} < 1$. For $j = 1, \dots, p$, the θ_{ij} -th-quantile of Y_{it} conditional on \mathcal{F}_{t-1} , denoted $q_{i,j,t}^*$, is

$$q_{i,j,t}^* := \inf\{y : F_{it}(y) \geq \theta_{ij}\}, \quad (2)$$

and if F_{it} is strictly increasing,

$$q_{i,j,t}^* = F_{it}^{-1}(\theta_{ij}).$$

Alternatively, $q_{i,j,t}^*$ can be represented as

$$\int_{-\infty}^{q_{i,j,t}^*} dF_{it}(y) = E[1_{[Y_{it} \leq q_{i,j,t}^*]} \mid \mathcal{F}_{t-1}] = \theta_{ij}, \quad (3)$$

where $dF_{it}(\cdot)$ is the Lebesgue-Stieltjes probability density function (PDF) of Y_{it} conditional on \mathcal{F}_{t-1} , corresponding to F_{it} .

Our objective is to jointly estimate the conditional quantile functions $q_{i,j,t}^*$ for $i = 1, \dots, n$ and $j = 1, 2, \dots, p$. For this, we write $q_t^* := (q_{1,t}^*, q_{2,t}^*, \dots, q_{n,t}^*)'$ with $q_{i,t}^* := (q_{i,1,t}^*, q_{i,2,t}^*, \dots, q_{i,p,t}^*)'$ and impose an additional appropriate structure. First, we ensure that the conditional distributions of Y_{it} are everywhere continuous, with positive densities at each of the conditional quantiles of interest, $q_{i,j,t}^*$. We let f_{it} denote the conditional probability density function

(PDF) which corresponds to F_{it} . In stating our next condition (and where helpful elsewhere), we make explicit the dependence of the conditional CDF F_{it} on $\omega \in \Omega$ by writing $F_{it}(\omega, y)$ in place of $F_{it}(y)$. Similarly, we may write $f_{i,t}(\omega, y)$ in place of $f_{i,t}(y)$. The realized values of the conditional quantiles are correspondingly denoted $q_{i,j,t}^*(\omega)$.

Our next assumption ensures the desired continuity and imposes specific structure on the quantiles of interest.

Assumption 2 (i) Y_{it} is continuously distributed such that for each $\omega \in \Omega$, $F_{it}(\omega, \cdot)$ and $f_{it}(\omega, \cdot)$ are continuous on \mathbb{R} , $t = 1, 2, \dots, T$; (ii) For the given $0 < \theta_{i1} < \dots < \theta_{ip} < 1$ and $\{q_{i,j,t}^*\}$ as defined above, we suppose the following: (a) for each i, j, t , and ω , $f_{it}(\omega, q_{i,j,t}^*(\omega)) > 0$; and (b) for the given finite integers k and m , there exist a stationary ergodic sequence of random $k \times 1$ vectors $\{\Psi_t\}$, with Ψ_t measurable- \mathcal{F}_{t-1} , and real vectors $\beta_{ij}^* := (\beta_{i,j,1}^*, \dots, \beta_{i,j,k}^*)'$ and $\gamma_{i,j,\tau}^* := (\gamma_{i,j,\tau,1}^*, \dots, \gamma_{i,j,\tau,n}^*)'$, where each $\gamma_{i,j,\tau,k}^*$ is a $p \times 1$ vector, such that for $i = 1, \dots, n$, $j = 1, \dots, p$, and all t ,

$$q_{i,j,t}^* = \Psi_t' \beta_{ij}^* + \sum_{\tau=1}^m q_{t-\tau}^* \gamma_{i,j,\tau}^* . \quad (4)$$

The structure of equation in (4) is a multivariate version of the MQ-CAViaR process of White, Kim, and Manganeli (2008), itself a multi-quantile version of the CAViaR process introduced by Engle and Manganeli (2004). Under suitable restrictions on $\gamma_{i,j,\tau}^*$, we obtain as special cases; (1) separate MQ-CAViaR processes for each element of Y_t ; (2) standard (single quantile) CAViaR processes for each element of Y_t ; or (3) multivariate CAViaR processes, in which a single quantile of each element of Y_t is related dynamically to the single quantiles of the (lags of) other elements of Y_t . Thus, we call any process that satisfies our structure ‘‘Multivariate MQ-CAViaR’’ (MVMQ-CAViaR) processes or naively ‘‘VAR for VaR.’’

For MVMQ-CAViaR, the number of relevant lags can differ across the elements of Y_t and the conditional quantiles; this is reflected in the possibility that for the given j , elements of $\gamma_{i,j,\tau}^*$ may be zero for values of τ greater than some given integer. For notational simplicity, we do not represent m as being dependent on i or j . Nevertheless, by convention, for no $\tau \leq m$ does $\gamma_{i,j,\tau}^*$ equal the zero vector for all i and j . The finitely dimensioned random vectors Ψ_t may contain lagged values of Y_t , as well as measurable functions of X_t and lagged X_t . In particular, Ψ_t may contain Stinchcombe and White’s (1998) GCR transformations, as discussed in White (2006).

For a particular quantile, say θ_{ij} , the coefficients to be estimated are β_{ij}^* and $\gamma_{ij}^* := (\gamma_{i,j,1}^*, \dots, \gamma_{i,j,m}^*)'$. Let $\alpha_{ij}^{*'} := (\beta_{ij}^{*'}, \gamma_{ij}^{*'})$, and write $\alpha^* = (\alpha_{11}^{*'}, \dots, \alpha_{1p}^{*'}, \dots, \alpha_{n1}^{*'}, \dots, \alpha_{np}^{*'})'$, an $\ell \times 1$ vector, where $\ell := np(k + npm)$. We call α^* the ‘‘MVMQ-CAViaR coefficient vector.’’ We estimate α^* using a

correctly specified model for the MVMQ-CAViaR process. First, we specify our model in the following assumption.

Assumption 3 (i) Let \mathbb{A} be a compact subset of \mathbb{R}^ℓ . For $i = 1, \dots, n$, and $j = 1, \dots, p$, we suppose the following: (a) the sequence of functions $\{q_{i,j,t} : \Omega \times \mathbb{A} \rightarrow \mathbb{R}^{p_i}\}$ is such that for each t and each $\alpha \in \mathbb{A}$, $q_{i,j,t}(\cdot, \alpha)$ is measurable- \mathcal{F}_{t-1} ; (b) for each t and each $\omega \in \Omega$, $q_{i,j,t}(\omega, \cdot)$ is continuous on \mathbb{A} ; and (c) for each i, j , and t , $q_{i,j,t}(\cdot, \alpha)$ is specified as follows:

$$q_{i,j,t}(\cdot, \alpha) = \Psi'_t \beta_{ij} + \sum_{\tau=1}^m q_{t-\tau}(\cdot, \alpha)' \gamma_{i,j,\tau}. \quad (5)$$

Next, we impose the correct specification assumption together with an identification condition. Assumption 4(i.a) below delivers the correct specification by ensuring that the MVMQ-CAViaR coefficient vector α^* belongs to the parameter space, \mathbb{A} . This ensures that α^* optimizes the estimation objective function asymptotically. Assumption 4(i.b) delivers the identification by ensuring that α^* is the only optimizer. In stating the identification condition, we define $\delta_{i,j,t}(\alpha, \alpha^*) := q_{i,j,t}(\cdot, \alpha) - q_{i,j,t}(\cdot, \alpha^*)$ and use the norm $\|\alpha\| := \max_{s=1, \dots, \ell} |\alpha_s|$, where for convenience we also write $\alpha = (\alpha_1, \dots, \alpha_\ell)'$.

Assumption 4 (i)(a) There exists $\alpha^* \in \mathbb{A}$ such that for all i, j, t ,

$$q_{i,j,t}(\cdot, \alpha^*) = q_{i,j,t}^*; \quad (6)$$

(b) There is a non-empty index set $\mathcal{I} \subseteq \{(1, 1), \dots, (1, p), \dots, (n, 1), \dots, (n, p)\}$ such that for each $\epsilon > 0$, there exists $\delta_\epsilon > 0$ such that for all $\alpha \in \mathbb{A}$ with $\|\alpha - \alpha^*\| > \epsilon$,

$$P[\cup_{(i,j) \in \mathcal{I}} \{|\delta_{i,j,t}(\alpha, \alpha^*)| > \delta_\epsilon\}] > 0.$$

Among other things, this identification condition ensures that there is sufficient variation in the shape of the conditional distribution to support the estimation of a sufficient number ($\#\mathcal{I}$) of the variation-free conditional quantiles. As in the case of MQ-CAViaR, distributions that depend on a given finite number of variation-free parameters, say r , will generally be able to support r variation-free quantiles. For example, the quantiles of the $N(\mu, 1)$ distribution all depend on μ alone, so there is only one “degree of freedom” for the quantile variation. Similarly, the quantiles of the scaled and shifted t -distributions depend on three parameters (location, scale, and kurtosis), so there are only three “degrees of freedom” for the quantile variation.

3 Asymptotic Theory

We estimate α^* by the quasi-maximum likelihood method. Specifically, we construct a quasi-maximum likelihood estimator (QMLE) $\hat{\alpha}_T$ as the solution to the optimization problem

$$\min_{\alpha \in \mathbb{A}} \bar{S}_T(\alpha) := T^{-1} \sum_{t=1}^T \left\{ \sum_{i=1}^n \sum_{j=1}^p \rho_{\theta_{ij}}(Y_{it} - q_{i,j,t}(\cdot, \alpha)) \right\}, \quad (7)$$

where $\rho_{\theta}(e) = e\psi_{\theta}(e)$ is the standard ‘‘check function,’’ defined using the usual quantile step function, $\psi_{\theta}(e) = \theta - 1_{[e \leq 0]}$.

We thus view

$$S_t(\alpha) := - \left\{ \sum_{i=1}^n \sum_{j=1}^p \rho_{\theta_{ij}}(Y_{it} - q_{i,j,t}(\cdot, \alpha)) \right\}$$

as the quasi log-likelihood for the observation t . In particular, $S_t(\alpha)$ is the log-likelihood of a vector of np independent asymmetric double exponential random variables (see White, 1994, ch. 5.3; Kim and White, 2003; Komunjer, 2005). Because $Y_{it} - q_{i,j,t}(\cdot, \alpha)$ does not need to actually have this distribution, the method can be regarded as a *quasi* maximum likelihood.

Once the QML estimator $\hat{\alpha}_T$ is obtained, one can compute the estimated conditional quantile functions $\hat{q}_{i,j,t} = q_{i,j,t}(\hat{\alpha}_T)$. Considering the natural monotonicity property of quantile functions, it is expected that $\hat{q}_{i,1,t} \leq \hat{q}_{i,2,t} \leq \dots \leq \hat{q}_{i,p,t}$ because $\theta_{i1} < \theta_{i2} < \dots < \theta_{ip}$. However, when multiple quantiles are jointly estimated, such a desirable ordering can be sometimes violated; that is, some estimated quantile functions can cross each other, which is known as the ‘quantile crossing’ problem. If the quantile model in (5) is correctly specified as imposed in Assumption 4(i), then the population quantile functions are monotonic and the estimated quantile functions will converge to the corresponding population quantile functions. Hence, the quantile crossing problem is simply a finite sample problem in such a case, and should be negligible when the sample size is sufficiently large. If either the quantile model is misspecified or the sample size is not large enough, then the quantile crossing problem can still be of concern. In that case, one can use some recently developed techniques to correct the problem such as the monotonization method by Chernozhukov et al. (2010) or the isotonization method suggested by Mammen (1991).⁴ In passing, we note that in the subsequent empirical study later, we exclusively focus on

⁴Since the former is known to outperform the latter in quantile regression models, we briefly explain the monotonization method only. Given the estimated quantile function $q_{i,j,t}(\hat{\alpha}_T)$, we can define a random variable $Y_{\mathcal{F}} = q_{i,\theta_j=U,t}(\hat{\alpha}_T)$ where U is the standard uniform random variable over the unit interval $[0,1]$. The θ^{th} -quantile of $Y_{\mathcal{F}}$ denoted by $q_{i,j,t}^m(\hat{\alpha}_T)$ is monotone with respect to θ_j by construction. Hence, it is taken as a monotone version of the original estimated quantile function $q_{i,j,t}(\hat{\alpha}_T)$.

estimating the MVMQ-CAViaR model at the 1% level only (i.e. $p = 1$ and $\theta = 0.01$) so that there is no quantile crossing problem in our example.

We establish consistency and asymptotic normality for $\hat{\alpha}_T$ through methods analogous to those of White, Kim, and Manganello (2008). For conciseness, we place the remaining regularity conditions (i.e., Assumptions 5,6 and 7) and technical discussions in the appendix.

Theorem 1 Suppose that Assumptions 1, 2(i,ii), 3(i), 4(i) and 5(i,ii) hold. Then, we have

$$\hat{\alpha}_T \xrightarrow{a.s.} \alpha^*.$$

Next we will show that $\hat{\alpha}_T$ is asymptotically normal. For this, we define the “error” $\varepsilon_{i,j,t} := Y_{it} - q_{i,j,t}(\cdot, \alpha^*)$ and let $f_{i,j,t}(\cdot)$ be the density of $\varepsilon_{i,j,t}$ conditional on \mathcal{F}_{t-1} . We also define $\nabla q_{i,j,t}(\cdot, \alpha)$ as the $\ell \times 1$ gradient vector of $q_{i,j,t}(\cdot, \alpha)$ differentiated with respect to α . With Q^* and V^* as given below, the asymptotic normality result is provided in the following theorem.

Theorem 2 Suppose that Assumptions 1-6 hold. Then, the asymptotic distribution of the QML estimator $\hat{\alpha}_T$ obtain from (7) is given by:

$$T^{1/2}(\hat{\alpha}_T - \alpha^*) \xrightarrow{d} N(0, Q^{*-1}V^*Q^{*-1}),$$

where

$$\begin{aligned} Q^* &:= \sum_{i=1}^n \sum_{j=1}^p E[f_{i,j,t}(0) \nabla q_{i,j,t}(\cdot, \alpha^*) \nabla' q_{i,j,t}(\cdot, \alpha^*)], \\ V^* &:= E(\eta_t^* \eta_t^{*\prime}), \\ \eta_t^* &:= \sum_{i=1}^n \sum_{j=1}^p \nabla q_{i,j,t}(\cdot, \alpha^*) \psi_{\theta_{ij}}(\varepsilon_{i,j,t}), \\ \varepsilon_{i,j,t} &:= Y_{it} - q_{i,j,t}(\cdot, \alpha^*) \end{aligned}$$

We note that the transformed error term of $\psi_{\theta_{ij}}(\varepsilon_{i,j,t}) = \theta_{ij} - 1_{[\varepsilon_{i,j,t} \leq 0]}$ appearing in Theorem 2 can be viewed as a generalized residual. Theorem 2 shows that the asymptotic behavior of the QML estimator $\hat{\alpha}_T$ is well described by the usual normal law. We emphasize that one particular condition that has implicitly played an important role for obtaining such a usual normal law is that all of quantile indexes $\theta_{i1}, \theta_{i2}, \dots, \theta_{ip}$ are fixed as $T \rightarrow \infty$. There have been important developments (see Chernozhukov, 2005, and Chernozhukov and Fernandez-Val, 2011) based on the extreme value (EV) theory in statistics about the asymptotic behavior of θ^{th} regression quantiles under the condition that the quantile index θ converges to zero as $T \rightarrow \infty$,

which is referred to as ‘extremal quantile regression.’ This approach intends to provide a better approximation (called the EV asymptotic law) to the finite sample distribution of the θ^{th} quantile estimator than the usual normal law when the quantile index θ is fairly small relative to the sample size. It might be interesting to apply the extremal quantile regression method to our setting, but it is beyond the scope of the current paper. Hence, we will assume that all of quantile indexes $\theta_{i1}, \theta_{i2}, \dots, \theta_{ip}$ are fixed as $T \rightarrow \infty$ for the rest of the paper.

To test restrictions on α^* or to obtain confidence intervals, we require a consistent estimator of the asymptotic covariance matrix $C^* := Q^{*-1}V^*Q^{*-1}$. First, we provide a consistent estimator \hat{V}_T for V^* ; then we propose a consistent estimator \hat{Q}_T for Q^* . Once \hat{V}_T and \hat{Q}_T are proved to be consistent for V^* and Q^* respectively, then it follows by the continuous mapping theorem that $\hat{C}_T := \hat{Q}_T^{-1}\hat{V}_T\hat{Q}_T^{-1}$ is a consistent estimator for C^* .

A straightforward plug-in estimator of V^* is constructed as follows:

$$\begin{aligned}\hat{V}_T &:= T^{-1} \sum_{t=1}^T \hat{\eta}_t \hat{\eta}_t', \\ \hat{\eta}_t &:= \sum_{i=1}^n \sum_{j=1}^p \nabla q_{i,j,t}(\cdot, \hat{\alpha}_T) \psi_{\theta_{ij}}(\hat{\varepsilon}_{i,j,t}), \\ \hat{\varepsilon}_{i,j,t} &:= Y_{it} - q_{i,j,t}(\cdot, \hat{\alpha}_T).\end{aligned}$$

The next result establishes the consistency of \hat{V}_T for V^* .

Theorem 3 Suppose that Assumptions 1-6 hold. Then, we have the following result:

$$\hat{V}_T \xrightarrow{p} V^*.$$

Next, we provide a consistent estimator of Q^* . We follow Powell’s (1984) suggestion of estimating $f_{i,j,t}(0)$ with $1_{[-\hat{c}_T \leq \hat{\varepsilon}_{i,j,t} \leq \hat{c}_T]} / 2\hat{c}_T$ for a suitably chosen sequence $\{\hat{c}_T\}$. This is also the approach taken in Kim and White (2003), Engle and Manganelli (2004), and White, Kim, and Manganelli (2008). Accordingly, our proposed estimator is

$$\hat{Q}_T = (2\hat{c}_T T)^{-1} \sum_{i=1}^n \sum_{t=1}^T \sum_{j=1}^p 1_{[-\hat{c}_T \leq \hat{\varepsilon}_{i,j,t} \leq \hat{c}_T]} \nabla q_{i,j,t}(\cdot, \hat{\alpha}_T) \nabla' q_{i,j,t}(\cdot, \hat{\alpha}_T).$$

Theorem 4 Suppose that Assumptions 1-7 hold. Then, we obtain the consistency result for \hat{Q}_T as follows:

$$\hat{Q}_T \xrightarrow{p} Q^*.$$

There is no guarantee that $\hat{\alpha}_T$ is asymptotically efficient. There is now considerable literature that investigates the efficient estimation in quantile models; see, for example, Newey and Powell (1990), Otsu (2003), Komunjer and Vuong (2006, 2007a, 2007b). Thus far, this literature has only considered single quantile models. It is not obvious how the results for the single quantile models extend to multivariate and multi-quantile models. Nevertheless, Komunjer and Vuong (2007a) show that the class of QML estimators is not large enough to include an efficient estimator, and that the class of M -estimators, which strictly includes the QMLE class, yields an estimator that attains the efficiency bound. Specifically, when $p = n = 1$, they show that replacing the usual quantile check function $\rho_{\theta_{ij}}(\cdot)$ in equation (7) with

$$\rho_{\theta_{ij}}^*(Y_{it} - q_{i,j,t}(\cdot, \alpha)) = (\theta_{ij} - 1_{[Y_{it} - q_{i,j,t}(\cdot, \alpha) \leq 0]})(F_{it}(Y_{it}) - F_{it}(q_{i,j,t}(\cdot, \alpha)))$$

will deliver an asymptotically efficient quantile estimator. We conjecture that replacing $\rho_{\theta_{ij}}$ with $\rho_{\theta_{ij}}^*$ in equation in (7) will improve the estimator efficiency for p and/or n greater than 1. Another promising efficiency improvement is the application of the semiparametric SUR-type quantile estimator proposed by Jun and Pinkse (2009) for multiple quantile equations. Our method implicitly assumes that the generalized errors $\psi_{\theta_{ij}}(\varepsilon_{i,j,t}) = \theta_{ij} - 1_{[\varepsilon_{i,j,t} \leq 0]}$ appearing in Theorem 2 are uncorrelated between different equations and different quantiles. This assumption is rather strict, and the estimation procedure in Jun and Pinkse (2009) is designed to improve efficiency when these errors are correlated in linear quantile models. As such, additional work may be required to make the procedure applicable in the context of non-linear quantile models as in our framework. This is an interesting topic for future work.

4 An Example of a Data Generating Process

In this section, we provide an example of a data generating process that can generate the MVMQ-CAViaR model analyzed in the previous sections. To fix ideas, we consider a situation where we observe two random variables (Y_{1t} and Y_{2t}). For instance, the first one Y_{1t} could represent the per-period return on a large portfolio or a financial index consisting of sufficiently many financial institutions, while the second Y_{2t} is the per-period return on a specific financial institution within the portfolio or the index. A possible data generating process for $Y_t = (Y_{1t}, Y_{2t})'$ can be specified as follows:

$$\begin{bmatrix} Y_{1t} \\ Y_{2t} \end{bmatrix} = \begin{bmatrix} \alpha_t & 0 \\ \beta_t & \gamma_t \end{bmatrix} \begin{bmatrix} \varepsilon_{1t} \\ \varepsilon_{2t} \end{bmatrix}, \quad (8)$$

where α_t, β_t and γ_t are F_t -measurable, and each element of $\varepsilon_t = (\varepsilon_{1t}, \varepsilon_{2t})'$ has the standard normal distribution and is mutually independent and identically distributed (IID). The triangular structure in (8) reflects the plausible

restriction that shocks to the large portfolio are allowed to have a direct impact on the return of the specific asset, but shocks to the specific asset do not have a direct impact on the whole portfolio.

We note that the standard deviations of Y_{1t} and Y_{2t} are given by $\sigma_{1t} = \alpha_t$ and $\sigma_{2t} = \sqrt{\beta_t^2 + \gamma_t^2}$ respectively. Further, let α_t, β_t and γ_t be specified to satisfy the following usual GARCH-type restrictions:

$$\begin{aligned}\sigma_{1t} &= \tilde{c}_1 + \tilde{a}_{11}|Y_{1t-1}| + \tilde{a}_{12}|Y_{2t-1}| \\ &\quad + \tilde{b}_{11}\sigma_{1t-1} + \tilde{b}_{12}\sigma_{2t-1}, \\ \sigma_{2t} &= \tilde{c}_2 + \tilde{a}_{21}|Y_{1t-1}| + \tilde{a}_{22}|Y_{2t-1}| \\ &\quad + \tilde{b}_{21}\sigma_{1t-1} + \tilde{b}_{22}\sigma_{2t-1}.\end{aligned}\tag{9}$$

We note that $q_{it} = \sigma_{it}\Phi^{-1}(\theta)$, $i = \{1, 2\}$ where $\Phi(z)$ is the cumulative distribution function of $N(0, 1)$. Hence, by substituting the result $\sigma_{it} = \Phi(\theta)q_{it}$ in (9), it can be formally shown that the respective θ^{th} -quantile processes associated with this DGP are given by the following form denoted as ‘MVMQ-CAViaR(1,1)’:

$$\begin{aligned}q_{1t} &= c_1(\theta) + a_{11}(\theta)|Y_{1t-1}| + a_{12}(\theta)|Y_{2t-1}| \\ &\quad + b_{11}(\theta)q_{1t-1} + b_{12}(\theta)q_{2t-1}, \\ q_{2t} &= c_2(\theta) + a_{21}(\theta)|Y_{1t-1}| + a_{22}(\theta)|Y_{2t-1}| \\ &\quad + b_{21}(\theta)q_{1t-1} + b_{22}(\theta)q_{2t-1},\end{aligned}\tag{10}$$

where $c_i(\theta) = \tilde{c}_i\Phi^{-1}(\theta)$, $a_{ij}(\theta) = \tilde{a}_{ij}\Phi^{-1}(\theta)$, $b_{ij}(\theta) = \tilde{b}_{ij}$. The bivariate quantile model in (10) can be written more compactly in matrix form as follows:

$$q_t = c + A|Y_{t-1}| + Bq_{t-1},\tag{11}$$

where q_t , Y_{t-1} , and c are 2-dimensional vectors, and A , B are (2,2)-matrices whose elements are obviously shown in (10).

5 The Pseudo Quantile Impulse Response Function

In this section, we discuss how an impulse response function can be developed in the proposed MVMQ-CAViaR framework. For this, we assume that the conditional quantiles of Y_t follow the simple MVMQ-CAViaR(1,1) model in (11). Since the DGP is not fully specified in quantile regression models, it is not obvious how to derive impulse response functions from structural shocks. Unlike the standard impulse response analysis where a one-off intervention δ is given to the error term ε_t , we will assume that the one-off intervention δ is given to the observable Y_{1t} only at time t so that

$\tilde{Y}_{1t} := Y_{1t} + \delta$. In all other times there is no change in Y_{1t} . In other words, the time path of Y_{1t} without the intervention would be

$$\{\dots, Y_{1t-2}, Y_{1t-1}, Y_{1t}, Y_{1t+1}, Y_{1t+2}, \dots\}$$

while the time path with the intervention would be

$$\{\dots, Y_{1t-2}, Y_{1t-1}, \tilde{Y}_{1t}, Y_{1t+1}, Y_{1t+2}, \dots\}.$$

We acknowledge that the set-up is extremely restrictive because it completely ignores the dynamic evolution in the second moment of Y_{1t} specified by (9) when the intervention δ is given, which forces no change in Y_{1t+s} for $s \geq 1$. However, this seems to be the only plausible way to obtain an impulse response function under the conditional quantile model that we consider, and such a strong limitation should be borne in mind when we discuss the empirical results in Section 6. To distinguish our approach from the standard one, the derived function tracing the effect of the one-off impulse δ given to Y_{1t} will be called the pseudo impulse response function.⁵

Our objective is to measure the impact of the one-off intervention at time t on the quantile dynamics. The pseudo θ^{th} -quantile impulse-response function (QIRF) for the i^{th} variable (Y_{it}) denoted as $\Delta_{i,s}(\tilde{Y}_{1t})$ is defined as

$$\Delta_{i,s}(\tilde{Y}_{1t}) = \tilde{q}_{i,t+s} - q_{i,t+s}, \quad s = 1, 2, 3, \dots$$

where $\tilde{q}_{i,t+s}$ is the θ^{th} -conditional quantile of the affected series (\tilde{Y}_{it+s}) and $q_{i,t+s}$ is the θ^{th} -conditional quantile of the unaffected series (Y_{it+s}).

First, we consider the case for $i = 1$, i.e. $\Delta_{1,s}(\tilde{Y}_{1t})$. When $s = 1$, the pseudo QIRF is given by

$$\Delta_{1,1}(\tilde{Y}_{1t}) = a_{11}(|\tilde{Y}_{1t}| - |Y_{1t}|) + a_{12}(|\tilde{Y}_{2t}| - |Y_{2t}|).$$

For $s > 1$, the pseudo QIRF is given by

$$\Delta_{1,s}(\tilde{Y}_{1t}) = b_{11}\Delta_{1,s-1}(\tilde{Y}_{1t}) + b_{12}\Delta_{2,s-1}(\tilde{Y}_{1t}).$$

The case for $i = 2$ is similarly obtained as follows. For $s = 1$,

$$\Delta_{2,1}(\tilde{Y}_{1t}) = a_{21}(|\tilde{Y}_{1t}| - |Y_{1t}|) + a_{22}(|\tilde{Y}_{2t}| - |Y_{2t}|),$$

⁵We note that we do not consider any dynamics in the first moments of Y_t . In the subsequent empirical study, Y_t is the vector of asset returns so that imposing no dynamics in the first moment can be appropriate. To the best of our knowledge, there has been no formal and complete analysis into the issue of generalizing the proper impulse-response analysis in fully dynamic quantile models. Using a quantile autoregression framework, Koenker and Xiao (2006) allude that quantile impulse-response functions may be stochastic. In the presence of full dynamics, it can be more complicated to derive proper quantile impulse-response functions. A very rudimentary analysis is currently under way in Kim et al. (2013).

while for $s > 1$,

$$\Delta_{2,s}(\tilde{Y}_{1t}) = b_{21}\Delta_{1,s-1}(\tilde{Y}_{1t}) + b_{22}\Delta_{2,s-1}(\tilde{Y}_{1t}).$$

Now, let us define

$$\Delta_s(\tilde{Y}_{1t}) := \begin{bmatrix} \Delta_{1,s}(\tilde{Y}_{1t}) \\ \Delta_{2,s}(\tilde{Y}_{1t}) \end{bmatrix},$$

and

$$D_t = |\tilde{Y}_t| - |Y_t|. \quad (12)$$

Then, we can show that the pseudo QIRF is compactly expressed as follows:

$$\begin{aligned} \Delta_s(\tilde{Y}_{1t}) &= AD_t && \text{for } s = 1 \\ \Delta_s(\tilde{Y}_{1t}) &= B^{(s-1)}AD_t && \text{for } s > 1. \end{aligned} \quad (13)$$

The pseudo QIRF when there is a shock (or intervention) to Y_{2t} only at time t can be analogously obtained.

It is important to be aware of two caveats in our analysis. First, if returns follow the structure in (8), shocks to ε_t will generally result in changes of Y_t which are correlated, contemporaneously and over time. In our empirical application, we take into account the contemporaneous correlation by identifying the structural shocks ε_{1t} and ε_{2t} in (8) using a standard Cholesky decomposition. However, since the DGP (8) is not fully specified, it is not possible to take into account the impact that these structural shocks have on future returns Y_{t+s} , $s > 1$, unless one is willing to impose additional structure on the distribution of the error terms. We leave this important issue for future research.

Second, it is not straightforward to define impulse response functions for non-linear models; this issue has been discussed by Gallant et al. (1993), Potter (2000) and Lütkepohl (2008). The problem is that the impulse response for non-linear, non affine functions generally depends on the type of non-linearity, the history of past observations and on the impulse itself. This issue affects also our derivation, as shown in equations (12) and (13) in which the pseudo QIRF depends on the initial value (Y_t), and is affected by the sign and magnitude of the intervention δ through the absolute function. In our implementation, we set the variable Y_t , which is originally shocked, equal to 0. Under this particular choice, the intervention δ always results in a larger value of $|\tilde{Y}_t|$ relative to the original observation $|Y_t|$, which in turn makes D_t in (12) always positive. Since the pseudo QIRFs considered in this paper are linear in D_t , the resulting impulse responses retain the standard interpretation with respect to D_t . In more general cases, however, additional care in the definition of shocks and the interpretation of the quantile impulse response functions needs to be exercised.

5.1 Standard Errors for the Pseudo Quantile Impulse Response Functions

Standard errors for the quantile impulse response function can be computed by exploiting the asymptotic properties of continuous transformations of random vectors (see for instance proposition 7.4 of Hamilton 1994). Specifically, recognizing that the above pseudo QIRF is a function of the vector of parameters $\hat{\alpha}_T$, we obtain:

$$T^{1/2}[\Delta_s(\tilde{Y}_{1t}; \hat{\alpha}_T) - \Delta_s(\tilde{Y}_{1t}; \alpha^*)] \xrightarrow{d} N(0, G_s(Q^{*-1}V^*Q^{*-1})G'_s),$$

where $G_s := \partial \Delta_s(\tilde{Y}_{1t}; \alpha) / \partial \alpha'$.

The matrix G_s can be computed analytically for $s > 1$ as follows:

$$\begin{aligned} G_s &= \partial(B^{(s-1)}AD_t) / \partial \alpha' \\ &= B^{(s-1)} \frac{\partial \text{vec}(AD_t)}{\partial \alpha'} + ((AD_t)' \otimes I_2) \frac{\partial \text{vec}(B^{(s-1)})}{\partial \alpha'}, \end{aligned}$$

where $\frac{\partial \text{vec}(AD_t)}{\partial \alpha'} = (D_t' \otimes I_2) \frac{\partial \text{vec}(A)}{\partial \alpha'}$ and $\frac{\partial \text{vec}(B^{(s-1)})}{\partial \alpha'} = [\sum_{i=0}^{s-2} (B')^{s-2-i} \otimes B^i] \frac{\partial \text{vec}(B)}{\partial \alpha'}$.

6 Empirics: Assessing Tail Reactions of Financial Institutions to System Wide Shocks

The financial crisis which started in 2007 has had a deep impact on the conceptual thinking of systemic risk among both academics and policy makers. There has been a recognition of the shortcomings of the measures that are tailored to dealing with institution-level risks. In particular, institution-level Value at Risk measures miss important externalities associated with the need to bail out systemically important banks in order to contain potentially devastating spillovers to the rest of the economy. Therefore, government and supervisory authorities may find themselves compelled to save ex post systemically important financial institutions, while these ignore ex ante any negative externalities associated with their behavior. There exists many contributions, both theoretical and empirical, as summarized, for instance, in Brunnermeier and Oehmke (2012) or Bisias et al. (2012). For the purpose of the application we have in mind, it is useful to structure the material around two contributions, the CoVaR of Adrian and Brunnermeier (2009) and the systemic expected shortfall (SES) of Acharya et al. (2010).

Both measures aim to capture the risk of a financial institution conditional on a significant negative shock hitting another financial institution or the whole financial system. Neglecting the time t subscript for notational

convenience, the $CoVaR_\theta^{j|i}$ is formally the VaR of financial institution j conditional on the return of financial institution i falling below its θ^{th} -quantile (denoted by q_i^θ):⁶

$$\Pr(Y_j < CoVaR_\theta^{j|i} | Y_i < q_i^\theta) = \theta.$$

The systemic expected shortfall is shown to be proportional to the marginal expected shortfall, which is analogously defined as:

$$MES_\theta^{j|i} = E(Y_j | Y_i < q_i^\theta).$$

The main difference with respect to CoVaR is that the expectation of Y_j conditional on Y_i being hit by a tail event, rather than just the quantile, is considered. In practice, loss distributions conditional on tail events are extremely hard to estimate. One strategy is to standardize the returns by estimated volatility or quantiles, and then apply non-parametric techniques, as done in Manganelli and Engle (2002) or Brownlees and Engle (2010). An alternative is to use the extreme value theory to impose a parametric structure on the tail behavior as done in Hartmann et al. (2004).

As we will show in the rest of this section, the theoretical framework developed in this paper lends itself to a coherent modeling of the dynamics of the tail interdependence implicit in both the CoVaR and systemic expected shortfall measures. One notable advantage of our multivariate regression quantiles framework - besides providing a robust, semi-parametric technique which does not rely on strong distributional assumptions - is that it is tailored to directly model the object of interest.

In this section, we apply our model to study the spillovers that occur in the equity return quantiles of a sample of 230 financial institution around the world by estimating a bivariate 1%-VaR model. This is a special case of the fully general MVMQ-CAViaR model in that we fix the quantile index at $\theta = 1\%$ and focus only on the multivariate aspect of the model.⁷

⁶It is straightforward to derive an estimate of the CoVaR from the model in (10). For instance, if the conditioning event C^i is defined as $Y_{2,t-1} = q_{2,t-1}$, (that is, financial institution 2 is hit by a shock equal to its quantile) the associated CoVaR for financial institution 1 is given by $q_{1,t} = c_1(\theta) + a_{11}(\theta)|Y_{1,t-1}| + a_{12}(\theta)|q_{2,t-1}| + b_{11}(\theta)q_{1,t-1} + b_{12}(\theta)q_{2,t-1}$. Incidentally, this identification scheme illustrates the potential pitfalls of choosing appropriate conditioning events for the CoVaR measures. Defining the conditioning event C^i as $Y_{2,t-1} = q_{2,t-1}$, as done before, neglects the fact that shock to the financial institution 2 may be correlated with that of other financial institutions, therefore producing a potentially misleading classification of the systemic importance of financial institutions.

⁷Although it may be computationally demanding, it is possible to focus not only on the multivariate aspect, but also the multi-quantile aspect of the full model. One possibility of allowing for such a multi-quantile aspect is to consider a robust skewness measure, such as the conditional Bowley coefficient in White et al. (2008). Another possibility is to use this framework to compute the Delta CoVaR of Adrian and Brunnermeier (2009), which is the difference between the 1% quantile and the median.

Theoretically, we can jointly analyze all of 230 financial institutions in our sample, but the excessive computational burden prevents the implementation of such a joint estimation. Instead, we examine bivariate models, whereby for each of these institutions, we estimate a bivariate CAViaR model where the first variable Y_{1t} is the return on a portfolio of financial institutions, and the second variable Y_{2t} is the return on the chosen financial institution. Hence, in the end, we will estimate 230 bivariate models in total. Since Y_{1t} is the return on a portfolio and Y_{2t} is the return on a specific asset, we assume that shocks to Y_{1t} are allowed to have a direct impact on Y_{2t} , but shocks to Y_{2t} do not have a direct impact on Y_{1t} . In principle, since the financial institution is part of the index, one must exclude this financial institution from the index to ensure perfect orthogonality. In practice, since our index is equally weighted and contains a large number of stocks (96 for Europe, 70 for North America and 64 for Asia; see Table 2), the inclusion of the financial institution has a negligible impact. Assuming that the θ^{th} -quantile processes for Y_{1t} and Y_{2t} follow the MVMQ-CAViaR(1,1) model, we employ the proposed method to estimate the bivariate model.⁸ Any empirical evidence for non-zero off-diagonal terms in either A or B will indicate the presence of tail-dependence between the two variables.

6.1 Data and Optimization Strategy

The data used in this section have been downloaded from Datastream. We considered three main global sub-indices: banks, financial services, and insurances. The sample includes daily closing prices from 1 January 2000 to 6 August 2010. Prices were transformed into continuously compounded log returns, giving an estimation sample size of 2765 observations. We use 453 additional observations up to 2 May 2012, for the out-of-sample exercises. We eliminated all the stocks whose times series started later than 1 January 2000, or which stopped after this date. At the end of this process, we were left with 230 stocks.

Table 1 reports the names of the financial institutions in our sample, together with the country of origin and the sector they are associated with, as from Datastream classification. It also reports for each financial institution the average (over the period January 2000-August 2010) market value and leverage. Leverage is provided by Datastream and is defined as the ratio of short and long debt over common equity. Table 2 shows the breakdown of the stocks by sector and by geographic area. There are twice as many financial institutions classified as banks in our sample relative to those classified as financial services or insurances. The distribution across geographic areas is more balanced, with a greater number of EU financial institutions and a

⁸We note that imposing the location-scale shift specification in (9) can result in the bivariate CAViaR model in (10), but the converse is not true. Hence, assuming the bivariate CAViaR model in (10) does not necessarily imply the location-scale shift specification.

slightly lower Asian representation. The proxy for the market index used in each bivariate quantile estimation is the equally weighted average of all the financial institutions in the same geographic area, in order to avoid asynchronicity issues.

We estimated 230 bivariate 1% quantile models between the market index and each of the 230 financial institutions in our sample. It is worth mentioning that an important data assumption required to estimate the bivariate CAViaR model is the stationarity condition in Assumption 1. Financial return data such as ours are well-known to be stationary whereas their levels are integrated so that the data assumption is satisfied in our application. Each model is estimated using, as starting values in the optimization routine, the univariate CAViaR estimates and initializing the remaining parameters at zero. Next, we minimized the regression quantile objective function (7) using the `fminsearch` optimization function in Matlab, which is based on the Nelder-Mead simplex algorithm. In calculating the standard errors, we have set the bandwidth as suggested by Koenker (2005, pp.81) and Machado and Silva (2013). In particular, we define the bandwidth \hat{c}_T as:

$$\hat{c}_T = \hat{\kappa}_T [\Phi^{-1}(\theta + h_T) - \Phi^{-1}(\theta - h_T)]$$

where h_T is defined as

$$h_T = T^{-1/3} (\Phi^{-1}(1 - 0.05/2))^{2/3} \left(\frac{1.5 (\phi(\Phi^{-1}(\theta)))^2}{2(\Phi^{-1}(\theta))^2 + 1} \right)^{1/3}$$

where $\Phi(z)$ and $\phi(z)$ are, respectively, the cumulative distribution and probability density functions of $N(0, 1)$. Following Machado and Silva (2013), we define $\hat{\kappa}_T$ as the median absolute deviation of the θ^{th} -quantile regression residuals.⁹

6.2 Results

Table 3 reports, as an example, the estimation results for four well-known financial institutions from different geographic areas: Barclays, Deutsche Bank, Goldman Sachs and HSBC. The diagonal autoregressive coefficients for the B matrix are around 0.90 and all of them are statistically significant,¹⁰ which indicates the VaR processes are significantly autocorrelated. These findings are consistent with what is typically found in the literature

⁹The figures and tables in the paper can be replicated using the data and Matlab codes available at www.simonemanganelli.org.

¹⁰It is noted that the standard errors in Tables 3 & 4 have been computed using the asymptotic distribution result in Theorem 2. As explained in Section 3, if readers are concerned about the extreme value theory, then those standard errors should be adjusted following the procedure in Chernozhukov and Fernandez-Val (2011). The feasible inference methodology for extremal quantile model proposed in Chernozhukov and Fernandez-Val (2011) is based on a linear quantile model while our proposed model is nonlinear.

using CAViaR models. Notice, however, that some of the non-diagonal coefficients for the A or B matrices are significantly different from zero. This is the case for Barclays, Goldman Sachs, and HSBC and the examples illustrate how the multivariate quantile model can uncover dynamics that cannot be detected by estimating univariate quantile models. In general, we reject the joint null hypothesis that all off-diagonal coefficients of the matrices A and B are equal to zero at the 5% level for around 100 financial institutions out of the 230 in our sample. The resulting estimated 1% quantiles for Barclays, Deutsche Bank, Goldman Sachs and HSBC are reported in Figure 1. The quantile plots clearly reveal the generalized sharp increase in risk following the Lehman bankruptcy. Careful inspection of the plots also reveals a noticeable cross-sectional difference, with the risk for Goldman Sachs being contained to about two thirds of the risk of Barclays at the height of the crisis.

Table 4 reports summary statistics for the full cross-section of coefficients. Average values are in line with the values reported in Table 3. For instance, the autoregressive coefficient for b_{11} and b_{22} are 0.84 and 0.86 respectively. At the same time, the cross-sectional standard deviation and the min-max range reveal quite substantial heterogeneity in the estimates.

Table 5 provides an assessment of the overall performance of the 230 estimated bivariate models. The performance is based on the number of VaR exceedances both in-sample and out-of-sample. Specifically, for each of the 230 bivariate VAR for VaR models, the time series of returns is transformed into a time series of indicator functions which take value one if the return exceeds the VaR and zero otherwise. When estimating a 1% VaR, on average one should expect stock market returns to exceed the VaR 1% of the times. The first line of the table reveals that the in-sample estimates are relatively precise, as shown by the accurate average and median number of exceedances, their very low standard deviations and the relatively narrow cross-sectional min-max range. The out-of-sample performance is less accurate, as to be expected, with substantially higher standard deviations and very large min-max range. The out-of-sample performance has also been assessed by applying the out-of-sample DQ test of Engle and Manganelli (2004), which tests not only whether the number of exceedances is close to the VaR confidence level, but also whether these exceedances are not correlated over time. The test reveals that the performance of the out-of-sample VaR is not rejected at a 5% confidence level for more than half of the stocks. Note that for the out-of-sample exercise the coefficients are held fixed at their estimated in-sample values.

The methodology introduced in this paper, however, allows us to go be-

Nonetheless, we conjecture that the procedure may be still applicable with some slight modifications, but some non-trivial complications might arise. A formal investigation is left for further research.

yond the analysis of the univariate quantiles, and directly looks at the tail codependence between financial institutions and the market index. Figure 2 displays the impulse response of the risks (and associated 95% confidence intervals) of the four financial institutions to a 2 standard deviation shock to the market index (see the discussion in Section 5 for a detailed explanation of how the pseudo impulse-response functions are computed). The horizontal axis measures the time (expressed in days), while the vertical axis measures the change in the 1% quantiles of the individual financial institutions (expressed in percentage returns) as a reaction to the market shock. The pseudo impulse response functions track how this shock propagates through the system and how long it takes to absorb it. The shock is completely reabsorbed after the pseudo impulse response function has converged again to zero.

A closer look at the pseudo impulse response functions of the four selected financial institutions reveals a few differences in how their long run risks react to shocks. For instance, Deutsche Bank and HSBC have a similar pseudo impulse response function, although HSBC's is not statistically different from zero. Goldman Sachs quantiles, instead, exhibit very little tail codependence with the market, and not statistically significant, as illustrated by the error bands straddling the zero line.

It should be borne in mind that each of the 230 bivariate models is estimated using a different information set (as the time series of the index and of a different financial institution is used for each estimation). Therefore, each pair produces a different estimate of the VaR of the index, simply because we condition on a different information set. Moreover, the coefficients and any quantities derived from them, such as pseudo impulse responses, are information set-specific. This means that naive comparisons across bivariate pairs can be misleading and are generally unwarranted. The proper context for comparing sensitivities and pseudo impulse responses is in a multivariate setting using a common information set. Because of the non trivial computational challenges involved, we leave this for future study.

These important caveats notwithstanding, averaging across the bivariate results can still provide useful summary information and suggest general features of the results. Accordingly, Figure 3 plots the average pseudo impulse-response functions $\Delta_{1,s}(\tilde{\varepsilon}_{2t})$ and $\Delta_{2,s}(\tilde{\varepsilon}_{1t})$ measuring the impact of a two standard deviation individual financial institution shock on the index and the impact of a two standard deviation shock to the index on the individual financial institution's risk. In the left column, the average is taken with respect to the geographical distribution. That is, the average pseudo impulse-response for the four largest euro area countries, for example, is obtained by averaging all the pseudo impulse-response functions for the German, French, Italian and Spanish financial institutions. We notice two things. First, the impact of a shock to the index (charts in the top row) is much stronger than the impact of a shock to the individual financial

institution (charts in the bottom row). This result is partly driven by our identification assumption that shocks to the index have a contemporaneous impact on the return of the single financial institutions, while the institution's specific shocks have only a lagged impact on the global financial index. Second, we notice that the risk of Japanese financial institutions appears to be on average somewhat less sensitive to global shocks than their European and North American counterparts.

The charts on the right column of Figure 3 plot the average pseudo impulse-response functions for the financial institutions grouped by line of business, i.e. banks, financial services, and insurances. We see that a shock to the index has a stronger initial impact on the group of insurance companies.

Two interesting dimensions along which pseudo impulse response functions can be aggregated are size and leverage, as reported in Table 1. Figure 4 plots the average pseudo impulse-responses to a market shock for the 30 largest and smallest financial institutions, together with those of the largest and smallest leverage. It is clear that the shocks to the index have a much greater impact on the largest and most leveraged financial institutions. A two standard deviation shock to the index produces an average initial increase in the daily VaR of the largest financial institutions of about 1.7% and for the most leveraged of about 1.4%. This compares to an average increase in VaR of around 0.9% for the 30 smallest and least leveraged financial institutions. Interestingly, there is little overlap between the two groups of stocks.

To gauge to what extent the model correctly identifies the financial institutions whose risks are most exposed to market shocks, Figure 5 plots the average quantiles of the two sets of financial institutions identified in Figure 4. Specifically, the charts in the top panels of the figure, track the estimated in-sample quantiles developments of the 30 largest/smallest and most/least leveraged financial institutions. The charts in the bottom panels replicate the same exercise with the out-of-sample data.

The figure presents two striking facts. First, during normal times, i.e. between 2004 and mid-2007, the quantiles of the largest/smallest financial institutions are roughly equal. Actually, there are some periods in 2003 in which the quantiles of the smallest financial institutions exceeded the quantiles of the largest ones. The second striking fact is that the situation changes abruptly in periods of market turbulence. For instance, at the beginning of the sample, in 2001-2003, the quantiles of the largest financial institutions increased significantly more than that of the smallest ones. The change in behavior during crisis periods is even more striking from 2008 onwards, showing a greater exposure to common shocks. The bottom panels reveal that similar results hold for the out-of-sample period. Of particular notice is the sharp drop in the out-of-sample quantile for the group of the largest financial institutions which occurred on 12 August, 2011, the beginning of

the second phase of the euro area sovereign debt crisis.

This application illustrates how the proposed methodology can usefully inform policy makers by helping identify the set of financial institutions which may be most exposed to common shocks, especially in times of crisis. Of course, this should only be considered as a partial model-based screening device for the identification of the most systemic banks. Further analysis, market intelligence and sound judgment are other necessary elements to produce a reliable risk assessment method for the larger and more complex financial groups.

Again, we emphasize that the results presented in these figures merely summarize the pattern of the results found in the bivariate analysis of our 230 financial institutions. Cross-comparisons could be improved by estimating for instance a 3- or 4- or n -variate system using a common information set, or adopting an appropriate factor structure which would minimize the number of parameters to be estimated. Alternatively, one could impose that the B matrix in (11) is diagonal, which would be equivalent to assuming that the parameters of the system are variation free, as in Engle et al. (1983). This assumption would have the added advantage of allowing a separate estimation of each quantile. That is, for an n -variate system, the optimization problem in (7) can be broken down into n independent optimization problems, which in turn would considerably increase the computational tractability.

7 Conclusion

We have developed a theory ensuring the consistency and asymptotic normality of multivariate and multi-quantile models. Our theory is general enough to comprehensively cover models with multiple random variables, multiple confidence levels and multiple lags of the quantiles.

We conducted an empirical analysis in which we estimate a vector autoregressive model for the Value at Risk – VAR for VaR – using returns of individual financial institutions from around the world. By examining the pseudo impulse-response functions, we can study the financial institutions' long run risk reactions to shocks to the overall index. Judging from our bivariate models, we found that the risk of Asian financial institutions tend to be less sensitive to system wide shocks, whereas insurance companies exhibit a greater sensitivity to global shocks. We also found wide differences on how financial institutions react to different shocks. Both in-sample and out-of-sample analyses reveal that largest and most leveraged financial institutions are those whose risk increases the most in periods of market turbulence.

The methods developed in this paper can be applied to many other contexts. For instance, many stress-test models are built from vector autoregressive models on credit risk indicators and macroeconomic variables.

Starting from the estimated mean and adding assumptions on the multivariate distribution of the error terms, one can deduce the impact of a macro shock on the quantile of the credit risk variables. Our methodology provides a convenient alternative for stress testing, by allowing researchers to estimate vector autoregressive processes directly on the quantiles of interest, rather than on the mean.

Appendix

We establish the consistency of $\hat{\alpha}_T$ by applying the results of White (1994). For this, we impose the following moment and domination conditions. In stating this next condition and where convenient elsewhere, we exploit stationarity to omit explicit reference to all values of t .

Assumption 5 (i) For $i = 1, \dots, n$, $E|Y_{it}| < \infty$; (ii) Let us define

$$D_{0,t} := \max_{i=1,\dots,n} \max_{j=1,\dots,p} \sup_{\alpha \in \mathbb{A}} |q_{i,j,t}(\cdot, \alpha)|.$$

Then $E(D_{0,t}) < \infty$.

Proof of Theorem 1 We verify the conditions of corollary 5.11 of White (1994), which delivers $\hat{\alpha}_T \rightarrow \alpha^*$, where

$$\hat{\alpha}_T := \arg \max_{\alpha \in \mathbb{A}} T^{-1} \sum_{t=1}^T \varphi_t(Y_t, q_t(\cdot, \alpha)),$$

and $\varphi_t(Y_t, q_t(\cdot, \alpha)) := -\{\sum_{i=1}^n \sum_{j=1}^p \rho_{\theta_{ij}}(Y_{it} - q_{i,j,t}(\cdot, \alpha))\}$. Assumption 1 ensures White's Assumption 2.1. Assumption 3(i) ensures White's Assumption 5.1. Our choice of $\rho_{\theta_{ij}}$ satisfies White's Assumption 5.4. To verify White's Assumption 3.1, it suffices that $\varphi_t(Y_t, q_t(\cdot, \alpha))$ is dominated on \mathbb{A} by an integrable function (ensuring White's Assumption 3.1(a,b)), and that for each α in \mathbb{A} , $\{\varphi_t(Y_t, q_t(\cdot, \alpha))\}$ is stationary and ergodic (ensuring White's Assumption 3.1(c), the strong uniform law of large numbers (ULLN)). Stationarity and ergodicity is ensured by Assumptions 1 and 3(i). To show domination, we write

$$\begin{aligned} |\varphi_t(Y_t, q_t(\cdot, \alpha))| &\leq \sum_{i=1}^n \sum_{j=1}^p |\rho_{\theta_{ij}}(Y_{it} - q_{i,j,t}(\cdot, \alpha))| \\ &= \sum_{i=1}^n \sum_{j=1}^p |(Y_{it} - q_{i,j,t}(\cdot, \alpha))(\theta_{ij} - 1_{[Y_{it} - q_{i,j,t}(\cdot, \alpha) \leq 0]})| \\ &\leq 2 \sum_{i=1}^n \sum_{j=1}^p (|Y_{it}| + |q_{i,j,t}(\cdot, \alpha)|) \\ &\leq 2p \sum_{i=1}^n |Y_{it}| + 2np |D_{0,t}|, \end{aligned}$$

so that

$$\sup_{\alpha \in \mathbb{A}} |\varphi_t(Y_t, q_t(\cdot, \alpha))| \leq 2p \sum_{i=1}^n |Y_{it}| + 2np |D_{0,t}|.$$

Thus, $2p \sum_{i=1}^n |Y_{it}| + 2np|D_{0,t}|$ dominates $|\varphi_t(Y_t, q_t(\cdot, \alpha))|$; this has finite expectation by Assumption 5(i,ii).

White's Assumption 3.2 remains to be verified; here, this is the condition that α^* is the unique maximizer of $E(\varphi_t(Y_t, q_t(\cdot, \alpha)))$. Given Assumptions 2(ii.b) and 4(i), it follows through the argument that directly parallels to that of the proof by White (1994, corollary 5.11) that for all $\alpha \in \mathbb{A}$,

$$E(\varphi_t(Y_t, q_t(\cdot, \alpha))) \leq E(\varphi_t(Y_t, q_t(\cdot, \alpha^*))).$$

Thus, it suffices to show that the above inequality is strict for $\alpha \neq \alpha^*$. Consider $\alpha \neq \alpha^*$ such that $\|\alpha - \alpha^*\| > \epsilon$, and let $\Delta(\alpha) := \sum_{i=1}^n \sum_{j=1}^p E(\Delta_{i,j,t}(\alpha))$ with $\Delta_{i,j,t}(\alpha) := \rho_{\theta_{ij}}(Y_{it} - q_{i,j,t}(\cdot, \alpha)) - \rho_{\theta_{ij}}(Y_{it} - q_{i,j,t}(\cdot, \alpha^*))$. It will suffice to show that $\Delta(\alpha) > 0$. First, we define the "error" $\varepsilon_{i,j,t} := Y_{it} - q_{i,j,t}(\cdot, \alpha^*)$ and let $f_{i,j,t}(\cdot)$ be the density of $\varepsilon_{i,j,t}$ conditional on \mathcal{F}_{t-1} . Noting that $\delta_{i,j,t}(\alpha, \alpha^*) := q_{i,j,t}(\cdot, \alpha) - q_{i,j,t}(\cdot, \alpha^*)$, we next can show through some algebra and Assumption 2(ii.a) that

$$\begin{aligned} E(\Delta_{i,j,t}(\alpha)) &= E\left[\int_0^{\delta_{i,j,t}(\alpha, \alpha^*)} (\delta_{i,j,t}(\alpha, \alpha^*) - s) f_{i,j,t}(s) ds\right] \\ &\geq E\left[\frac{1}{2}\delta_\epsilon^2 \mathbf{1}_{\|\delta_{i,j,t}(\alpha, \alpha^*)\| > \delta_\epsilon} + \frac{1}{2}\delta_{i,j,t}(\alpha, \alpha^*)^2 \mathbf{1}_{\|\delta_{i,j,t}(\alpha, \alpha^*)\| \leq \delta_\epsilon}\right] \\ &\geq \frac{1}{2}\delta_\epsilon^2 E[\mathbf{1}_{\|\delta_{i,j,t}(\alpha, \alpha^*)\| > \delta_\epsilon}]. \end{aligned}$$

The first inequality above comes from the fact that Assumption 2(ii.a) implies that for any $\delta > 0$ sufficiently small, we have $f_{i,j,t}(s) > \delta$ for $|s| < \delta$. Thus,

$$\begin{aligned} \Delta(\alpha) &:= \sum_{i=1}^n \sum_{j=1}^p E(\Delta_{i,j,t}(\alpha)) \geq \frac{1}{2}\delta_\epsilon^2 \sum_{i=1}^n \sum_{j=1}^p E[\mathbf{1}_{\|\delta_{i,j,t}(\alpha, \alpha^*)\| > \delta_\epsilon}] \\ &= \frac{1}{2}\delta_\epsilon^2 \sum_{i=1}^n \sum_{j=1}^p P[\|\delta_{i,j,t}(\alpha, \alpha^*)\| > \delta_\epsilon] \geq \frac{1}{2}\delta_\epsilon^2 \sum_{(i,j) \in \mathcal{I}} P[\|\delta_{i,j,t}(\alpha, \alpha^*)\| > \delta_\epsilon] \\ &\geq \frac{1}{2}\delta_\epsilon^2 P[\cup_{(i,j) \in \mathcal{I}} \{\|\delta_{i,j,t}(\alpha, \alpha^*)\| > \delta_\epsilon\}] > 0, \end{aligned}$$

where the final inequality follows from Assumption 4(i.b). As α is arbitrary, the result follows. ■

Next, we establish the asymptotic normality of $T^{1/2}(\hat{\alpha}_T - \alpha^*)$. We use a method originally proposed by Huber (1967) and later extended by Weiss (1991). We first sketch the method before providing formal conditions and the proof.

Huber's method applies to our estimator $\hat{\alpha}_T$, provided that $\hat{\alpha}_T$ satisfies

the asymptotic first order conditions

$$T^{-1} \sum_{t=1}^T \left\{ \sum_{i=1}^n \sum_{j=1}^p \nabla q_{i,j,t}(\cdot, \hat{\alpha}_T) \psi_{\theta_{ij}}(Y_{it} - q_{i,j,t}(\cdot, \hat{\alpha}_T)) \right\} = o_p(T^{1/2}), \quad (14)$$

where $\nabla q_{i,j,t}(\cdot, \alpha)$ is the $\ell \times 1$ gradient vector with elements $(\partial/\partial \alpha_s)q_{i,j,t}(\cdot, \alpha)$, $s = 1, \dots, \ell$, and $\psi_{\theta_{ij}}(Y_{it} - q_{i,j,t}(\cdot, \hat{\alpha}_T))$ is a generalized residual. Our first task is thus to ensure that equation (14) holds.

Next, we define

$$\lambda(\alpha) := \sum_{i=1}^n \sum_{j=1}^p E[\nabla q_{i,j,t}(\cdot, \alpha) \psi_{\theta_{ij}}(Y_{it} - q_{i,j,t}(\cdot, \alpha))].$$

With $\lambda(\alpha)$ continuously differentiable at α^* interior to \mathbb{A} , we can apply the mean value theorem to obtain

$$\lambda(\alpha) = \lambda(\alpha^*) + Q_0(\alpha - \alpha^*), \quad (15)$$

where Q_0 is an $\ell \times \ell$ matrix with $(1 \times \ell)$ rows $Q_{0,s} = \nabla' \lambda(\bar{\alpha}_{(s)})$, where $\bar{\alpha}_{(s)}$ is a mean value (different for each s) lying on the segment connecting α and α^* , $s = 1, \dots, \ell$. It is straightforward to show that the correct specification ensures that $\lambda(\alpha^*)$ is zero. We will also show that

$$Q_0 = -Q^* + O(\|\alpha - \alpha^*\|), \quad (16)$$

where $Q^* := \sum_{i=1}^n \sum_{j=1}^p E[f_{i,j,t}(0) \nabla q_{i,j,t}(\cdot, \alpha^*) \nabla' q_{i,j,t}(\cdot, \alpha^*)]$ with $f_{i,j,t}(0)$ representing the value at zero of the density $f_{i,j,t}$ of $\varepsilon_{i,j,t} := Y_{it} - q_{i,j,t}(\cdot, \alpha^*)$, conditional on \mathcal{F}_{t-1} . Combining equations (15) and (16) and putting $\lambda(\alpha^*) = 0$, we obtain

$$\lambda(\alpha) = -Q^*(\alpha - \alpha^*) + O(\|\alpha - \alpha^*\|^2). \quad (17)$$

The next step is to show that

$$T^{1/2} \lambda(\hat{\alpha}_T) + H_T = o_p(1), \quad (18)$$

where $H_T := T^{-1/2} \sum_{t=1}^T \eta_t^*$, with $\eta_t^* := \sum_{i=1}^n \sum_{j=1}^p \nabla q_{i,j,t}(\cdot, \alpha^*) \psi_{\theta_{ij}}(\varepsilon_{i,j,t})$. Equations (17) and (18) then yield the following asymptotic representation of our estimator $\hat{\alpha}_T$:

$$T^{1/2}(\hat{\alpha}_T - \alpha^*) = Q^{*-1} T^{-1/2} \sum_{t=1}^T \eta_t^* + o_p(1). \quad (19)$$

As we impose conditions sufficient to ensure that $\{\eta_t^*, \mathcal{F}_t\}$ is a martingale difference sequence (MDS), a suitable central limit theorem (e.g., theorem

5.24 in White, 2001) is applied to equation (19) to yield the desired asymptotic normality of $\hat{\alpha}_T$:

$$T^{1/2}(\hat{\alpha}_T - \alpha^*) \xrightarrow{d} N(0, Q^{*-1}V^*Q^{*-1}), \quad (20)$$

where $V^* := E(\eta_t^* \eta_t^{*\prime})$.

We now strengthen the conditions given in the text to ensure that each step of the above argument is valid.

Assumption 2 (iii) (a) There exists a finite positive constant f_0 such that for each i and t , each $\omega \in \Omega$, and each $y \in \mathbb{R}$, $f_{it}(\omega, y) \leq f_0 < \infty$; (b) There exists a finite positive constant L_0 such that for each i and t , each $\omega \in \Omega$, and each $y_1, y_2 \in \mathbb{R}$, $|f_{it}(\omega, y_1) - f_{it}(\omega, y_2)| \leq L_0|y_1 - y_2|$.

Next we impose sufficient differentiability of q_t with respect to α .

Assumption 3 (ii) For each t and each $\omega \in \Omega$, $q_t(\omega, \cdot)$ is continuously differentiable on \mathbb{A} ; (iii) For each t and each $\omega \in \Omega$, $q_t(\omega, \cdot)$ is twice continuously differentiable on \mathbb{A} .

To exploit the mean value theorem, we require that α^* belongs to $\text{int}(\mathbb{A})$, the interior of \mathbb{A} .

Assumption 4 (ii) $\alpha^* \in \text{int}(\mathbb{A})$.

Next, we place domination conditions on the derivatives of q_t .

Assumption 5 (iii) We define

$$D_{1,t} := \max_{i=1,\dots,n} \max_{j=1,\dots,p} \max_{s=1,\dots,\ell} \sup_{\alpha \in \mathbb{A}} |(\partial/\partial\alpha_s)q_{i,j,t}(\cdot, \alpha)|.$$

Then (a) $E(D_{1,t}) < \infty$; (b) $E(D_{1,t}^2) < \infty$;

(iv) Let us define

$$D_{2,t} := \max_{i=1,\dots,n} \max_{j=1,\dots,p} \max_{s=1,\dots,\ell} \max_{h=1,\dots,\ell} \sup_{\alpha \in \mathbb{A}} |(\partial^2/\partial\alpha_s\partial\alpha_h)q_{i,j,t}(\cdot, \alpha)|.$$

Then (a) $E(D_{2,t}) < \infty$; (b) $E(D_{2,t}^2) < \infty$.

Assumption 6 (i) $Q^* := \sum_{i=1}^n \sum_{j=1}^p E[f_{i,j,t}(0) \nabla q_{i,j,t}(\cdot, \alpha^*) \nabla' q_{i,j,t}(\cdot, \alpha^*)]$ is positive definite; (ii) $V^* := E(\eta_t^* \eta_t^{*\prime})$ is positive definite.

Assumptions 3(ii) and 5(iii.a) are additional assumptions that help to ensure that equation (14) holds. Further imposing Assumptions 2(iii), 3(iii.a), 4(ii), and 5(iv.a) suffices to ensure that equation (17) holds. The additional

regularity provided by Assumptions 5(iii.b), 5(iv.b), and 6(i) ensures that equation (18) holds. Assumptions 5(iii.b) and 6(ii) help ensure the availability of the MDS central limit theorem. We now have conditions that are sufficient to prove the asymptotic normality of our MVMQ-CAViaR estimator.

Proof of Theorem 2 As outlined above, we first prove

$$T^{-1/2} \sum_{t=1}^T \left\{ \sum_{i=1}^n \sum_{j=1}^p \nabla q_{i,j,t}(\cdot, \hat{\alpha}_T) \psi_{\theta_{ij}}(Y_{it} - q_{i,j,t}(\cdot, \hat{\alpha}_T)) \right\} = o_p(1). \quad (21)$$

The existence of $\nabla q_{i,j,t}$ is ensured by Assumption 3(ii). Let e_i be the $\ell \times 1$ unit vector with the i^{th} element equal to one and the rest zero, and let

$$G_s(c) := T^{-1/2} \sum_{t=1}^T \sum_{i=1}^n \sum_{j=1}^p \rho_{\theta_{ij}}(Y_{it} - q_{i,j,t}(\cdot, \hat{\alpha}_T + ce_s)),$$

for any real number c . Then, by the definition of $\hat{\alpha}_T$, $G_s(c)$ is minimized at $c = 0$. Let $H_s(c)$ be the derivative of $G_s(c)$ with respect to c from the right. Then

$$H_s(c) = -T^{-1/2} \sum_{t=1}^T \sum_{i=1}^n \sum_{j=1}^p \nabla_s q_{i,j,t}(\cdot, \hat{\alpha}_T + ce_s) \psi_{\theta_{ij}}(Y_{it} - q_{i,j,t}(\cdot, \hat{\alpha}_T + ce_s)),$$

where $\nabla_s q_{i,j,t}(\cdot, \hat{\alpha}_T + ce_s)$ is the s^{th} element of $\nabla q_{i,j,t}(\cdot, \hat{\alpha}_T + ce_s)$. Using the facts that (i) $H_s(c)$ is non-decreasing in c and (ii) for any $\epsilon > 0$, $H_s(-\epsilon) \leq 0$ and $H_s(\epsilon) \geq 0$, we have

$$\begin{aligned} |H_s(0)| &\leq H_s(\epsilon) - H_s(-\epsilon) \\ &\leq T^{-1/2} \sum_{t=1}^T \sum_{i=1}^n \sum_{j=1}^p |\nabla_s q_{i,j,t}(\cdot, \hat{\alpha}_T)| 1_{[Y_{it} - q_{i,j,t}(\cdot, \hat{\alpha}_T) = 0]} \\ &\leq T^{-1/2} \max_{1 \leq t \leq T} D_{1,t} \sum_{t=1}^T \sum_{i=1}^n \sum_{j=1}^p 1_{[Y_{it} - q_{i,j,t}(\cdot, \hat{\alpha}_T) = 0]}, \end{aligned}$$

where the last inequality follows from the domination condition imposed in Assumption 5(iii.a). Because $D_{1,t}$ is stationary, $T^{-1/2} \max_{1 \leq t \leq T} D_{1,t} = o_p(1)$. The second term is bounded in probability given Assumption 2(i,ii.a) (see Koenker and Bassett, 1978, for details): that is,

$$\sum_{t=1}^T \sum_{i=1}^n \sum_{j=1}^p 1_{[Y_{it} - q_{i,j,t}(\cdot, \hat{\alpha}_T) = 0]} = O_p(1).$$

Since $H_s(0)$ is the s^{th} element of $T^{-1/2} \sum_{t=1}^T \sum_{i=1}^n \sum_{j=1}^p \nabla q_{i,j,t}(\cdot, \hat{\alpha}_T) \psi_{\theta_{ij}}(Y_{it} - q_{i,j,t}(\cdot, \hat{\alpha}_T))$, the claim in (21) is proven.

Next, for each $\alpha \in \mathbb{A}$, Assumptions 3(ii) and 5(iii.a) ensure the existence and finiteness of the $\ell \times 1$ vector

$$\begin{aligned} \lambda(\alpha) &:= \sum_{i=1}^n \sum_{j=1}^p E[\nabla q_{i,j,t}(\cdot, \alpha) \psi_{\theta_{ij}}(Y_{it} - q_{i,j,t}(\cdot, \alpha))] \\ &= \sum_{i=1}^n \sum_{j=1}^p E[\nabla q_{i,j,t}(\cdot, \alpha) \int_{\delta_{i,j,t}(\alpha, \alpha^*)}^0 f_{i,j,t}(s) ds], \end{aligned}$$

where $\delta_{i,j,t}(\alpha, \alpha^*) := q_{i,j,t}(\cdot, \alpha) - q_{i,j,t}(\cdot, \alpha^*)$ and $f_{i,j,t}(s) = (d/ds)F_{it}(s + q_{i,j,t}(\cdot, \alpha^*))$ represents the conditional density of $\varepsilon_{i,j,t} := Y_{it} - q_{i,j,t}(\cdot, \alpha^*)$ with respect to Lebesgue measure. The differentiability and domination conditions provided by Assumptions 3(iii) and 5(iv.a) ensure (e.g., by Bartle, 1966, corollary 5.9) the continuous differentiability of $\lambda(\alpha)$ on \mathbb{A} , with

$$\nabla \lambda(\alpha) = \sum_{i=1}^n \sum_{j=1}^p E[\nabla \{ \nabla' q_{i,j,t}(\cdot, \alpha) \int_{\delta_{i,j,t}(\alpha, \alpha^*)}^0 f_{i,j,t}(s) ds \}].$$

Since α^* is interior to \mathbb{A} by Assumption 4(ii), the mean value theorem applies to each element of $\lambda(\alpha)$ to yield

$$\lambda(\alpha) = \lambda(\alpha^*) + Q_0(\alpha - \alpha^*), \quad (22)$$

for α in a convex compact neighborhood of α^* , where Q_0 is an $\ell \times \ell$ matrix with $(1 \times \ell)$ rows $Q_s(\bar{\alpha}_{(s)}) = \nabla' \lambda(\bar{\alpha}_{(s)})$, where $\bar{\alpha}_{(s)}$ is a mean value (different for each s) lying on the segment connecting α and α^* with $s = 1, \dots, \ell$. The chain rule and an application of the Leibniz rule to $\int_{\delta_{i,j,t}(\alpha, \alpha^*)}^0 f_{i,j,t}(s) ds$ then give

$$Q_s(\alpha) = A_s(\alpha) - B_s(\alpha),$$

where

$$\begin{aligned} A_s(\alpha) &:= \sum_{i=1}^n \sum_{j=1}^p E[\nabla_s \nabla' q_{i,j,t}(\cdot, \alpha) \int_{\delta_{i,j,t}(\alpha, \alpha^*)}^0 f_{i,j,t}(s) ds] \\ B_s(\alpha) &:= \sum_{i=1}^n \sum_{j=1}^p E[f_{i,j,t}(\delta_{i,j,t}(\alpha, \alpha^*)) \nabla_s q_{i,j,t}(\cdot, \alpha) \nabla' q_{i,j,t}(\cdot, \alpha)]. \end{aligned}$$

Assumption 2(iii) and the other domination conditions (those of Assumption 5) then ensure that

$$\begin{aligned} A_s(\bar{\alpha}_{(s)}) &= O(\|\alpha - \alpha^*\|) \\ B_s(\bar{\alpha}_{(s)}) &= Q_s^* + O(\|\alpha - \alpha^*\|), \end{aligned}$$

where $Q_s^* := \sum_{i=1}^n \sum_{j=1}^p E[f_{i,j,t}(0) \nabla_s q_{i,j,t}(\cdot, \alpha^*) \nabla' q_{i,j,t}(\cdot, \alpha^*)]$. Letting $Q^* := \sum_{i=1}^n \sum_{j=1}^p E[f_{i,j,t}(0) \nabla q_{i,j,t}(\cdot, \alpha^*) \nabla' q_{i,j,t}(\cdot, \alpha^*)]$, we obtain

$$Q_0 = -Q^* + O(\|\alpha - \alpha^*\|). \quad (23)$$

Next, we have that $\lambda(\alpha^*) = 0$. To show this, we write

$$\begin{aligned} \lambda(\alpha^*) &= \sum_{i=1}^n \sum_{j=1}^p E[\nabla q_{i,j,t}(\cdot, \alpha^*) \psi_{\theta_{ij}}(Y_{it} - q_{i,j,t}(\cdot, \alpha^*))] \\ &= \sum_{i=1}^n \sum_{j=1}^p E(E[\nabla q_{i,j,t}(\cdot, \alpha^*) \psi_{\theta_{ij}}(Y_{it} - q_{i,j,t}(\cdot, \alpha^*)) \mid \mathcal{F}_{t-1}]) \\ &= \sum_{i=1}^n \sum_{j=1}^p E(\nabla q_{i,j,t}(\cdot, \alpha^*) E[\psi_{\theta_{ij}}(Y_{it} - q_{i,j,t}(\cdot, \alpha^*)) \mid \mathcal{F}_{t-1}]) \\ &= \sum_{i=1}^n \sum_{j=1}^p E(\nabla q_{i,j,t}(\cdot, \alpha^*) E[\psi_{\theta_{ij}}(\varepsilon_{i,j,t}) \mid \mathcal{F}_{t-1}]) \\ &= 0, \end{aligned}$$

as $E[\psi_{\theta_{ij}}(\varepsilon_{i,j,t}) \mid \mathcal{F}_{t-1}] = \theta_{ij} - E[1_{[Y_{it} \leq q_{i,j,t}^*]} \mid \mathcal{F}_{t-1}] = 0$, by definition of $q_{i,j,t}^*$ for $i = 1, \dots, n$ and $j = 1, \dots, p$ (see equation (3)). Combining $\lambda(\alpha^*) = 0$ with equations (22) and (23), we obtain

$$\lambda(\alpha) = -Q^*(\alpha - \alpha^*) + O(\|\alpha - \alpha^*\|^2). \quad (24)$$

The next step is to show that

$$T^{1/2} \lambda(\hat{\alpha}_T) + H_T = o_p(1) \quad (25)$$

where $H_T := T^{-1/2} \sum_{t=1}^T \eta_t^*$, with $\eta_t^* := \eta_t(\alpha^*)$ and $\eta_t(\alpha) := \sum_{i=1}^n \sum_{j=1}^p \nabla q_{i,j,t}(\cdot, \alpha) \psi_{\theta_{ij}}(Y_{it} - q_{i,j,t}(\cdot, \alpha))$. Let $u_t(\alpha, d) := \sup_{\{\tau: \|\tau - \alpha\| \leq d\}} \|\eta_t(\tau) - \eta_t(\alpha)\|$. By the results of Huber (1967) and Weiss (1991), to prove (25) it suffices to show the following: (i) there exist $a > 0$ and $d_0 > 0$ such that $\|\lambda(\alpha)\| \geq a \|\alpha - \alpha^*\|$ for $\|\alpha - \alpha^*\| \leq d_0$; (ii) there exist $b > 0$, $d_0 > 0$, and $d \geq 0$ such that $E[u_t(\alpha, d)] \leq bd$ for $\|\alpha - \alpha^*\| + d \leq d_0$; and (iii) there exist $c > 0$, $d_0 > 0$, and $d \geq 0$ such that $E[u_t(\alpha, d)^2] \leq cd$ for $\|\alpha - \alpha^*\| + d \leq d_0$.

The condition that Q^* is positive-definite in Assumption 6(i) is sufficient

for (i). For (ii), we have that for the given (small) $d > 0$

$$\begin{aligned}
& u_t(\alpha, d) \\
& \leq \sup_{\{\tau:|\tau-\alpha|\leq d\}} \sum_{i=1}^n \sum_{j=1}^p \|\nabla q_{i,j,t}(\cdot, \tau) \psi_{\theta_{ij}}(Y_{it}-q_{i,j,t}(\cdot, \tau)) - \nabla q_{i,j,t}(\cdot, \alpha) \psi_{\theta_{ij}}(Y_{it}-q_{i,j,t}(\cdot, \alpha))\| \\
& \leq \sum_{i=1}^n \sum_{j=1}^p \sup_{\{\tau:|\tau-\alpha|\leq d\}} \|\psi_{\theta_{ij}}(Y_{it}-q_{i,j,t}(\cdot, \tau))\| \times \sup_{\{\tau:|\tau-\alpha|\leq d\}} \|\nabla q_{i,j,t}(\cdot, \tau) - \nabla q_{i,j,t}(\cdot, \alpha)\| \\
& \quad + \sum_{i=1}^n \sum_{j=1}^p \sup_{\{\tau:|\tau-\alpha|\leq d\}} \|\psi_{\theta_{ij}}(Y_{it}-q_{i,j,t}(\cdot, \alpha)) - \psi_{\theta_{ij}}(Y_{it}-q_{i,j,t}(\cdot, \tau))\| \\
& \quad \quad \quad \times \sup_{\{\tau:|\tau-\alpha|\leq d\}} \|\nabla q_{i,j,t}(\cdot, \alpha)\| \\
& \leq npD_{2,t}d + D_{1,t} \sum_{i=1}^n \sum_{j=1}^p \mathbb{1}_{\{|Y_{it}-q_{i,j,t}(\cdot, \alpha)| < D_{1,t}d\}}
\end{aligned}$$

using the following: (i) $\|\psi_{\theta_{ij}}(Y_{it}-q_{i,j,t}(\cdot, \tau))\| \leq 1$; (ii) $\|\psi_{\theta_{ij}}(Y_{it}-q_{i,j,t}(\cdot, \alpha)) - \psi_{\theta_{ij}}(Y_{it}-q_{i,j,t}(\cdot, \tau))\| \leq \mathbb{1}_{\{|Y_{it}-q_{i,j,t}(\cdot, \alpha)| < |q_{i,j,t}(\cdot, \tau) - q_{i,j,t}(\cdot, \alpha)|\}}$; and (iii) the mean value theorem applied to $\nabla q_{i,j,t}(\cdot, \tau)$ and $q_{i,j,t}(\cdot, \alpha)$. Hence, we have

$$E[u_t(\alpha, d)] \leq npC_0d + 2npC_1f_0d$$

for some constants C_0 and C_1 , given Assumptions 2(iii.a), 5(iii.a), and 5(iv.a). Hence, (ii) holds for $b = npC_0 + 2npC_1f_0$ and $d_0 = 2d$. The last condition (iii) can be similarly verified by applying the c_r -inequality to the last equation above with $d < 1$ (so that $d^2 < d$) and using Assumptions 2(iii.a), 5(iii.b), and 5(iv.b). As a result, equation (25) is verified.

Combining equations (24) and (25) yields

$$Q^*T^{1/2}(\hat{\alpha}_T - \alpha^*) = T^{-1/2} \sum_{t=1}^T \eta_t^* + o_p(1).$$

However, $\{\eta_t^*, \mathcal{F}_t\}$ is a stationary ergodic martingale difference sequence (MDS). In particular, η_t^* is measurable- \mathcal{F}_t , and we can show that

$$\begin{aligned}
E(\eta_t^* | \mathcal{F}_{t-1}) &= E\left(\sum_{i=1}^n \sum_{j=1}^p \nabla q_{i,j,t}(\cdot, \alpha^*) \psi_{\theta_{ij}}(\varepsilon_{i,j,t}) \mid \mathcal{F}_{t-1}\right) \\
&= \sum_{i=1}^n \sum_{j=1}^p \nabla q_{i,j,t}(\cdot, \alpha^*) E(\psi_{\theta_{ij}}(\varepsilon_{i,j,t}) \mid \mathcal{F}_{t-1}) \\
&= 0
\end{aligned}$$

because $E[\psi_{\theta_{ij}}(\varepsilon_{i,j,t}) \mid \mathcal{F}_{t-1}] = 0$ for all $i = 1, \dots, n$ and $j = 1, \dots, p$. Assumption 5(iii.b) ensures that $V^* := E(\eta_t^* \eta_t^{*\prime})$ is finite. The MDS central limit the-

orem (e.g., theorem 5.24 of White, 2001) applies, provided V^* is positive definite (as ensured by Assumption 6(ii)) and that $T^{-1} \sum_{t=1}^T \eta_t^* \eta_t^{*'} = V^* + o_p(1)$, which is ensured by the ergodic theorem. The standard argument now gives

$$V^{*-1/2} Q^* T^{1/2} (\hat{\alpha}_T - \alpha^*) \xrightarrow{d} N(0, I),$$

which completes the proof. ■

To establish the consistency of \hat{Q}_T , we strengthen the domination condition on $\nabla q_{i,j,t}$ and impose conditions on $\{\hat{c}_T\}$.

Assumption 5 (iii)(c) $E(D_{1,t}^3) < \infty$.

Assumption 7 $\{\hat{c}_T\}$ is a stochastic sequence and $\{c_T\}$ is a non-stochastic sequence such that (i) $\hat{c}_T/c_T \xrightarrow{p} 1$; (ii) $c_T = o(1)$; and (iii) $c_T^{-1} = o(T^{1/2})$.

Proof of Theorems 3 & 4: Theorems 3 & 4 can be proved by extending similar results in White, Kim, and Manganeli (2008). We do not report the proof to save space, but the complete proof of Theorems 3 & 4 can be found at the following website: <http://web.yonsei.ac.kr/thkim/downloadable.html>.

Note: Estimated coefficients are in the first row. Standard errors are reported in italic in the second row. The coefficients correspond to the VAR for VaR model reported in equation (8) of the paper. Coefficients significant at the 10%, 5% and 1% confidence level are denoted by *, **, ***, respectively.

Table 4 – Summary statistics of the full cross section of coefficients

	c_1	a_{11}	a_{12}	b_{11}	b_{12}
average	-0.07	-0.32	-0.02	0.84	0.02
std. dev.	0.17	0.13	0.07	0.20	0.12
min	-0.98	-0.70	-0.32	-0.79	-0.34
max	1.56	0.03	0.14	1.28	0.88
	c_2	a_{21}	a_{22}	b_{21}	b_{22}
average	-0.16	-0.18	-0.24	0.02	0.86
std. dev.	0.31	0.23	0.22	0.21	0.16
min	-3.49	-1.12	-1.91	-1.11	-0.03
max	0.82	0.62	0.09	1.39	1.49

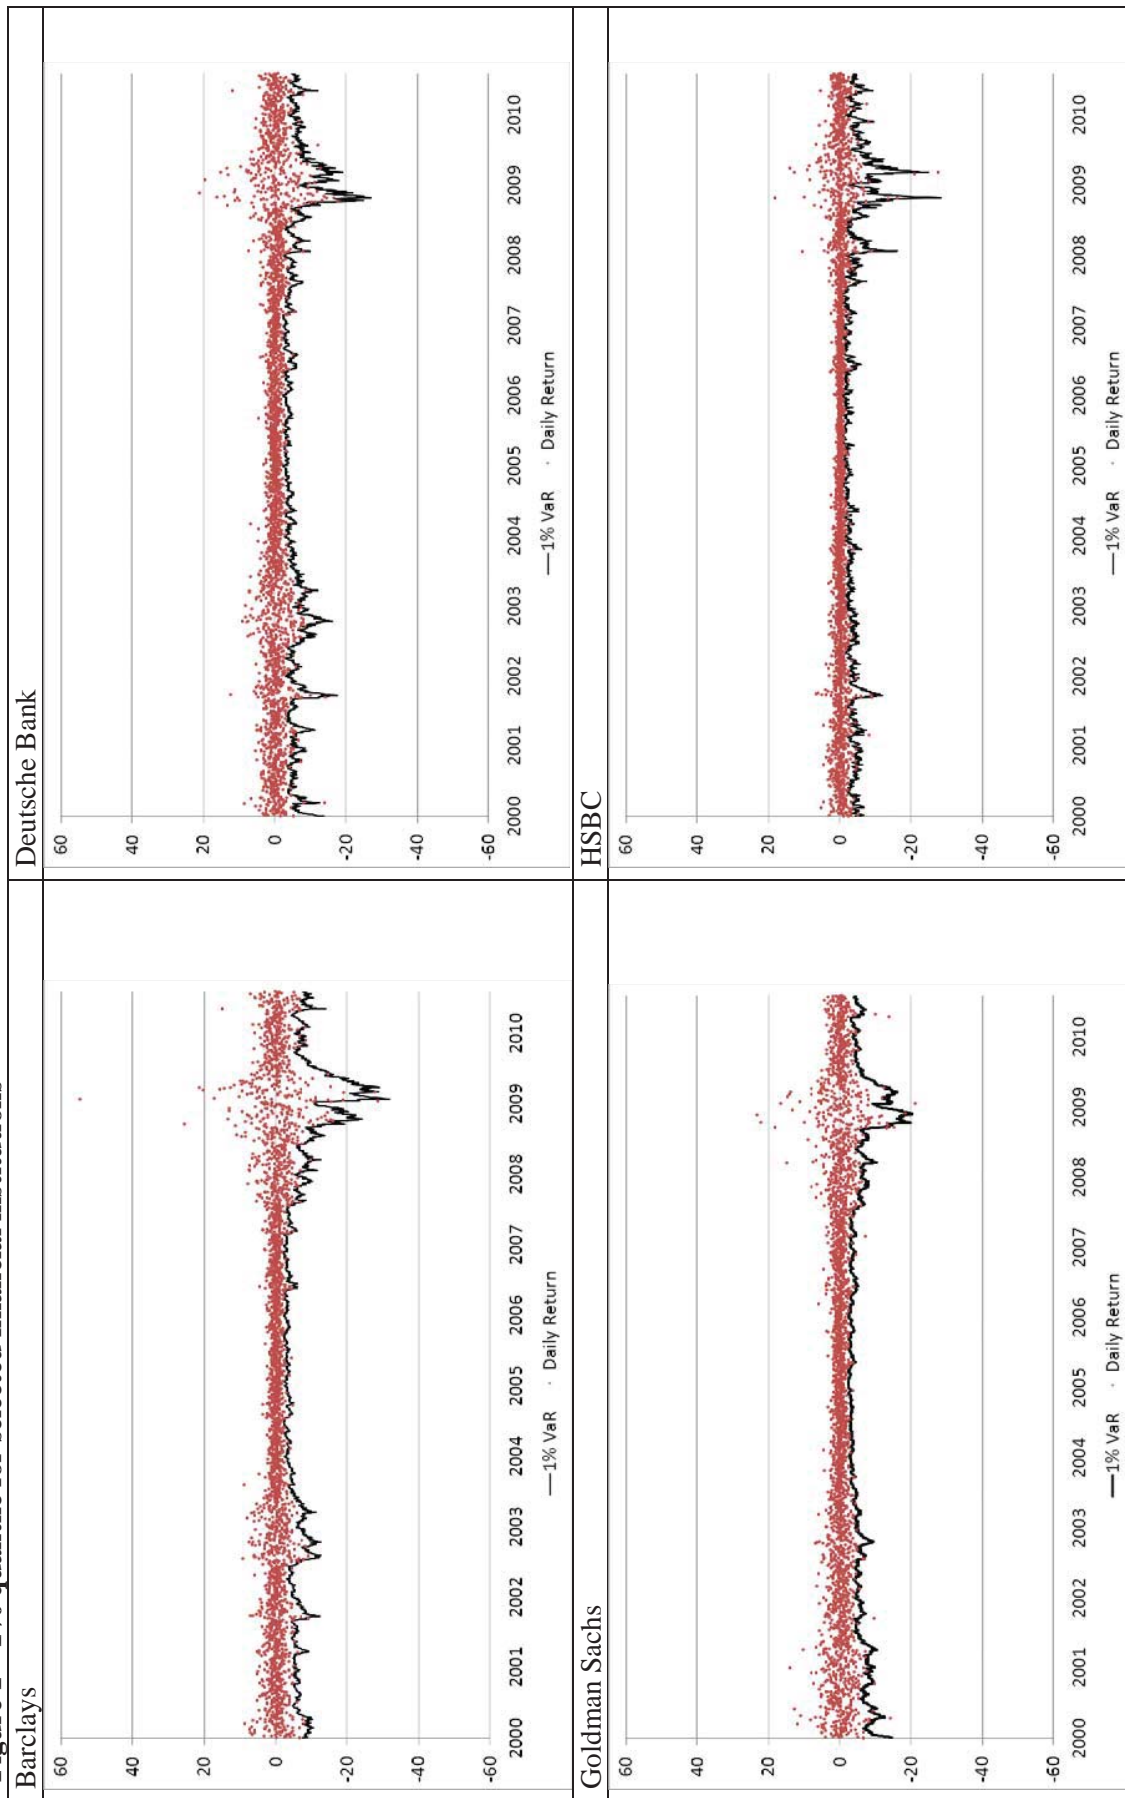

Note: The table reports the summary statistics of the coefficient estimates of the 230 bivariate VAR for VaR models. The table reveals quite substantial heterogeneity in the estimates.

Table 5 – Performance evaluation

	average	median	std. dev.	min	max	# stocks passing DQ test
In-sample	1.00%	1.01%	0.07%	0.25%	1.45%	-
Out-of-sample	1.33%	0.88%	5.81%	0.00%	87.64%	123

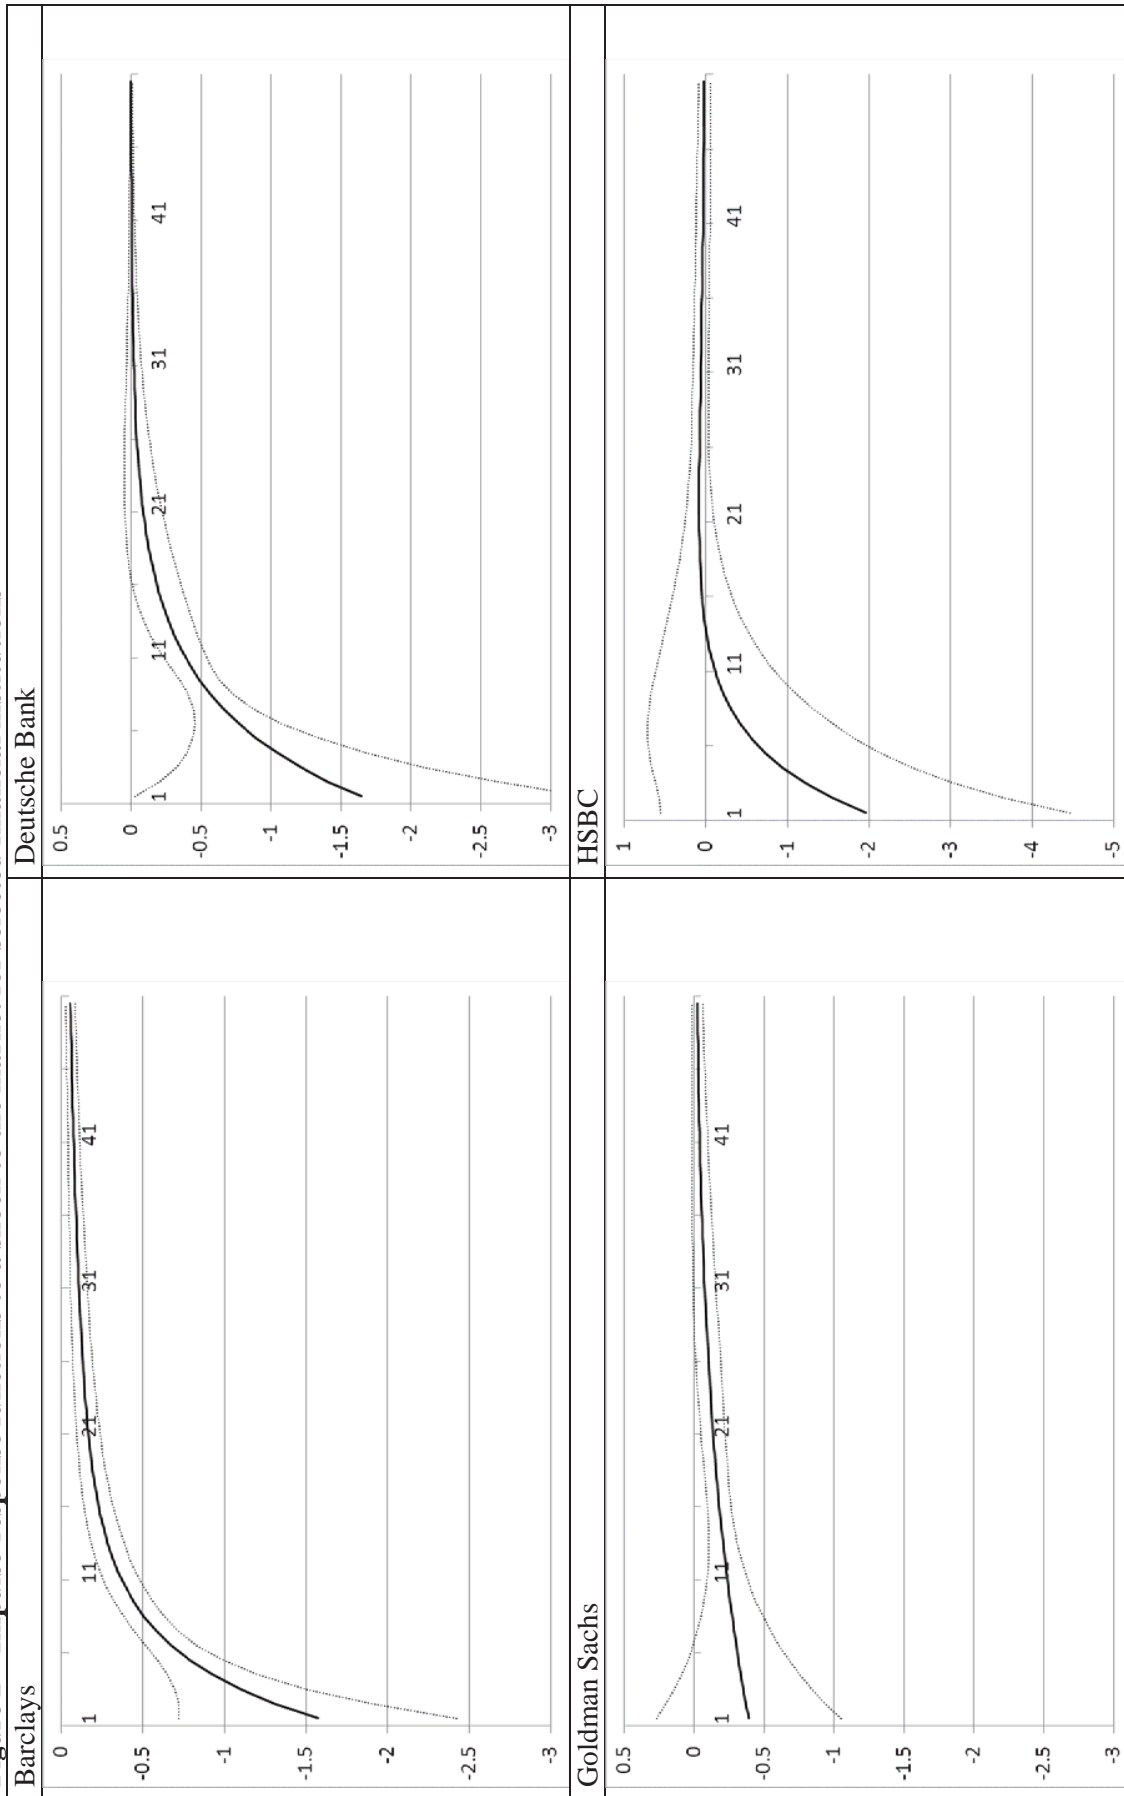

Note: The table reports the summary statistics of VaR performance evaluation, based on the number of VaR exceedances both in-sample and out-of-sample. For each of the 230 bivariate VAR for VaR models, the time series of returns is transformed into a time series of indicator functions which take value one if the return exceeds the VaR and zero otherwise. When estimating a 1% VaR, on average one should expect stock market returns to exceed the VaR 1% of the times. The first line reveals that the in-sample estimates are relatively precise, as shown by the accurate average and median, the very low standard deviations and the relatively narrow min-max range. The out-of-sample performance is less accurate, as to be expected, with substantially higher standard deviation and very large min-max range. The out-of-sample performance has been assessed also applying the out-of-sample DQ test of Engle and Manganelli (2004), which tests not only whether the number of exceedances is close to the VaR confidence level, but also that these exceedances are not correlated over time. The test reveals that the performance of the out-of-sample VaR is not rejected at a 5% confidence level for more than half of the stocks. Note that for the out-of-sample exercise the coefficients are held fixed at their estimated in-sample values.

Figure 1 – 1% quantile for selected financial institutions

Note: The four charts report the in-sample 1% daily Value at Risk (VaR) for four selected institutions from 1 January 2000 to 6 August 2010, together with daily returns. The VaR is computed from a bivariate VAR for VaR, where the first equation contains the quantile of the regional index and the second equation the quantile of the individual financial institution. The empirical specification follows equation (8) in the paper: $q_t = c + A|Y_{t-1}| + Bq_{t-1}$. The crisis following the Lehman default is clearly visible in the plots.

Figure 2 – Impulse-response functions to a shock to the market for selected financial institutions

Note: The four charts report the quantile impulse-response functions to a shock to the market for four selected institutions, together with 95% confidence intervals. The impulse-responses are derived from a bivariate VAR for VaR, where the first equation contains the quantile of the regional index and the second equation the quantile of the individual financial institution. The identification of the market shock relies on a Choleski decomposition of the daily returns, which implicitly assumes that shocks to the market can simultaneously affect the regional index and the individual financial institution, while shocks to the financial institution can affect the market only with a lag.

Figure 3 – Impulse-response functions by sectoral and geographic aggregation

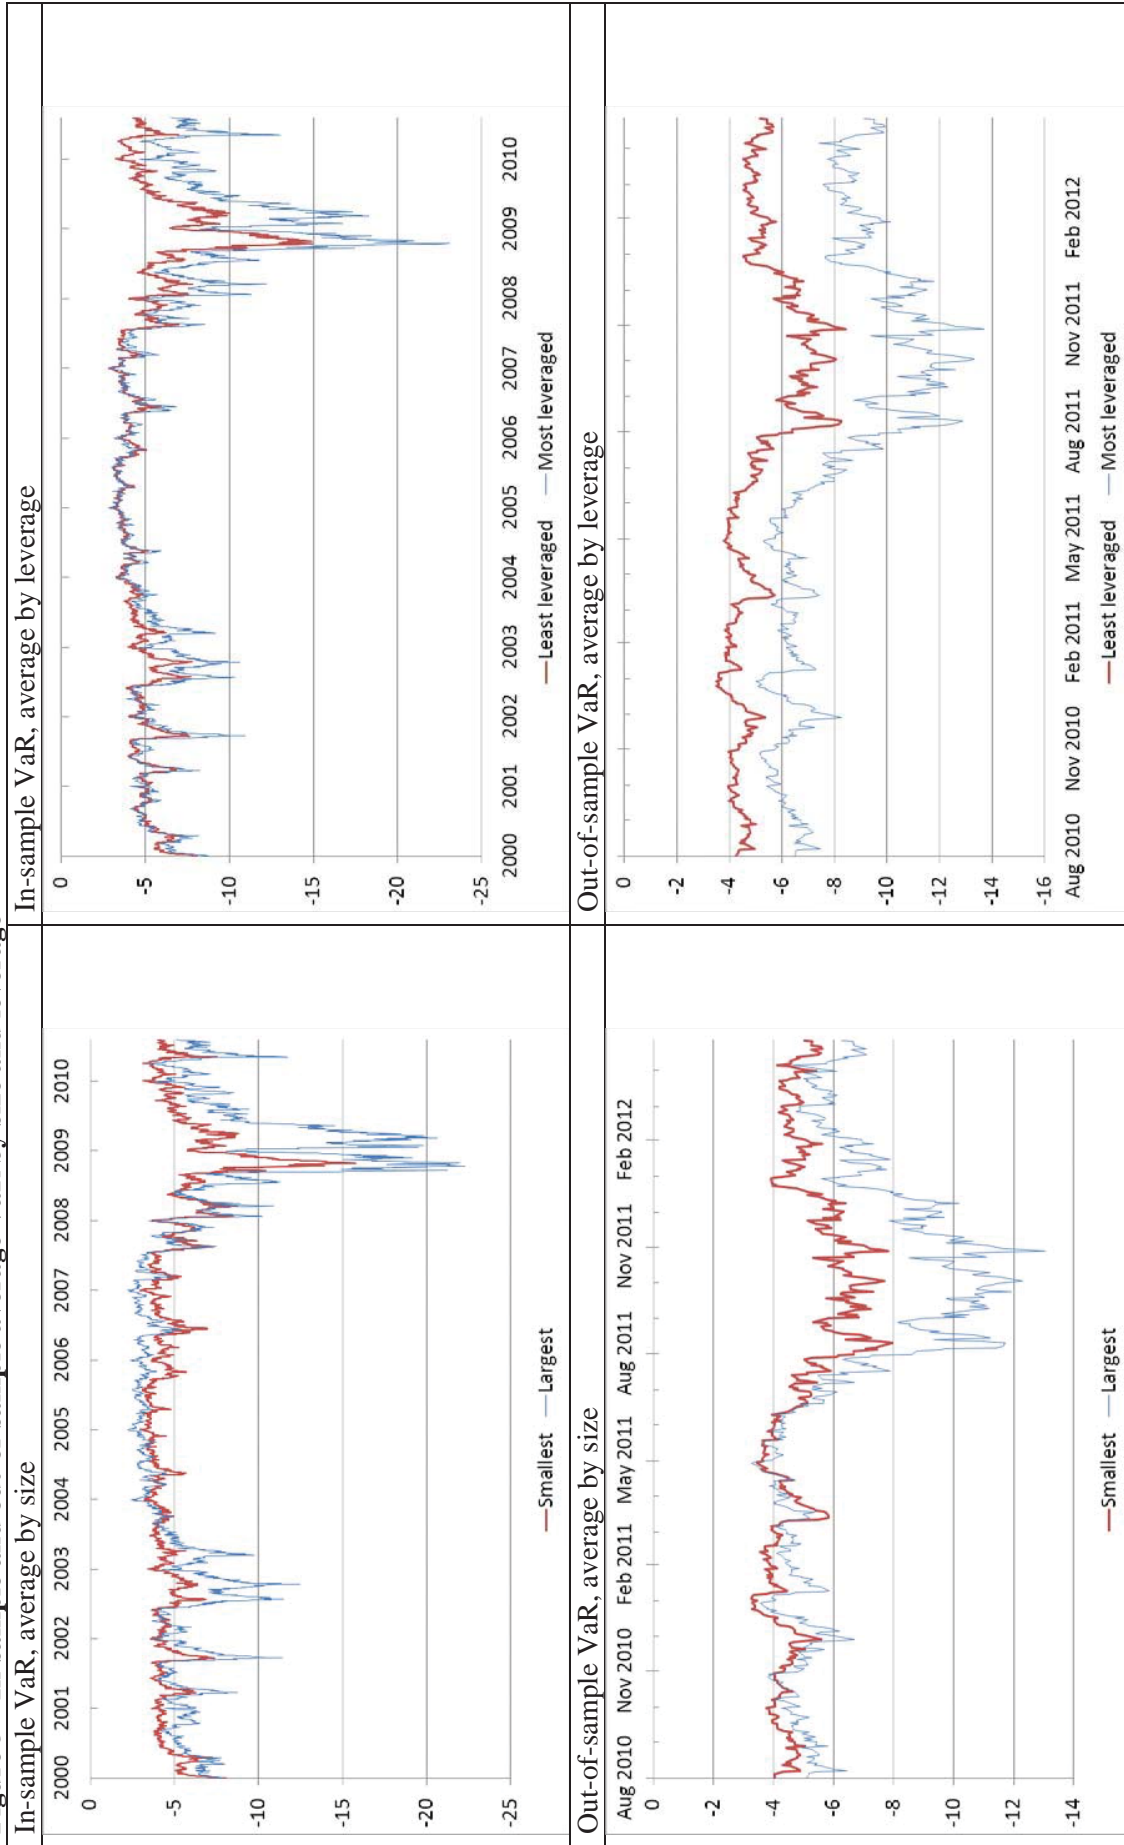

Note: The four charts report the average quantile impulse-response functions. Averages are taken along the geographic and sectoral dimension. The first row is the average impulse response of financial institutions' quantiles to a shock to the market. The second row is the average impulse response of markets' quantiles to a shock to the individual financial institutions. As usual, the impulse-responses are derived from a bivariate VAR for VaR, where the first equation contains the quantile of the regional index and the second equation the quantile of the individual financial institution. The first row reveals that shocks to European financial institutions are absorbed relatively quicker than in Japan or the US. The risk of insurance companies is on average more sensitive to market shocks than financial institutions in the banking and financial services sectors. Market risk reactions to shocks to individual financial institutions are more muted.

Figure 4 – Impulse-response functions for institutions sorted by size and leverage

Note: The figure reports the average impulse-response function of the 30 financial institutions with the largest and smallest market capitalisation and leverage. Largest and most leveraged financial institution display a relatively similar risk response to market shocks, despite only four institutions belong to both groups. The average reaction is about twice the impulse-responses of smallest and least leverage banks.

Figure 5 – In-sample and out-of-sample average VaR by size and leverage

Note: The figure reports the average VaR of the 30 financial institutions with the largest and smallest market capitalisation and leverage. All groups of financial institutions have similar VaR during tranquil periods. Between 2004 and 2007, largest financial institutions had actually a lower average VaR than smallest ones. In times of crisis, however, the VaR of the largest and most leveraged financial institutions increases much more than for the small and least leverage ones. This behaviour is consistent with the largest and most leveraged financial institutions having a stronger quantile impulse-response function, as illustrated in figure 4. The out-of-sample plots are computed using the estimated in-sample coefficients and reveal similar patterns to those identified in-sample.

Acknowledgements

We would like to thank Peter Christoffersen, Rob Engle, Demian Pouzo, Rossen Valkanov, as well seminar participants at the ECB, the Fourth Annual SoFIE Conference in Chicago, the Cass Business School, the London Business School, the Fourth Tremblant Risk Management Conference, the Vienna Graduate School of Finance and the Fourteenth International Korean Economic Association Conference. We are also grateful to two anonymous referees and Co-Editor Yacine Ait-Sahalia for their invaluable comments which substantially improved the paper. Francesca Fabbri and Thomas Kostka provided data support. The phrase “VAR for VaR” was first used by Andersen et al. (2003), in the title of their section 6.4. The views expressed in this paper are those of the authors and do not necessarily reflect those of the European Central Bank or the Eurosystem. Tae-Hwan Kim is grateful for financial support from the National Research Foundation of Korea — a grant funded by the Korean Government (NRF-2009-327-B00088).
