#### Abstract

Constructing joint confidence bands for structural impulse response functions based on a VAR model is a difficult task because of the non-linear nature of such functions. We propose new joint confidence bands that cover the entire true structural impulse response function up to a chosen maximum horizon with a prespecified probability $(1-\alpha)$, at least asymptotically. Such bands are based on a certain bootstrap procedure from the multiple-testing literature. We compare the finite-sample properties of our method with those of existing methods via extensive Monte Carlo simulations. We also investigate the effect of endogenizing the lag order in our bootstrap procedure on the finite-sample properties. Furthermore, an empirical application to a real data set is provided.

KEY WORDS: Bootstrap; impulse response functions;
joint confidence bands; vector autoregressive process.
JEL CLASSIFICATION NOS: C12, C32

## 1 Introduction

Impulse response analysis based on low-dimensional structural vector autoregressions (VARs) is still a popular tool in applied work; for example, see Barsky and Sims (2011), Kurmann and Otrok (2013), and Bian and Gete (2015). In practice, the impulse response functions have to be estimated from the data and it is standard in the literature to report the corresponding estimation uncertainty in the form of confidence bands.

It is by now a well-known fact that simply connecting individual marginal confidence intervals with nominal confidence level $(1-\alpha)$ does not result in confidence bands that cover the entire true impulse response function with the prespecified confidence level ( $1-\alpha$ ). Instead, such a procedure results in joint confidence bands that are too narrow and hence cover the true impulse responses with probability less than the desired level. ${ }^{1}$ Consequently, the literature has proposed a substantial number of methods to construct 'proper' joint confidence bands that are designed to actually the entire true impulse response function with a prespecified probability; for example, see Staszewska (2007), Jordà (2009), and Lütkepohl et al. (2015a,b).

The finite-sample properties of the existing methods are compared in Lütkepohl et al. (2015a,b) via extensive Monte Carlo experiments. They find that the traditional Bonferroni bands and the Wald bands of Lütkepohl et al. (2015b) mostly exhibit empirical coverage rates close to or above the nominal level but that the bands can be excessively wide. In contrast, the bands of the other competing methods - namely, the bands of Staszewska (2007) and Jordà (2009) as well as the size-adjusted Bonferroni and Wald bands of Lütkepohl et al. (2015a,b) are narrower but suffer from finite-sample coverage rates below the nominal level in certain scenarios. Consequently, there is no method so far that produces joint confidence bands for impulse response functions that enjoys both (i) robust empirical coverage rates close to the nominal confidence level and (ii) moderate volumes compared to the Bonferroni and Wald bands.

We propose new joint confidence bands for impulse response functions that are based on the methodology of Romano and Wolf (2010) who provide a bootstrap-based method to construct rectangular joint confidence bands for a generic parameter $\theta \in \mathbb{R}^{d}$. Furthermore, they prove that, under weak regularity conditions, their proposed joint confidence bands have asymptotically the correct coverage probability and are also asymptotically balanced The resulting joint confidence bands are subsequently labeled as balanced bootstrap (BB) bands.

In addition, we conduct a Monte Carlo experiment to compare the finite-sample properties of the proposed BB bands with those of a set of competing methods. We find that the BB bands are smaller than the Bonferroni and the Wald bands. Furthermore, the BB confidence bands seem to work reliably in scenarios where the ratio of the sample size to the number of coefficients is not small (that is, in medium to high-degrees-of-freedom scenarios), even when the maximum propagation horizon is large.

[^1]The remainder of the paper is organized as follows. Section 2 reviews impulse response functions of structural vector autoregressions. Section 3 presents the new confidence bands. Section 4 briefly describes the competing methods to construct confidence bands. Section 5 describes the Monte Carlo experiment and presents the empirical findings. Section 6 presents an empirical application. Section 7 concludes. The Appendix contains additional details about the estimation of impulse response functions, an algorithm to construct the BB bands, all figures, and the Supplementary Material (containing detailed tables with the simulation results and figures corresponding to the empirical application).

## 2 Structural Impulse Response Functions

Consider an $m$-dimensional reduced-form $\operatorname{VAR}(p)$ process of the form

$$
\begin{equation*}
y_{t}=\nu+A_{1} y_{t-1}+\ldots+A_{p} y_{t-p}+u_{t} \tag{1}
\end{equation*}
$$

where $y_{t}$ is a $m$-dimensional random vector, the $A_{i}$ are $m \times m$ coefficient matrices, $\nu$ is an $m$-dimensional intercept vector, and $\left\{u_{t}\right\}$ is an $m$-dimensional independent and identically distributed (i.i.d.) process with $\mathbb{E}\left[u_{t}\right]=0$ and positive-definite covariance matrix $\Sigma_{u}:=\mathbb{E}\left[u_{t} u_{t}^{\prime}\right]$. The process in (1) is stable and stationary if and only if

$$
\operatorname{det}\left(I_{m}-A_{1} z^{1}-\ldots-A_{p} z^{p}\right) \neq 0 \quad \text { for all } z \in \mathbb{C} \text { with }|z| \leq 1 .
$$

A stationary $\operatorname{VAR}(p)$ process admits a Wold vector moving average (VMA) representation of the form

$$
\begin{equation*}
y_{t}=\mu+\sum_{i=0}^{+\infty} \phi_{i} u_{t-i}, \tag{2}
\end{equation*}
$$

where $\mu:=\mathbb{E}\left[y_{t}\right]=\left(I_{m}-A_{1}-\ldots-A_{p}\right)^{-1} \nu$ and the $\phi_{i}$ are fixed $m \times m$ MA-coefficient matrices that satisfy $\phi_{0}=I_{m}$ and $\phi_{s}=\sum_{j=1}^{s} \phi_{s-j} A_{j}$, for $s \in \mathbb{N}_{+}$.

The structural representation of (1) is given by

$$
\begin{equation*}
B_{0} y_{t}=B_{0} \nu+B_{0} A_{1} y_{t-1}+\ldots+B_{0} A_{p} y_{t-p}+B_{0} u_{t} \tag{3}
\end{equation*}
$$

where $B_{0} \in \mathbb{R}^{m \times m}$ is a linear mapping that transforms the reduced-form errors $u_{t}$ into the structural shocks $\varepsilon_{t}$, that is, $\varepsilon_{t}:=B_{0} u_{t}$. The key restriction on the impact matrix $B_{0}$ emerges from imposing that the structural shocks are instantaneously uncorrelated and have unit variance. ${ }^{2}$ Thus, $B_{0}$ needs to satisfy the following set of $m$ equations:

$$
\begin{equation*}
\Sigma u=B_{0} B_{0}^{\prime} . \tag{4}
\end{equation*}
$$

[^2]Simple accounting reveals that there are $m(m-1) / 2$ degrees of freedom in specifying $B_{0}$, whereas there are only $m$ equations; hence, further restrictions are needed to achieve identification. ${ }^{3}$ The literature offers a wide variety of different identification strategies; for example, see Lütkepohl (2005, Section 9.1) for a brief overview.

However, we will be agnostic about the particular identification procedure, as our goal is to provide new joint confidence bands with good finite-sample properties rather than to propose a new identification procedure. Thus, at this point, we only assume that the structural VAR is exactly identified via an arbitrary identification procedure.

The identification of the impact matrix $B_{0}$ allows to exactly express the reduced-form $\operatorname{VAR}(p)$ process $\left\{y_{t}\right\}$ as a structural vector moving average process

$$
\begin{equation*}
y_{t}=\mu+\sum_{i=0}^{+\infty} \Theta_{i} \epsilon_{t-i} \tag{5}
\end{equation*}
$$

where $\Theta_{h}:=\phi_{h} B_{0}$. The $(i, j)$-th structural impulse response function with a maximum propagation horizon $H \in \mathbb{N}$, denoted by $\boldsymbol{\Theta}_{i j, H}$, measures the partial effect of a one-standarddeviation shock ${ }^{4}$ in the $j$-th variable on the $i$-th variable over $H+1$ periods and is given by the vector that collects the $(i, j)$-th element of the corresponding structural vector moving average (VMA) coefficient matrices, that is,

$$
\boldsymbol{\Theta} i j, H:=\left(\begin{array}{c}
\frac{\partial y_{t, i}}{\partial \epsilon_{t, j}}  \tag{6}\\
\vdots \\
\frac{\partial y_{t+H, i}}{\partial \epsilon_{t, j}}
\end{array}\right)=\left(\begin{array}{c}
\Theta_{i j, 0} \\
\vdots \\
\Theta_{i j, H}
\end{array}\right) \quad \text { for } i, j=1, \ldots, k
$$

The structural VMA coefficient matrices at propagation horizon $h \in\{0, \ldots, H\}$ can be obtained as $\Theta_{i j, h}=\left(\left(J A^{h} J^{\prime}\right) B_{0}\right) i j$, where $J:=\left[I_{m}: 0: \ldots: 0\right] \in \mathbb{R}^{m \times m p}$ is a selector matrix and $A$ denotes the reduced-form coefficient matrix of the mp-dimensional companion form of a $\operatorname{VAR}(p)$ process. Thus, the structural impulse response function $\Theta_{i j, H}$ is a non-linear function of the reduced-form model coefficients $\left(A_{1}, \ldots, A_{p}\right)$ and the impact matrix $B_{0}$, that is,

$$
\begin{equation*}
\boldsymbol{\Theta}_{i j, H}=\boldsymbol{\Theta}_{i j, H}\left(A_{1}, \ldots, A_{p}, B_{0}\right) \tag{7}
\end{equation*}
$$

The reduced-form coefficient matrices $\left(A_{1}, \ldots, A_{p}\right)$ are usually estimated by a standard procedure such as least squares (LS). The impact matrix $B_{0}$ is in general a function of the reduced-form coefficient matrices $\left(A_{1}, \ldots, A_{p}, \Sigma_{u}\right)$ and a set of identifying restrictions. An estimator for $B_{0}$, denoted by $\hat{B}_{0}$, is found by replacing the true coefficient matrices by corresponding estimators (and by imposing the identifying restrictions). Thus, a plug-in estimator of the impulse response function is obtained as

$$
\begin{equation*}
\widehat{\boldsymbol{\Theta}}_{i j, H}:=\boldsymbol{\Theta}_{i j, H}\left(\hat{A}_{1}, \ldots, \hat{A}_{p}, \hat{B}_{0}\right) \tag{8}
\end{equation*}
$$

[^3]The estimator in (8) is consistent if the estimators ( $\hat{A}_{1}, \ldots, \hat{A}_{p}, \hat{B}_{0}$ ) are consistent because $\boldsymbol{\Theta}_{i j, H}(\cdot)$ is a continuous function.

## 3 New Joint Confidence Bands

### 3.1 Motivation and Notation

Romano and Wolf (2010) propose a method to construct joint confidence bands for a generic parameter $\theta \in \mathbb{R}^{d}$. For them, this method is just a means to an end, where the end is stepwise multiple testing procedure that controls the familywise error rate. But we can adapt this method to our 'direct' end of constructing joint confidence bands for impulse response functions. The method of Romano and Wolf (2010) is based on the availability of a consistent estimator for the parameter of interest and a bootstrap procedure that estimates the sampling distribution of the aforementioned estimator. Therefore, it can be used one-to-one to construct joint confidence bands for impulse response functions of structural vector autoregressions because both a consistent estimator for $\boldsymbol{\Theta}_{i j, H}$ and such a bootstrap procedure are available; for example, see Kilian (1998b).

The asymptotic properties of the generic bands hinge on a set of regularity conditions about the asymptotic distribution of the estimator (of the parameter of interest) and the bootstrap; see Romano and Wolf (2010, Theorem 3.1). A discussion of the validity of the regularity conditions in the present context - that is, the construction of joint confidence bands for impulse response functions of structural vector autoregressions - is found in Section 3.3 below.

The bands of Romano and Wolf (2010) are rectangular by construction in contrast to methods that produce joint confidence sets of a non-rectangular shape in first place, from which then rectangular joint confidence bands are obtained by projection on the axes; an example of the latter approach are the Wald bands of Lütkepohl et al. (2015b). Such projection methods usually result in conservative joint confidence bands, even asymptotically, that are excessive in volume and thus leads to a loss in information.

Furthermore, the method of Romano and Wolf (2010) is attractive from a computational point of view, since it involves only the computation of the estimator of the impulse response function $\boldsymbol{\Theta}_{i j, H}$ and an estimator (via the bootstrap) of the sampling distribution of the statistic $\max \sqrt{T}\left|\widehat{\boldsymbol{\Theta}}_{i j, H}-\boldsymbol{\Theta}_{i j, H}\right|$, where $T$ denotes the sample size and both the maximum and the absolute value of a vector are understood to be element-wise operators. Both quantities are straightforward to compute and do not contain any sort of potential numerical difficulties such as, for example, the inversion of a large-dimensional matrix.

In contrast, the construction of the size-adjusted Wald joint confidence bands of Lütkepohl et al. (2015b) requires on the one hand the computation and the inversion of the (potentially large-dimensional) asymptotic covariance matrix of the vectorized estimators of ( $A_{1}, \ldots, A_{p}, \Sigma_{u}$ ) and on the other hand an iterative procedure to decrease the volume of the confidence bands; see Section 4.3.

Next, the following notation is introduced:

- Let $\left\{\sqrt{T}\left|\widehat{\Theta}_{i j, h, b}^{*}-\widehat{\Theta}_{i j, h}\right|\right\}_{b=1}^{B}$ denote the marginal bootstrap distribution at propagation horizon $h \in\{0, \ldots, H\}$ based on $B$ bootstrap replications.
- Let $\widehat{\mathrm{H}}_{h}^{*}(t), h \in\{0, \ldots, H\}$, denote the following empirical distribution function

$$
\forall t \in \mathbb{R}, \quad \widehat{\mathrm{H}}_{h}^{*}(t):=\frac{1}{B} \sum_{b=1}^{B} \mathbb{1}_{\left\{\sqrt{T}\left|\widehat{\Theta}_{i j, h, b}^{*}-\widehat{\Theta}_{i j, h}\right| \leq t\right\}},
$$

and the corresponding empirical quantile function is then given by

$$
\widehat{\mathrm{H}}_{h}^{*,-1}(p):=\inf \left\{t: \widehat{H}_{h}(t) \geq p\right\} .
$$

- Let $\widehat{\mathrm{L}}^{*}(t)$ denote the following empirical distribution function

$$
\forall t \in \mathbb{R}, \quad \widehat{\mathrm{~L}}^{*}(t):=\frac{1}{B} \sum_{b=1}^{B} \mathbb{1}_{\left\{\max _{h \in \widehat{S}}\left\{\widehat{H}_{h}\left(\sqrt{T}\left|\widehat{\Theta}_{i j, h, b}^{*}-\widehat{\Theta}_{i j, h, b}\right|\right)\right\} \leq t\right\},, ~ ; ~},
$$

where $\tilde{S} \subseteq\{0, \ldots, H\}$ denotes the propagation horizons where $\widehat{\Theta}_{i j, h}$ exhibits a nondegenerate distribution. The corresponding empirical quantile function is then given by

$$
\widehat{\mathrm{L}}^{*,-1}(p):=\inf \{t: \widehat{L}(t) \geq p\} .
$$

### 3.2 Balanced Bootstrap Joint Confidence Bands

Based on equation (3.7) in Romano and Wolf (2010), we define the balanced bootstrap (BB) joint confidence bands for $\boldsymbol{\Theta}_{i j, H}$ with nominal coverage probability $(1-\alpha)$ as the Cartesian product of the following ( $H+1$ ) marginal intervals:

$$
\begin{equation*}
\left[\widehat{\Theta}_{i j, h}-\frac{1}{\sqrt{T}} \widehat{\mathrm{H}}_{h}^{*,-1}\left(\widehat{\mathrm{~L}}^{*,-1}(1-\alpha)\right), \widehat{\Theta}_{i j, h}+\frac{1}{\sqrt{T}} \widehat{\mathrm{H}}_{h}^{*,-1}\left(\widehat{\mathrm{~L}}^{*,-1}(1-\alpha)\right)\right] \quad \text { for } h=0, \ldots, H \tag{9}
\end{equation*}
$$

A detailed algorithm for the construction of the BB bands is found in Appendix C. In the following, the BB bands for $\boldsymbol{\Theta}_{i j, H}$ with a nominal coverage of $(1-\alpha)$ are denoted by $\mathrm{CB}_{\mathrm{BB}, i j}^{(1-\alpha)}$. It is worth providing some further discussion about the BB joint confidence bands.

As is evident from (9), the BB bands are based on the estimated sampling distributions of the non-studentized roots $\sqrt{T}\left|\widehat{\Theta}_{i j, h}-\Theta_{i j, h}\right|$. Often confidence intervals based on studentized roots are preferred from a higher-order asymptotic point of view; for example, see Hinkley and Wei (1984). However, under the assumption of stationarity of $\left\{y_{t}\right\}$, the standard deviations of the scaled estimator $\sqrt{T} \widehat{\Theta}_{i j, h}$, denoted by $\sigma_{h}$, are decreasing in the propagation horizon (for fixed $T$ ), that is, $\sigma_{h} \rightarrow 0$, and the same is true for the standard errors $\hat{\sigma}_{h}$; for example, see Lütkepohl (1990). As a consequence, using the estimated sampling distributions of the
studentized roots $\sqrt{T}\left|\widehat{\Theta}_{i j, h}-\Theta_{i j, h}\right| / \hat{\sigma}_{h}$ results in joint confidence bands that can have excessively large volume, as pointed out by Lütkepohl et al. (2015a).

The construction of the BB bands involves the prepivoting transformation of Beran (1987); that is, the roots that underlie the joint confidence bands are monotonically transformed by their estimated empirical distribution function $\widehat{H}_{h}^{*}$. Beran (1987) argues that the prepivoting transformation reduces the coverage bias of marginal confidence intervals and also results in improved higher-order properties, similar to studentized roots. Consequently, using the prepivoting transformation results in BB joint confidence bands with good coverage properties but without excessive volume; see the Monte Carlo simulations in Section 5.

The BB bands are symmetric around the estimated the impulse response function. The methodology of Romano and Wolf (2010) also allows the construction of asymmetric, 'equaltailed' joint confidence bands based on the estimated distribution of the one-sided roots $\sqrt{T}\left(\widehat{\Theta}_{i j, h}-\Theta_{i j, h}\right)$. But simulation results (not reported here) suggest that the symmetric bands are superior to the asymmetric bands in terms of finite-sample coverage properties.

Remark 3.1. Cao and Sun (2011) derive the asymptotic distribution of structural impulse response functions of short panel vector autoregressions. Furthermore, Cao and Sun (2011) compare the finite-sample coverage properties of marginal confidence for individual responses based on the asymptotic distribution with the properties of various bootstrap intervals, but joint confidence bands for the entire impulse response function are not considered in their study. We expect that our proposed method can also be applied to construct joint confidence bands for impulse response functions of short panel vector autoregressions. However, a detailed analysis of this topic is beyond the scope of this paper.

### 3.3 Asymptotic Properties

The regularity conditions underlying Theorem 3.1 of Romano and Wolf (2010), which states the asymptotic properties of the generic bootstrap joint confidence bands, involve the asymptotic distribution of the estimator of the impulse response function and the asymptotic validity of the bootstrap. Thus, for the sake of completeness, both assumptions are subsequently reviewed.

Under standard assumptions and when LS is used for the estimation of $\left(A_{1}, \ldots, A_{p}, \Sigma_{u}\right)$, the asymptotic distribution of $\sqrt{T}\left(\widehat{\boldsymbol{\Theta}}_{i j, H}-\mathbf{\Theta}_{i j, H}\right)$ is generally derived via an application of the delta method; for example, see Lütkepohl (1990). Thus, the asymptotic distribution of the (standardized) estimator of the impulse response function is typically normal because the (vectorized) LS estimator of ( $A_{1}, \ldots, A_{p}, \Sigma_{u}$ ) is asymptotically normal under weak high-level assumptions: for example, see Lütkepohl (2005, Section 3.7). However, Lütkepohl (1989) and Benkwitz et al. (2000) note that the asymptotic covariance matrix, denoted by $\Sigma_{\widehat{\Theta}}$, is singular in certain scenarios; hence, in such scenarios, the limiting distribution of $\sqrt{T}\left(\widehat{\boldsymbol{\Theta}}_{i j, H}-\boldsymbol{\Theta}_{i j, H}\right)$ is not normal, but degenerate normal instead.

This characteristic of the asymptotic distribution of the estimated impulse response function (that is, normal versus degenerate normal) has an impact on the consistency of the bootstrap for
the joint sampling distribution of $\sqrt{T}\left(\widehat{\boldsymbol{\Theta}}_{i j, H}-\boldsymbol{\Theta}_{i j, H}\right)$. More specifically, in case the asymptotic distribution is non-degenerate normal, the bootstrap is consistent because the usual smoothness conditions underlying the bootstrap are satisfied; for example, see Horowitz (2001). However, the bootstrap may not be consistent when the asymptotic distribution is degenerate normal; for example, see Benkwitz et al. (2000).

It is evident that assumptions B1-B4 of Romano and Wolf (2010, p. 607) are satisfied if the asymptotic distribution of $\widehat{\boldsymbol{\Theta}}_{i j, H}$ is non-degenerate normal, which is the case if $\Sigma_{\widehat{\Theta}}$ is positive definite. Thus, the asymptotic properties of $\mathrm{CB}_{\mathrm{BB}, i j}^{(1-\alpha)}$ can then deduced from Theorem 3.1 of Romano and Wolf (2010). More specifically, it holds that

$$
\begin{equation*}
\lim _{T \rightarrow \infty} \mathbb{P}\left(\Theta_{i j, H} \in \mathrm{CB}_{\mathrm{BB}, i j}^{(1-\alpha)}\right)=(1-\alpha) \tag{10}
\end{equation*}
$$

if $\Sigma_{\widehat{\Theta}}$ is positive definite. Furthermore, let $\mathrm{CB}_{\mathrm{BB}, i j, h}^{(1-\alpha)}$ denote the $h$-th marginal confidence interval for $\Theta_{i j, h}$, then it holds that

$$
\begin{equation*}
\lim _{T \rightarrow \infty} \mathbb{P}\left(\boldsymbol{\Theta}_{i j, h} \in \mathrm{CB}_{\mathrm{BB}, i j, h}^{(1-\alpha)}\right)=\rho \in(0,1) \quad \forall h \in\{0, \ldots, H\} \tag{11}
\end{equation*}
$$

if $\Sigma_{\widehat{\Theta}}$ is positive definite. Summarizing, under the condition of a positive definite covariance matrix $\Sigma_{\widehat{\Theta}}$, the BB joint confidence bands have asymptotically the correct coverage rate and are asymptotically balanced in the sense that coverage rate of the marginal intervals $\mathrm{CB}_{\mathrm{BB}, i j, h}^{(1-\alpha)}$ are asymptotically independent of $h \in\{0, \ldots, H\}$.

Data generating processes that give rise to a singular asymptotic covariance matrix $\Sigma_{\widehat{\Theta}}$ are included in the Monte Carlo experiment in Section 5 to gain some simulation-based insights about the properties of the BB bands in scenarios with an asymptotic degenerate normal distribution.

Remark 3.2. The traditional Bonferroni bands and the size-adjusted Bonferroni bands of Lütkepohl et al. (2015a) have a similar handicap: These joint confidence bands are also only proven to work if the bootstrap is consistent for all marginal distributions $\sqrt{T}\left(\widehat{\Theta}_{i j, h}-\Theta_{i j, h}\right)$, which is the case if $\sqrt{T}\left(\widehat{\Theta}_{i j, h}-\Theta_{i j, h}\right)$ converges to a non-degenerate normal distribution for all $h \in\{0, \ldots, H\}$; for more details, see Lütkepohl et al. (2015b, p. 9).

The simultaneous test of $H_{0, h}: \Theta_{i j, h}=0, h \in\{0, \ldots, H\}$, is of great interest in applied work. Such a test can be carried out by 'inverting' the joint confidence bands for $\boldsymbol{\Theta}_{i j, H}$. In particular, any $H_{0, h}$ is rejected for which zero is not contained the in marginal confidence interval $\mathrm{CB}_{\mathrm{BB}, i j, h}^{(1-\alpha)}$. It follows from Corollary 3.1 of Romano and Wolf (2010) that such a testing procedure asymptotically controls the probability of falsely rejecting at least one true hypothesis $H_{0, h}$, that is,

$$
\begin{equation*}
\lim _{T \rightarrow \infty} \mathbb{P}\left(\text { reject at least one true hypothesis } H_{0, h}\right) \leq \alpha \tag{12}
\end{equation*}
$$

at least as long as $\Sigma_{\widehat{\Theta}}$ is positive definite. In other words, for all $h \in\{0, \ldots, H\}$ for which zero is not contained in the corresponding marginal confidence interval, one can be jointly confident that the true impulse response $\Theta_{i j, h}$ is non-zero; that is, the confidence holds jointly jointly for all such $h$ and not just individually (for a given such $h$ ).

## 4 Competing Methods

In order to assess the finite-sample performance of our proposed method, we compare its finitesample properties with those of relevant competing methods in the literature. More specifically, the list of the competing bands consists of the Naïve bands, the traditional Bonferroni bands, and the recently proposed Wald and Adjusted-Wald bands of Lütkepohl et al. (2015b). In the following, each of the four competing methods is briefly outlined; more details are found in the corresponding references.

### 4.1 Naïve Confidence Bands

The Naïve confidence bands for $\boldsymbol{\Theta}_{i j, H}$, as defined in Lütkepohl et al. (2015a), are given by the collection of the $(H+1)$ marginal confidence intervals with individual confidence level $(1-\alpha)$, that is,

$$
\begin{equation*}
\mathrm{CB}_{\text {Naïve }, i j}^{(1-\alpha)}:=\left[q_{0, \frac{\alpha}{2}}^{*, i j}, q_{0,\left(1-\frac{\alpha}{2}\right)}^{*, i j}\right] \times \cdots \times\left[q_{H, \frac{\alpha}{2}}^{*, i j}, q_{H,\left(1-\frac{\alpha}{2}\right)}^{*, i j}\right], \tag{13}
\end{equation*}
$$

where $q_{h, \frac{\alpha}{2}}^{*, i j}$ and $q_{h,\left(1-\frac{\alpha}{2}\right)}^{*, i j}$ denote the $\frac{\alpha}{2}$ and $1-\frac{\alpha}{2}$ quantiles of the bootstrap distribution of the estimated impulse response coefficient at horizon $h \in\{0, \ldots, H\}$.

### 4.2 Bonferroni Joint Confidence Bands

The Bonferroni joint confidence bands for $\boldsymbol{\Theta}_{i j, H}$ consist of the Cartesian product of $(H+1)$ marginal confidence intervals for the individual responses $\Theta_{h, i j}, h \in\{0, \ldots, H\}$, where the nominal confidence level of the marginal intervals is adjusted via Bonferroni's inequality in order to ensure that the joint coverage probability is, asymptotically, at least $1-\alpha$. (Of course, this can only be guaranteed if the underlying bootstrap method is consistent.) More specifically, the adjusted marginal nominal confidence level is equal to $(1-\beta)$ where $\beta:=\alpha /(H+1) .{ }^{5}$ The rectangular Bonferroni joint confidence bands for $\boldsymbol{\Theta}_{i j, H}$, as defined in Lütkepohl et al. (2015a), are given by

$$
\begin{equation*}
\mathrm{CB}_{\mathrm{B}, i j}^{(1-\alpha)}:=\left[q_{0, \frac{B}{2}}^{*, i j}, q_{0,\left(1-\frac{\beta}{2}\right)}^{*, i j}\right] \times \cdots \times\left[q_{H, \beta}^{*, i j}, q_{H,(1-\beta)}^{*, i j}\right], \tag{14}
\end{equation*}
$$

where $q_{h, \frac{\beta}{2}}^{* i j}$ and $q_{h,\left(1-\frac{\beta}{2}\right)}^{*, i j}$ denote the $\frac{\beta}{2}$ and $1-\frac{\beta}{2}$ quantiles of the bootstrap distribution of the estimated impulse response coefficient at horizon $h \in\{0, \ldots, H\}$.

### 4.3 Wald and Adjusted-Wald Joint Confidence Bands

The Wald joint confidence bands for $\boldsymbol{\Theta}_{i j}(H)$ of Lütkepohl et al. (2015b) are constructed in a two-step fashion. First, the bootstrap Wald test for the relevant reduced-form parameters of the underlying VAR is inverted to obtain a joint confidence ellipse. Second, the ellipse is

[^4]projected onto the axes of the impulse response space, resulting in rectangular joint confidence bands for $\boldsymbol{\Theta}_{i j}(H)$.

More specifically, the Wald joint confidence ellipse for the relevant reduced-form coefficients, denoted by $\theta$, with a nominal confidence level of $(1-\alpha)$ is given by

$$
\mathcal{W}_{(1-\alpha)}^{\theta}=\left\{\theta: T(\hat{\theta}-\theta)^{\prime}\left(\widehat{\Sigma}_{\theta}\right)^{-1}(\hat{\theta}-\theta) \leq w_{(1-\alpha)}^{*}\right\}
$$

where $\hat{\theta}$ denotes a consistent estimator for $\theta, \widehat{\Sigma}_{\theta}$ denotes a consistent estimator of the asymptotic variance of $\hat{\theta}$, and $w_{(1-\alpha)}^{*}$ denotes the $(1-\alpha)$ quantile of the bootstrap distribution of the Wald statistic. ${ }^{6}$ The bootstrap impulse responses are ordered according to the set of increasing bootstrap Wald statistics $\left\{w_{1}^{*} \leq \cdots \leq w_{B}^{*}\right\}$ in the sense that $\widehat{\boldsymbol{\Theta}}_{i j, H, n}^{*}$ corresponds to $w_{n}^{*}$. Finally, the rectangular Wald joint confidence bands for $\boldsymbol{\Theta}_{i j}(H)$ with nominal confidence level $(1-\alpha)$ are given as the envelope of the ordered set of bootstrap impulse response functions $\left\{\widehat{\boldsymbol{\Theta}}_{i j, H, 1}^{*}, \ldots, \widehat{\boldsymbol{\Theta}}_{i j, H,(1-\alpha) \times B}^{*}\right\}$, that is,

$$
\begin{equation*}
\mathrm{CB}_{\mathrm{Wald}, i j}^{(1-\alpha)}:=\left[l_{i j, 0}^{*}, u_{i j, 0}^{*}\right] \times \cdots \times\left[l_{i j, H}^{*}, u_{i j, H}^{*}\right], \tag{15}
\end{equation*}
$$

where $l_{i j, s}^{*}:=\min \left\{\widehat{\Theta}_{i j, b, n}^{*}: n=1, \ldots,(1-\alpha) \times B\right\}$, and $u_{i j, s}^{*}$ is defined as the corresponding upper bound; we assume here tacitly that $(1-\alpha) \times B$ is an integer, otherwise take the next largest integer.

Lütkepohl et al. (2015b) point out that the Wald bands are conservative by construction, and hence usually cover more than $(1-\alpha) \times B$ of the bootstrap impulse response functions. Thus, a volume adjustment of the Wald bands can be considered and Lütkepohl et al. (2015b) propose the following iterative adjustment: ${ }^{7}$ Remove iteratively the last element in the set of ordered bootstrap impulse responses until the bootstrap coverage of the envelope of the remaining functions is as close as possible to $(1-\alpha)$ while at least $(1-\alpha)$. The resulting rectangular Adjusted-Wald joint confidence bands for $\boldsymbol{\Theta}_{i j}(H)$ with a nominal confidence level $(1-\alpha)$ are given as the envelope of the remaining bootstrap impulse responses, that is,

$$
\begin{equation*}
\mathrm{CB}_{\mathrm{Adj}-\mathrm{W}, i j}^{(1-\alpha)}:=\left[\tilde{l}_{i j, 0}^{*}, \tilde{u}_{i j, 0}^{*}\right] \times \cdots \times\left[\tilde{l}_{i j, H}^{*}, \tilde{u}_{i j, H}^{*}\right], \tag{16}
\end{equation*}
$$

where $\tilde{l}_{i j, h}^{*}:=\min \left\{\widehat{\Theta}_{i j, b, h}^{*}: b=1, \ldots, \tilde{B}\right\}$, where $\tilde{B}$ denotes index of the first bootstrap impulse response that is not removed, and $\tilde{u}_{i j, H}^{*}$ is defined as the corresponding upper bound.

[^5]
## 5 Monte Carlo Simulation

### 5.1 Lag Selection and Estimation of Impulse Responses

The lag order is selected using the Akaike information criterion (AIC), as Kilian (2001) provides simulation evidence that confidence intervals (for individual responses) based on the AIC exhibit superior finite-sample coverage properties compared to confidence intervals based on the Schwarz Information Criterion and the Hannan-Quinn Criterion. The maximum lag order pmax is determined endogenously using the rule of thumb proposed in Schwert (1989). According to this rule, the maximum lag order is given by

$$
p_{\max }:=\left\lfloor 12(T / 100)^{0.25}\right\rfloor
$$

where $\lfloor\cdot\rfloor$ denotes the integer part of a real number and $T$ denotes the sample size. Thus, the maximum lag order is given by 12,14 , and 16 for sample sizes of 100,200 , and 400 , respectively. In the following, $\hat{p}$ denotes the lag order selected by the AIC, that is, $\hat{p}:=\hat{p}_{A I C}$.

We estimate the reduced-form coefficients $\left(\nu, A_{1}, \ldots, A_{\hat{p}}\right)$ of the VAR model by least squares; see Lütkepohl (2005, Section 3.2) for more details. It is well known that the LS estimator is biased in finite samples due to the presence of lagged endogenous variables. Thus, we correct for the finite-sample bias using the closed-form bias estimator of Pope (1990); see Appendix A for details. The corresponding bias-corrected estimators of the slope coefficients are given by

$$
\hat{A}_{i}^{\mathrm{BC}}:=\hat{A}_{\mathrm{LS}, i}-\widehat{\operatorname{Bias}}\left(\hat{A}_{\mathrm{LS}, i}\right), \quad \text { for } i=1, \ldots, \hat{p},
$$

where $\hat{A}_{\mathrm{LS}, i}$ denotes the LS estimator of $A_{i}$ and $\widehat{\operatorname{Bias}}\left(\hat{A}_{\mathrm{LS}, i}\right)$ denotes Pope's corresponding bias estimator. Furthermore, in scenarios where the bias correction causes nonstationarity that is, where the process corresponding to $\left(\nu, \hat{A}_{\mathrm{LS}, 1}, \ldots, \hat{A}_{\mathrm{LS}, \hat{p}}\right)$ is stationary but the process corresponding to $\left(\nu^{\mathrm{BC}}, \hat{A}_{1}^{\mathrm{BC}}, \ldots, \hat{A}_{\hat{p}}^{\mathrm{BC}}\right)$ is non-stationary - the stationarity correction of Kilian (1998b) is applied instead; see Appendix B for details.

We assume a recursive structure of the structural VAR model, that is, the impact matrix $B_{0}$ is given by the lower-triangular Cholesky decomposition of $\Sigma_{u}$. The corresponding estimator is naturally given by

$$
\widehat{B}_{0}:=\operatorname{chol}\left(\widehat{\Sigma}_{u}^{\mathrm{BC}}\right)
$$

where $\widehat{\Sigma}_{u}^{B C}$ denotes the estimated residual covariance matrix based on the bias-corrected VAR coefficient estimators. Summarizing, the estimated structural impulse response functions $\widehat{\boldsymbol{\Theta}}_{i j, H}$ are obtained as

$$
\begin{equation*}
\widehat{\boldsymbol{\Theta}}_{i j, H}:=\boldsymbol{\Theta}_{i j, H}\left(\hat{A}_{1}^{\mathrm{BC}}, \ldots, \hat{A}_{\hat{p}}^{\mathrm{BC}}, \operatorname{chol}\left(\widehat{\Sigma}_{u}^{\mathrm{BC}}\right)\right) . \tag{17}
\end{equation*}
$$

### 5.2 Bootstrap Details

The bootstrap distribution of the estimator of the structural impulse response functions is generated by the following nonparametric bootstrap procedure of Kilian (1998b):
a) Given $\left\{y_{t}\right\}_{t=1}^{T}, \hat{p},\left(\hat{\nu}_{\mathrm{BC}}, \hat{A}_{1}^{\mathrm{BC}}, \ldots, \hat{A}_{\hat{p}}^{\mathrm{BC}}\right)$ and the corresponding series of residuals $\left\{\hat{u}_{t}\right\}_{t=\hat{p}+1}^{T}$, generate a bootstrap sample $\left\{y_{1}^{*}, \ldots, y_{T}^{*}\right\}$ via the following recursion

$$
y_{t}^{*}=\left\{\begin{array}{ll}
y_{t}, & t=1, \ldots, \hat{p}  \tag{18}\\
\hat{\nu}^{\mathrm{BC}}+\hat{A}_{1}^{\mathrm{BC}} y_{t-1}^{*}+\ldots+\hat{A}_{\hat{p}}^{\mathrm{BC}} y_{t-\hat{p}}^{*}+e_{t}^{*}, & t=\hat{p}+1, \ldots, T
\end{array},\right.
$$

where $e_{t}^{*}$ is a random draw with replacement from the empirical distribution of the residuals that are rescaled and centered to have mean zero ${ }^{8}$.
b) Obtain $\left(\hat{A}_{1}^{*, B C}, \ldots, \hat{A}_{\hat{p}}^{*, \mathrm{BC}}\right)$ and $\widehat{\Sigma}_{u}^{*, \mathrm{BC}}$ by fitting a $\operatorname{VAR}(\hat{p})$ model to $\left\{y_{t}^{*}\right\}_{t=1}^{T}$.
c) Obtain $\widehat{\boldsymbol{\Theta}}_{i j, H}^{*}=\boldsymbol{\Theta}_{i j, H}\left(\hat{A}_{1}^{*, \mathrm{BC}}, \ldots, \hat{A}_{\hat{p}}^{*, \mathrm{BC}}, \operatorname{chol}\left(\widehat{\Sigma}_{u}^{*, \mathrm{BC}}\right)\right)$.
d) Repeat steps a) to c) $B$ times resulting in the bootstrap sample $\left\{\widehat{\boldsymbol{\Theta}}_{i j, H, b}^{*}\right\}_{b=1}^{B}$.

The previously outlined bootstrap algorithm is subsequently referred to as the exogenous bootstrap because the lag order is not re-estimated based on the bootstrap sample $\left\{y_{1}^{*}, \ldots, y_{T}^{*}\right\}$.

The Wald-type joint confidence bands of Lütkepohl et al. (2015b) bands can only be constructed using the exogenous bootstrap because the computation of the bootstrap Wald statistic requires that the vector of the estimator of the slope coefficients ( $\left.\hat{A}_{1}, \ldots, \hat{A}_{\hat{p}}\right)$ and the bootstrap analogues $\left(\hat{A}_{1}^{*}, \ldots, \hat{A}_{\hat{p}^{*}}^{*}\right)$ have the same dimension and hence the same lag order, that is, $\hat{p}=\hat{p}^{*}$. Therefore, a fair comparison of the finite-sample performance of the BB bands with the competing methods should be based on the exogenous bootstrap.

Remark 5.1. The exogenous bootstrap algorithm differs from the original algorithm in Kilian (1998b) in one minor aspect. The LS parameter estimates of the reduced-form coefficients are corrected for their finite-sample bias using the closed-form bias formula of Pope (1990) instead of a bootstrap-based bias correction as in Kilian (1998b). This modification can be justified, on the one hand, since both procedures remove only the first-order bias and, on the other hand, since both procedure exhibit a similar finite-sample performance, as is shown in the Monte Carlo study by Engsted and Pedersen (2014).

Kilian (1998a) provides simulation-based evidence that endogenizing the lag order selection in the bootstrap procedure results in an improved coverage accuracy of marginal bootstrap intervals for impulse responses of structural vector autoregressions. In order to investigate whether a similar effect can be observed for joint confidence bands, the BB bands, the Naïve bands, and the Bonferroni bands will be additionally constructed based on the endogenous bootstrap procedure of Kilian (1998a).

Remark 5.2. There are recent bootstrap procedures - such as the linear process bootstrap of Jentsch and Kreiss (2010), the sieve bootstrap of Meyer and Kreiss (2015), and the hybrid bootstrap of Jentsch and Politis (2015) - that can be applied in the present context to

[^6]generate the bootstrap data $\left\{y_{1}^{*}, \ldots, y_{T}^{*}\right\}$. However, an in-depth analysis of the effect of employing different bootstrap procedures on the finite-sample performances of confidence bands for structural impulse response functions is beyond the scope of this paper.

### 5.3 Data Generating Processes

### 5.3.1 Bivariate VAR(1) Models

We first consider the bivariate data generating processes from Kilian (1998b), which were previously considered in Lütkepohl et al. (2015a) and Lütkepohl et al. (2015b) in the context of joint confidence bands for structural impulse response functions, that is,

$$
\text { DGP-1 } \quad y_{t}=\left(\begin{array}{cc}
\rho & 0.0  \tag{19}\\
0.5 & 0.5
\end{array}\right) y_{t-1}+u_{t}
$$

with $\rho \in\{0.95,0.9,0.5,0,-0.5,-0.9,-0.95\}$. The specific variants of DGP- 1 will be denoted by DGP-1i, $i \in\{a, \ldots, g\}$, depending on the specific value of $\rho$. The characteristic roots of the processes are presented in Table 1.

| DGP | Roots |
| :---: | :---: |
| 1 a | $(2.000,1.053)$ |
| 1 b | $(2.000,1.111)$ |
| 1 c | $(2.000,2.000)$ |
| 1 d | $(2.000)$ |
| 1 e | $(2.000,-2.000)$ |
| 1 f | $(2.000,-1.111)$ |
| 1 g | $(2.000,-1.053)$ |

Table 1: Characteristic roots of the various variants of DGP-1.
Some properties of DGP-1 are worth mentioning: First, all processes are stationary but some are persistent (DGP-1a, DGP-1g). Second, independently of $\rho$, the true response of the first variable to a shock in the second variable is zero at all propagation horizons, that is $\boldsymbol{\Theta}_{12, H}=0 \in \mathbb{R}^{H+1}$, and hence the asymptotic distribution of the estimator is degenerate normal as noted in Benkwitz et al. (2000). Third, for $\rho=0$ (DGP-1d), the true response of the first variable to a shock in the first variable is also zero at all propagation horizons, that is, $\boldsymbol{\Theta}_{11, H}=0$, and hence the estimator is also asymptotically degenerate normal.

Furthermore, we use $u_{t} \stackrel{i . i . d}{\sim} \mathcal{N}\left(0, \Sigma_{u}^{1}\right)$, where the population covariance matrix is given by

$$
\Sigma_{u}^{1}=\left(\begin{array}{ll}
1.00 & 0.30 \\
0.30 & 1.00
\end{array}\right)
$$

In the Monte Carlo simulation, data samples of length $T \in\{100,400\}$ are generated for each variant of DGP-1 and the propagation horizon is $H \in\{10,20\}$; Lütkepohl et al. (2015a,b) use the same choices of $T$ and $H$.

### 5.3.2 Trivariate VAR(4) Model

DGP-2 is a trivariate VAR(4) model previously considered in Staszewska-Bystrova (2011). More specifically, the population parameters of DGP-2 are the estimates of a model of the inflation rate, the unemployment rate, and the federal fund rate using US quarterly data from 1960-Q1 through 2004-Q1; for more details about the data set, see Stock and Watson (2001) or Staszewska-Bystrova (2011). The DGP is given by

$$
\begin{equation*}
\text { DGP-2 } \quad y_{t}=\nu+A_{1} y_{t-1}+A_{2} y_{t-2}+A_{3} y_{t-3}+A_{4} y_{t-4}+u_{t} \tag{20}
\end{equation*}
$$

where

$$
\begin{aligned}
A_{1} & :=\left(\begin{array}{ccc}
0.549 & -0.965 & 0.164 \\
0.029 & 1.480 & 0.003 \\
0.084 & -1.567 & 0.962
\end{array}\right), \quad A_{2}:=\left(\begin{array}{ccc}
0.118 & 1.506 & -0.128 \\
-0.013 & -0.494 & 0.043 \\
0.197 & 1.763 & -0.364
\end{array}\right) \\
A_{3} & :=\left(\begin{array}{ccc}
0.060 & -0.954 & 0.054 \\
0.002 & -0.029 & -0.024 \\
-0.070 & -0.848 & 0.333
\end{array}\right), \quad A_{4}:=\left(\begin{array}{ccc}
0.261 & 0.250 & -0.098 \\
-0.012 & -0.014 & 0.008 \\
-0.046 & 0.563 & -0.010
\end{array}\right)
\end{aligned}
$$

and $\nu:=(1.076,0.125,0.347)^{\prime}$. Furthermore, we use $u_{t} \stackrel{i . i . d .}{\sim} \mathcal{N}\left(0, \Sigma_{u}^{2}\right)$, where the population covariance matrix of DGP-2 is the covariance estimate based on the same data as the intercept and the slope coefficients and is given by

$$
\Sigma_{u}^{2}:=\left(\begin{array}{ccc}
0.962 & -0.018 & 0.116 \\
-0.018 & 0.049 & -0.087 \\
0.116 & -0.087 & 0.693
\end{array}\right)
$$

In the Monte Carlo study, data samples of length $T \in\{100,200,400\}$ are generated and the maximum propagation horizon is $H \in\{4,8,12,16,20,24,28\}$. The choices of $H$ reflect the fact that DGP-2 is an empirical DGP based on quarterly data and hence the considered values of the maximum propagation horizon $H$ correspond to impulse responses over one up to seven years.

### 5.4 Simulation Parameters and Performance Evaluation

The nominal confidence level of the various joint confidence bands is $90 \%$. The number of bootstrap replications is $B=2000$ throughout and the number of Monte Carlo replications is also 2000. The finite-sample performance of the various bands is evaluated via the empirical
volume and the empirical coverage rate. More specifically, the empirical coverage rate is calculated in the usual way, that is,

$$
E C:=\frac{1}{2000} \sum_{m=1}^{2000} \mathbb{1}_{\left\{\boldsymbol{\Theta}_{i j, H} \in \mathrm{CB}_{m, i j}\right\}},
$$

where $\mathrm{CB}_{m, i j}$ denotes particular joint confidence bands for $\boldsymbol{\Theta}_{i j, H}$ and $\mathbb{1}_{\{A\}}$ denotes the indicator function of an event $A$. The empirical volume of particular joint confidence bands for $\boldsymbol{\Theta}_{i j, H}$ is computed as the average of the sum of the lengths of the corresponding marginal intervals, that is,

$$
V:=\frac{1}{2000} \sum_{m=1}^{2000} \sum_{h=0}^{H}\left(u_{m, h}-l_{m, h}\right)
$$

where $u_{m, h}$ denotes the upper bound of the $h$-th marginal interval of the bands in the $m$-th Monte Carlo repetition and $l m, h$ denotes the corresponding lower bound.

### 5.5 Results

### 5.5.1 DGP-1: Bivariate VAR(1) Models

The tables with the simulation results are relegated to the Supplementary Material for the sake of clarity. Boxplots summarizing the performance of the various methods across different scenarios are found in Appendices D and E. The focus is on the finite-sample performance of the BB bands because the performance of the competing methods have already been investigated individually for this specific DGP in Lütkepohl et al. (2015a,b). The main conclusions are as follows:

- For $T=100$ and $H=10$, the BB bands exhibit coverages rates close to or mildly below the nominal level of $90 \%$ except in the scenarios where the asymptotic distribution of the estimator of the impulse response function is degenerate normal (that is, joint confidence bands for $\Theta_{1,1}$ of DGP-1d and $\Theta_{1,2}$ of all processes) and the scenario where joint confidence bands are constructed for $\Theta_{1,1}$ of DGP-1g. The bands of the former scenarios exhibit coverage rates above the nominal level, whereas the bands for the latter scenario exhibit substantial undercoverage. Furthermore, the BB bands are robust with respect to the propagation horizon. Overall, the coverage bias of the BB bands is substantially reduced for the large sample size of $T=400$; see Figures D. 1 and D.2.
- In general, the coverage bias of the BB bands is comparable to the Adjusted-Wald bands, but smaller than the coverage bias of the Naïve bands, the Bonferroni bands, and the Wald bands.
- In all scenarios, the BB bands are smaller than the Bonferroni bands, where the excess volume (vis-à-vis the volume of the BB bands) of the Bonferroni bands ranges from $0.7 \%$
to $55 \%$. Overall, the excess volume tends to increase with the sample size $T$ and the maximum propagation horizon $H$. However, there does not seem to be a clear pattern between the stationary characteristics of the processes and the excess volume of the Bonferroni bands.
- In 108 out of the 112 scenarios, the BB bands exhibit a smaller volume than the conservative Wald bands. In these scenarios, the volume of the Wald bands is substantially larger and the excess volume (vis-à-vis the volume of the BB bands) ranges from $24.5 \%$ to $82.9 \%$. Furthermore, the excess volume decreases with the maximum propagation horizon $H$ and the sample size $T$ in almost all scenarios.
- In 98 out of the 112 scenarios, the volume of the Adjusted-Wald bands is smaller than the volume of the BB bands. However, the difference is usually small. As expected, the BB bands are larger than the Naïve bands which completely ignore the inherent simultaneity in the construction of the bands.

### 5.5.2 DGP-2: Trivariate VAR(4) Model

The complexity of DGP-2 is substantially larger compared to the bivariate $\operatorname{VAR}(1)$ models of DGP-1. The true impulse response functions of DGP-2 depend on 42 population reduced-from coefficients (compared to 7 population coefficients in DGP-1). Thus, the results for $T=100$ give some indication about the performance of the joint confidence bands in scenarios where the ratio of the sample size to the number of coefficients is small (that is, low degrees of freedom). ${ }^{9}$ The tables with the simulation results are relegated to the Supplementary Material. Boxplots summarizing the performance of the various methods across different scenarios are found in Appendices F and G. The main conclusions are as follows:

- For $T=100$, there are systematic differences in the coverage rates of the BB bands, that is the bands for $\Theta_{1,1}, \Theta_{1,3}, \Theta_{3,3}$ perform worse than the bands for the other impulse responses; see Figure H.1. More specifically, the bands for $\Theta_{1,1}, \Theta_{1,3}, \Theta_{3,3}$ exhibit substantial undercoverage whereas the bands for the remaining impulse responses exhibit only mild under- and overcoverage even for large $H$. Overall, the coverage distortion as well as the variation in coverage rates are substantially reduced for a sample size of $T=200$, except the coverage rates of the bands for $\Theta_{1,1}$ which are still seriously below $90 \%$. For $T=400$, the coverage rates of the BB bands are consistently close to the nominal coverage of $90 \%$, even for large $H$; see Figure H.2.
- In principle, the BB bands are smaller than the two conservative bands (Bonferroni and Wald) and larger than the Naïve bands. Interestingly, the BB bands are even smaller than the Adjusted-Wald bands in 172 out of 189 scenarios. In general, the volume of the BB bands is strictly decreasing in the sample size, but strictly increasing in the propagation horizon.

[^7]- For $T=100$, there are systematic differences in the coverage rates of the Bonferroni bands. The Bonferroni bands for $\Theta_{1,1}, \Theta_{1,3}, \Theta_{3,3}$ exhibit massive to substantial undercoverage in some scenarios, whereas the bands for the other impulse responses exhibit only mild under- and overcoverage. For a larger sample size of $T=200$, the coverage rates are close or above the nominal level of $90 \%$ except the coverage rates of the bands for $\Theta_{1,1}$, which are still seriously below $90 \%$. For $T=400$, all coverage rates are above the nominal level.
- The coverage rates of the Wald bands are markedly above the nominal level of $90 \%$ in 173 out of 189 scenarios. Overall, the positive coverage bias is enhanced with the sample size; see Figures H. 1 and H.2. In all scenarios, the Wald bands exhibit the largest volume and are substantially larger than the Bonferroni bands.
- For $T=100$, the Adjusted-Wald bands exhibit coverage rates that are substantially distorted and systematically differ among the different impulse response functions; see Figure H.1. Nevertheless, the coverage distortions and the systematic variation in coverage rates are mitigated as the sample size increases; see Figure H.2.
- The Naïve bands massively under-represent the joint estimation uncertainty in all scenarios. The empirical coverage rate falls below $40 \%$ in some scenarios with $T=100$. Thus, these results provide additional evidence that the Naïve bands should not be used in practice, at least not when joint confidence bands are desired.

### 5.5.3 Exogenous vs. Endogenous Bootstrap

The tables with the simulation results for the Naïve bands, the Bonferroni bands, and the BB bands based on the endogenous bootstrap are found in the Supplementary Material. The main conclusions are as follows:

- The simulation results for the the bivariate $\operatorname{VAR}(1)$ models show that endogenizing the lag uncertainty in general results in an upward shift of the coverage rates of the BB bands for both $T=100$ and $T=400$; see Figure H.3. The effect on the coverage rates of endogenizing the lag uncertainty is ambiguous as there are scenarios where the coverage bias is reduced (for example, bands for $\Theta_{1,1}$ of DGP-1g), but also scenarios where the opposite is true (for example, bands for $\Theta_{1,1}$ of DGP-1e). However, the BB bands based on the endogenous bootstrap are larger than the BB bands based on the exogenous bootstrap.
- The results for the trivariate $\operatorname{VAR}(4)$ model show that the coverage rates of the BB bands based on the endogenous bootstrap are surprisingly inferior to those of the $B B$ bands based on exogenous bootstrap for $T=100$; see Figure H.4. For $T=200,400$, there are scenarios where the BB bands based on the endogenous bootstrap are superior, but in the majority of the scenarios, the bands based on the exogenous bootstrap are superior. For $T=100$, endogenizing the lag uncertainty results in bands that are smaller than
the bands based on the exogenous bootstrap. The same is true for the majority of the scenarios with $T=200,400$, although the differences are decreasing in the sample size.
- The results for the the bivariate $\operatorname{VAR}(1)$ models show that the coverage rates of the Bonferroni bands based on the endogenous bootstrap are larger than those of the Bonferroni bands based on the exogenous bootstrap in the majority of the scenarios, although the differences tend to decrease with the sample size. Hence, endogenizing the lag uncertainty increases the coverage bias of the Bonferroni bands, as the Bonferroni bands based on the exogenous bands exhibit coverage rates above the nominal level.
- The simulation results for the trivariate $\operatorname{VAR}(4)$ model show that the effect of endogenizing the lag uncertainty on the Bonferroni bands is ambiguous (for all sample sizes); there are scenarios where the bands based on the endogenous are superior but also scenarios where the opposite is true. The Bonferroni bands based on the endogenous bootstrap are smaller than the Bonferroni bands based on the exogenous bootstrap in almost all scenarios.

### 5.6 Summary of Simulation Evidence

We have conducted a Monte Carlo simulation to compare the finite-sample properties of the BB bands with a number of competing methods. We have included several bivariate VAR(1) models and an empirical trivariate VAR(4) model in the set of data generating processes.

The simulation results of the bivariate VAR(1) models show that the BB bands and the Adjusted-Wald bands exhibit both a smaller coverage bias and a smaller volume than the Bonferroni and the Wald bands. Both methods are robust with respect to the maximum propagation horizon and also produce reasonable joint confidence bands when the true impulse response is zero, and hence the asymptotic distribution of the estimator is degenerate.

The simulation results of the trivariate VAR(4) model show that the coverage rates of the BB bands, the Bonferroni bands, and the Adjusted-Wald bands are potentially downward biased in low-degrees-of-freedom scenarios. In such scenarios, the Wald bands may be preferred to avoid the use of bands that underestimate the estimation uncertainty, but the price to pay is the large volume of the Wald bands, especially for large maximum propagation horizons. For $T=400$, the BB bands exhibit the smallest coverage bias and at the same time the smallest volume among all joint confidence bands (except the Naïve bands).

Overall, both the Adjusted-Wald bands and the BB bands work reliably in small models. However, the simulation results of the trivariate $\operatorname{VAR}(4)$ model show that the BB bands generally outperform the Adjusted-Wald bands in more complex models.

Endogenizing the lag uncertainty reduces the coverage bias of the BB bands only in particular scenarios. However, in the majority of the scenarios, the BB bands based on the exogenous bootstrap are superior in that regard. The effect on the volume is ambiguous and depends on the data generating process; the same holds for the Bonferroni bands. Based on these findings,
we do not promote the endogenous bootstrap.
Furthermore, the results of the trivariate $\operatorname{VAR}(4)$ model confirm two of the main empirical findings in Lütkepohl et al. (2015b). First, the Wald bands tend to exhibit a larger volume than the Bonferroni bands. Second, the volume-adjustment of the Wald bands can result in coverage rates markedly below the nominal level in low-degrees-of-freedom scenarios.

## 6 Empirical Application

We illustrate the BB joint confidence bands and the competing methods using the structural VAR model of Kilian (2009). The three-dimensional VAR model of Kilian includes the following three variables:

- $\Delta$ prod $_{t}$ : the percentage change in global crude oil production
- realt: a business cycle index of global real activity (expressed in logs)
- $r p o_{t}$ : the real price of oil (expressed in logs)

The monthly data set from 1973-01 through 2007-12 is downloaded from the homepage of the American Economic Review. ${ }^{10}$ We estimate the parameters of the reduced-form $\operatorname{VAR}(3)$ model (as suggested by the AIC) by the same methodology as in the Monte Carlo simulation. Following Kilian (2009), we use a recursive identification scheme where $B_{0}$ is the lower-triangular Cholesky decomposition of the reduced-form residual covariance matrix and the maximum propagation horizon is $H=18$. The $90 \%$ joint confidence bands are constructed based on the bootstrap procedure of Kilian (1998b) with $B=2000$ replications.

|  | BB | Bon | Wald | A-Wald | Naïve |
| :---: | :---: | :---: | :---: | :---: | :---: |
| $\Theta_{11}$ | 31.77 | 35.69 | 42.63 | 34.50 | 20.25 |
| $\Theta_{21}$ | 23.06 | 27.77 | 33.72 | 24.09 | 16.24 |
| $\Theta_{31}$ | 21.25 | 25.27 | 32.03 | 21.82 | 14.48 |
| $\Theta_{12}$ | 41.73 | 54.35 | 62.56 | 44.54 | 31.99 |
| $\Theta_{22}$ | 59.99 | 73.66 | 94.45 | 64.41 | 44.67 |
| $\Theta_{32}$ | 45.72 | 62.34 | 75.75 | 44.79 | 34.25 |
| $\Theta_{13}$ | 65.61 | 88.09 | 107.61 | 65.31 | 51.12 |
| $\Theta_{23}$ | 89.19 | 114.63 | 128.32 | 95.58 | 67.83 |
| $\Theta_{33}$ | 85.05 | 115.42 | 133.36 | 87.68 | 64.98 |

Table 2: Volume of joint confidence bands for $H=18$.
Table 2 presents the volumes of the $90 \%$ joint confidence bands of all impulse responses with a maximum propagation horizon of $H=18$. The Wald and the Bonferroni bands exhibit the largest volumes in all scenarios. The BB bands have the smallest volume (of the proper

[^8]joint confidence bands) in seven out of nine scenarios. These findings are completely in line with the simulation-based findings about the volumes of the various joint confidence bands.

Figure 1 displays the estimated structural response of $\Delta p r o d_{t}$ to a one-standard-deviation shock in $\varepsilon_{t, 2}$ over a maximum propagation horizon of $H=18$ (that is, $\widehat{\boldsymbol{\Theta}}_{12,18}$ ) and the corresponding nominal $90 \%$ joint confidence bands. ${ }^{11}$. The figure illustrates the different shapes

Figure 1: Estimated impulse response of $\Delta p r o d_{t}$ to a one-standard-deviation shock in $\varepsilon_{t, 2}$ over a maximum propagation horizon of $H=18$ (solid line) and the corresponding nominal $90 \%$ joint confidence bands.
and volumes of the joint confidence bands. Inference based on the BB bands results in rejecting the null hypothesis of a zero response for propagation horizons $h=4-18$ (as the marginal intervals do not cover zero). Inverting the other confidence bands results in different conclusions about the simultaneous test of the $H+1$ hypotheses. More specifically, inference based on the Bonferroni bands results in rejecting the null hypothesis of a zero response for only two

[^9]propagation horizons ( $h=3,4$ ), inference based the Wald bands results in accepting the null hypothesis of a zero response at all propagation horizons $h \in\{0, \ldots, 18\}$, and inference based on the Adjusted-Wald bands results in rejecting the null hypothesis of a zero response for propagation horizons $h=3-18$.

## 7 Conclusion

Impulse response analysis based on low-dimensional structural vector autoregressions is still a popular tool in applied work. It is standard in applications to equip the estimated impulse response function with confidence bands that indicate the underlying estimation uncertainty. The literature has proposed several methods to construct joint confidence bands designed to cover the entire true impulse response function with a prespecified probability. The so far existing methods suffer from deficiencies: They can exhibit empirical coverage rates substantially below the desired nominal level in certain scenarios or they can be excessively large in terms of the aggregate volume.

We have proposed new joint confidence bands for impulse response functions of structural vector autoregressions based on multiple-testing methodology of Romano and Wolf (2010). Under weak regularity conditions, these balanced bootstrap (BB) bands have asymptotically the desired coverage probability and are also asymptotically balanced.

We have compared the finite-sample properties of the BB bands to those of existing bands by means of a Monte Carlo simulation. The BB bands (i) have smaller volume than the two conservative bands - the traditional Bonferroni bands and the Wald bands of Lütkepohl et al. (2015b) - and (ii) have similar volume compared to the Adjusted-Wald bands of Lütkepohl et al. (2015b). In terms of coverage probability, the performance of the BB bands is overall the best.

Nevertheless, the BB bands - just like the Adjusted-Wald bands - can suffer from undercoverage for small sample sizes. It stands to reason that this problem can be fixed, or at least mitigated, by a double-bootstrap approach. However, studying the finite-sample properties of such an approach via Monte Carlo simulations does not seem feasible given current computing power.

## A Bias Correction

Let $A$ denote the matrix of true slope coefficients of the VAR(1) representation of a general $\operatorname{VAR}(p)$ process. Under some regularity conditions, Pope (1990) derives the following approximation for the finite-sample bias of the least squares (LS) estimator of $A$ :

$$
\operatorname{Bias}(\hat{A})=-\frac{b}{T}+\mathcal{O}\left(T^{-\frac{3}{2}}\right)
$$

where

$$
b:=\Sigma_{U}\left[\left(I_{k p}-A\right)^{-1}+A^{\prime}\left(I_{k p}-\left(A^{\prime}\right)^{2}\right)^{-1}+\sum_{i=1}^{k} \lambda_{i}\left(I_{k p}-\lambda_{i} A^{\prime}\right)^{-1}\right] \Sigma_{Y}^{-1}
$$

Here, $I_{k p}$ denotes the $k p \times k p$ identity matrix, $\lambda_{i}$ denotes the $i$-th eigenvalue of $A, \Sigma_{Y}$ denotes the covariance matrix of $Y_{t}:=\left(y_{t}^{\prime}, y_{t-1}^{\prime}, \ldots, y_{t-p+1}^{\prime}\right)^{\prime}$ and $\Sigma_{U}$ denotes the covariance matrix of $U_{t}:=\left(u_{t}, 0, \ldots, 0\right)^{\prime}$. Neglecting higher order terms and replacing true parameters by its LS estimators yields the following estimator for the finite-sample bias of $\hat{A}$ :

$$
\widehat{\operatorname{Bias}}(\hat{A}):=-\frac{1}{T} \hat{\Sigma}_{U}\left[\left(I_{k p}-\hat{A}\right)^{-1}+\hat{A}^{\prime}\left(I_{k p}-\left(\hat{A}^{\prime}\right)^{2}\right)^{-1}+\sum_{i=1}^{k} \hat{\lambda}_{i}\left(I_{k p}-\hat{\lambda}_{i} \hat{A}^{\prime}\right)^{-1}\right] \hat{\Sigma}_{Y}^{-1}
$$

Thus, the bias-corrected LS estimator is given by

$$
\hat{A}^{\mathrm{BC}}:=\hat{A}-\widehat{\operatorname{Bias}}(\hat{A})
$$

## B Stationarity Correction

In order to prevent that stationary parameter estimates are pushed outside the stationary region by the bias correction, Kilian (1998b) proposes the following adjustment procedure:
a) Calculate the modulus of the largest root of the (uncorrected) LS estimate $\hat{A}$ and denote this quantity by $r(\hat{A})$. If $r(\hat{A}) \geq 1$, set $\hat{\hat{A}}:=\hat{A}$. If $r(\hat{A})<1$, construct the bias-corrected estimator $\hat{A}^{\mathrm{BC}}:=\hat{A}-\widehat{\operatorname{Bias}}(\hat{A})$.
b) If $r\left(\hat{A}^{\mathrm{BC}}\right) \geq 1$, obtain $\tilde{A}_{i}:=\hat{A}-\delta_{i} \widehat{\operatorname{Bias}}(\hat{A})$ with $\delta_{1}=1$ and $\delta_{i}=\delta_{i-1}-0.01$.
c) Repeat step b) until $r\left(\tilde{A}_{i}\right)<1$.
d) Set $\hat{\hat{A}}:=\tilde{A}_{i}$.

## C Construction of BB Bands

The following algorithm provides a step-by-step instruction for the construction of the BB bands with nominal confidence level of $(1-\alpha)$ for an arbitrary identification procedure.

1. Fit a $\operatorname{VAR}(\hat{p})$ model to the the observed time series $\left\{y_{1}, \ldots, y_{T}\right\}$, where $\hat{p}$ denotes the estimated lag order.
2. Compute the impact matrix $\hat{B}_{0}$ according to the chosen approach of identification.
3. Estimate the structural impulse response function of interest with maximum propagation horizon $H$, that is,

$$
\widehat{\boldsymbol{\Theta}}_{i j, H}=\boldsymbol{\Theta}_{i j, H}\left(\hat{A}_{1}, \ldots, \hat{A}_{\hat{p}}, \hat{B}_{0}\right)
$$

where the $\hat{A}_{1}, \ldots, \hat{A}_{\hat{p}}$ are the estimated reduced-form coefficients.
4. Generate a bootstrap sample $\left\{\sqrt{T}\left|\widehat{\boldsymbol{\Theta}}_{i j, H, b}^{*}-\widehat{\boldsymbol{\Theta}}_{i j, H}\right|\right\}_{b=1}^{B}$. The number $B$ of bootstrap replications should be at least 2000 .
5. Compute the following $(H+1)$ empirical distribution functions

$$
\widehat{H}_{h}(t)=\frac{1}{B} \sum_{b=1}^{B} \mathbb{1}_{\left\{\sqrt{T}\left|\widehat{\Theta}_{i j, h, b}^{*}-\widehat{\Theta}_{i j, h}\right| \leq t\right\}} \quad \text { for } h=0, \ldots, H
$$

Statistical software packages usually provide a built-in function for computing the empirical distribution function; for example the function ecdf in the software package $R$.
6. Compute the following bootstrap sample $\left\{\max _{h \in \tilde{S}}\left\{\widehat{H}_{h}\left(\sqrt{T}\left(\widehat{\Theta}_{i j, h, b}^{*}-\widehat{\Theta}_{i j, h}\right)\right)\right\}\right\}_{b=1}^{B}$ and the corresponding $(1-\alpha)$ quantile. Statistical software packages usually provide a built-in function for computing empirical quantiles; for example, the function quantile in the software package R.
7. Construct the BB confidence bands for $\boldsymbol{\Theta}_{i j, H}$ with nominal confidence level $(1-\alpha)$ by computing $(H+1)$ marginal intervals

$$
\left[\widehat{\Theta}_{i j, h} \pm \frac{1}{\sqrt{T}} \widehat{H}_{h}^{-1}\left(\widehat{L}^{-1}(1-\alpha)\right)\right] \quad h=0, \ldots, H
$$

where $\widehat{H}_{h}^{-1}(p):=\inf \left\{t: \widehat{H}_{h}(t) \geq p\right\}$ and $\widehat{L}^{-1}(1-\alpha)$ denotes the $(1-\alpha)$ quantile from step 6.

Remark C.1. The methodology of Romano and Wolf (2010) allows to construct joint confidence bands that do not cover all but 'only' at least $H-k+2, k \geq 2$, of the elements of $\Theta_{i j, H}$ with nominal confidence level $1-\alpha$. Step 6 . in the previous algorithm has to be modified to construct such bands. More specifically, one has to compute the empirical ( $1-\alpha$ ) quantile of

$$
\left\{k-\max _{h \in \tilde{S}}\left\{\widehat{H}_{h}\left(\sqrt{T}\left(\widehat{\Theta}_{i j, h, b}^{*}-\widehat{\Theta}_{i j, h}\right)\right)\right\}\right\}_{b=1}^{B}
$$

where $k$-max is the function that returns the $k$-th largest element of a vector.

Table 22: Average volumes of nominal $90 \%$ joint confidence bands based on the endogenous bootstrap with $T=400$, and normal errors.

## I. 2 Figures

Figure I.1: Estimated impulse response of $\Delta p r o d_{t}$ to a one-standard-deviation shock in $\varepsilon_{t, 1}$ over a maximum propagation horizon of $H=18$ (solid line) and the corresponding nominal $90 \%$ joint confidence bands.

Figure I.2: Estimated impulse response of real $_{t}$ to a one-standard-deviation shock in $\varepsilon_{t, 1}$ over a maximum propagation horizon of $H=18$ (solid line) and the corresponding nominal $90 \%$ joint confidence bands.

Figure I.3: Estimated impulse response of $r p o_{t}$ to a one-standard-deviation shock in $\varepsilon_{t, 1}$ over a maximum propagation horizon of $H=18$ (solid line) and the corresponding nominal $90 \%$ joint confidence bands.

Figure I.4: Estimated impulse response of real $_{t}$ to a one-standard-deviation shock in $\varepsilon_{t, 2}$ over a maximum propagation horizon of $H=18$ (solid line) and the corresponding nominal $90 \%$ joint confidence bands.

Figure I.5: Estimated impulse response of $r p o_{t}$ to a one-standard-deviation shock in $\varepsilon_{t, 2}$ over a maximum propagation horizon of $H=18$ (solid line) and the corresponding nominal $90 \%$ joint confidence bands.

Figure I.6: Estimated impulse response of $\Delta \operatorname{prod}_{t}$ to a one-standard-deviation shock in $\varepsilon_{t, 3}$ over a maximum propagation horizon of $H=18$ (solid line) and the corresponding nominal $90 \%$ joint confidence bands.

Figure I.7: Estimated impulse response of real $_{t}$ to a one-standard-deviation shock in $\varepsilon_{t, 3}$ over a maximum propagation horizon of $H=18$ (solid line) and the corresponding nominal $90 \%$ joint confidence bands.

Figure I.8: Estimated impulse response of $r p o_{t}$ to a one-standard-deviation shock in $\varepsilon_{t, 3}$ over a maximum propagation horizon of $H=18$ (solid line) and the corresponding nominal $90 \%$ joint confidence bands.

[^1]:    ${ }^{1}$ This property is obvious from a theoretical point of view; in addition, for example, see Lütkepohl et al. (2015a) for Monte Carlo evidence.

[^2]:    ${ }^{2}$ This implies that the covariance matrix of the $\varepsilon_{t}$ is equal to the $m$-dimensional identity matrix, that is, $\mathbb{E}\left[\varepsilon_{t} \varepsilon_{t}^{\prime}\right]=I_{m}$.

[^3]:    ${ }^{3}$ Rubio-Ramirez et al. (2010) provide a necessary and sufficient condition for global (exact) identification of structural VARs; in particular, the necessary condition of Rubio-Ramirez et al. (2010) is equivalent to the widely used (necessary) rank condition of Rothenberg (1971).
    ${ }^{4}$ Given the normalization $\mathbb{E}\left[\varepsilon_{t} \varepsilon_{t}^{\prime}\right]=I_{m}$, a one-standard-deviation shock is equivalent to a unit shock.

[^4]:    ${ }^{5}$ In case the initial response is zero by construction, $\beta$ is equal to $\alpha / H$.

[^5]:    ${ }^{6}$ This is the empirical distribution of $w_{b}^{*}:=T\left(\hat{\theta}_{b}^{*}-\hat{\theta}\right)^{\prime}\left(\widehat{\Sigma}_{\theta}^{*}\right)^{-1}\left(\hat{\theta}_{b}^{*}-\hat{\theta}\right), b=1, \ldots, B$, where $\hat{\theta}_{b}^{*}$ and $\widehat{\Sigma}_{\theta}^{*}$ are estimators based on bootstrap data $\left\{y_{1}^{*}, \ldots, y_{T}^{*}\right\}$.
    ${ }^{7}$ Lütkepohl et al. (2015b) also propose another adjustment procedure and the resulting joint confidence bands are called Bonferroni-adjusted Wald bands, see Lütkepohl et al. (2015b, p. 11).

[^6]:    ${ }^{8}$ The centering and rescaling is carried out as suggested in Stine (1987).

[^7]:    ${ }^{9}$ For $T=100$, there are 300 individual data points to estimate the 42 coefficients.
