DISCUSSION PAPER SERIES NO. 2016-12

The *PIDS Discussion Paper Series* constitutes studies that are preliminary and subject to further revisions. They are being circulated in a limited number of copies only for purposes of soliciting comments and suggestions for further refinements. The studies under the *Series* are unedited and unreviewed.

The views and opinions expressed are those of the author(s) and do not necessarily reflect those of the Institute.

Not for quotation without permission from the author(s) and the Institute.

April 2016

Abstract

This discussion paper presents an analysis of the performance of national (NIS) and communal irrigation systems (CIS) by region, complemented by technical and institutional assessments of 30 sample NIS and 66 sample CIS in Luzon. It shows that there is value in looking at subnational trends. Using secondary data from the central and regional offices of the National Irrigation Administration and the systems, complemented by key informant interviews and ocular inspections, this study establishes key institutional and technical constraints to improving performance of NIS and CIS systems.

In addition to the selected key performance indicators, some ratios are used to characterize the capacities of the systems in terms of manpower, level of functionality, financial structure, and productivity of the systems. This study examines the NIS cases by *province*, *size* (large, medium, small), *technology* (gravity type vs pump type), *location* (upstream, midstream, downstream), *vintage* (pre-NIA, 1965–1980, 1981–2013), and by some measures of “*success*” and presents a number of instructive results.

Keywords: irrigation performance, management and development of irrigation systems, irrigators’ association, Luzon

EXECUTIVE SUMMARY

This paper presents findings and some preliminary recommendations on irrigation related to technical/physical and institutional aspects of irrigation management and development for both national and communal systems.

Key Findings

There is value in looking at sub-national trends given insights which cannot be inferred from national trends. Using secondary data from the Central and regional offices of NIA and the systems, complemented by key informant interviews and ocular inspections, this study establishes key institutional and technical constraints to improving performance of both national and communal irrigation systems.

Specifically, for national irrigation systems, we found the following:

- National and regional trends in NIS

Service area growth has slowed down in the last decade and growth has been concentrated in just four regions. Firmed up service area difference with service area indicate on average a land conversion rate or declared permanently non-restorable area of about 10%. Most NIS systems are diversion systems and the few operational pump systems available are in five regions (Regions 1, 2, 3, 5 and 13).

Cropping intensity only slightly increased over the years. In fact wet season irrigation intensity appears to have largely slowed down. In Luzon, some increases in dry season irrigation intensities can be seen while wet season intensities appear to have stagnated. However, in Mindanao, similar increasing patterns for both wet and dry seasons irrigation intensities are observed.

Collection efficiency has only noticeably improved in two (the rest of Regions 2 and 4) regions only in Luzon and in MRIIS and slightly in UPRIIS while worst in Region 6. The Mindanao regions appear to have been performing better in terms of this indicator, consistent with the corresponding improvements in cropping intensity. Aside from this, possibly other factors maybe at play given the performance in Regions 2 and 11 and in MRIIS and higher cropping intensities in the rest of Mindanao.

- NIS Cases - Performance and Issues

Of the 21 NIS cases, six are from Ilocos, five from Cagayan (including 2 MRIIS), seven from Region 3 (including 3 UPRIIS), three from Regions 4a and 4b, and one from Region 5. The sample also included four pump systems.¹ Except for UPRIIS and MRIIS, the rest of the systems are diversion/gravity type.

¹Part of UPRIIS and MRIIS systems are served by pumps.

The performance of the NIS cases are analyzed in terms of size of IAs (defined as large, medium, small based on their FUSA), technology (diversion/gravity, pump, reservoir), location (upstream, midstream, downstream of the main canals), vintage (before 1965, 1965-80, 1981-2013), and by some measures of “success” which largely capture institutional and financial/economic aspects of irrigation system management by IAs/NIA. “Success” is measured similarly as NIA loosely defines it -- based on functionality ratings and active and functional IA organization, high collection efficiency and payment of ISF to NIA. These typologies capture various technical and institutional aspects of providing irrigation service by national systems. Pump systems will have different challenges from reservoir and diversion systems. Size of IAs based on firmed-up service area will likely be correlated with complexity of design, and operation of physical structures and facilities, and the corresponding type of management. Vintage entails different technical and institutional concerns between relatively old vs. newer systems. “Successful” IAs entail institutional factors at play but also probably technical aspects contributing to such performance.

The analysis according to size indicates that there is disparity between small and large IAs. The small IAs reported the highest incidence of inadequate water during dry seasons, flooding during wet season, high counts of canal problems especially lateral canals, and siltation/solid waste problems. The large systems/IAs indicated adequate water supply, least occurrence of siltation problems, lowest count of irrigation headwork and main canal problems, minimal occurrence of flooding and adequacy of budget. These IAs also have a high percentage of “successful” IAs compared with the small and medium size IAs. This apparent advantage of large IAs may be linked to their degree of influence by virtue of their size and ability to access funds which result in favorable physical states of their systems, which in turn led to their success.

Looking at systems according to technology, reservoir systems show clear advantages over the other types of schemes. And while pumped systems are shown to be doing well, these systems are in fact heavily subsidized. The IA sample irrigated by diversion system (gravity) reported the highest count of inadequacy in water supply especially during the dry season. The IAs which used pump systems have the highest counts of siltation, lateral canals and institutional problems. Despite these concerns, these IAs reported adequacy and dependability of water supply even during dry season, no flooding problem, and higher collection efficiencies compared to the situation of IAs with diversion/gravity system. The IAs in reservoir systems claimed to be most successful of the three groups. This group reported adequate water supply, lowest count of siltation problems, largest percentage of financially strong IAs, very high IA functionality ratings and high collection efficiencies.

As to the location of the IAs relative to main canals, downstream IAs are shown to be heavily disadvantaged over the rest of the IAs. The sample has the following characteristics: highest count of siltation and/or solid waste problems, highest count of lack of water supply, highest occurrence of flooding during wet seasons, highest count of damaged farm-to-market roads, highest percentage of financially weak IAs and lowest ratings of water delivery service in terms of adequacy and timeliness. The upstream IAs on the other hand, reported the least incidence of water supply problems, lowest count of solid waste and/or siltation problems, highest

irrigation structure problems, highest count of lack of machineries and equipment and a high percentage of financially strong IAs. Irrigation canal problems were ranked first in the list of problems, and followed by institutional problems and then by calamities/pest infestation causing production problems.

In terms of vintage, the profile of IAs and irrigation systems also differs. This measure splits the sample into three periods which coincide with the distinct trends in irrigation investment and development. Interestingly, the pre-NIA systems are characterized as those with the least irrigation structure problems, concern for lack of machineries and equipment and inadequacy of water supply. However, the IAs in these systems have the lowest functionality ratings. Systems constructed between 1965 and 1980 have the following attributes: highest count of poor headwork and control structures condition, highest concern of lack of machineries and equipment, highest count of financially weak IAs, highest count of lack of water supply, and highest incidence of damaged FMRs. Yet, these systems have the least siltation/solid waste problems relative to systems from the other periods. Prevalent problems in decreasing order include: inadequate of water during dry seasons, poor conditions of lateral canal and control structures. The IAs with systems built between 1981 and 2013 reported the highest count of main and lateral canal problems. They also have the highest incidence of siltation problems and the largest count of institutional problems. However, this group has the largest number of financially strong IAs, the highest count of “successful” IAs, the least occurrence of flooding, with adequate water supply and least damaged FMRs. This observation seems ironic as it implies that IAs can still be financially strong and “successful” despite technical and institutional problems.

Profiling IAs according to “success” or failure indicates distinct differences between these groups. “Successful” IAs in the sample are characterized as those with adequate water supply, less institutional problems, adequate budget and facilities, machineries and equipment. However, these IAs experience higher incidence of siltation and problems with physical state of main canals, lateral canals and control structures. The hierarchy of problems of successful IAs are as follows in decreasing order: lateral canal condition problems, institutional problems, crop production problems due to calamities/pest infestations and damaged irrigation structures. The “not successful” IAs have the higher count of inadequate water during dry seasons, irrigation headwork problems, lack of facilities, machineries and equipment, with inadequate budget and lower IA functionality ratings, indicating poor management performance. In order of importance, inadequacy of water comes first, followed by institutional problems, and then by the lack of irrigation facilities/infrastructures, machineries and equipment.

Lastly, using an alternative approach to analyzing the sample NIS performance, the results show that irrigation performance has much to improve. This approach establishes an irrigation performance index (IPI) measured in terms of five aspects: financial, economic, institutional, technical and environmental factors. The *financial factors* include: 1) IAs rating of their financial strength – financial capability of the IA is critical in the organization’s development; 2) collection efficiency – a higher collection efficiency means higher ISF shares by IAs and better incentive; and 3) collection delinquency – a higher delinquency decreases the

performance index. Financially strong IAs can carry out better O&M and repairs so that irrigation systems can deliver good/sustainable irrigation service.

The *economic factors* include average annual yields and gross profits of IA members which would be indicative of benefits that reach beneficiary farmers. Higher annual yields can lead to higher annual profits. Also, higher incomes can mean farmer members would be better able to pay ISF resulting in IAs financial strength. The *institutional component* includes: 1) effectiveness of policies; 2) flexibility index rating; 3) reliability index rating; and 4) satisfaction rating on farm to market road.

The *technical component* indicators include canal structures ease of operability and canal structure's operability vs. design. Canal structure ease of operability pertains to the ease in operating irrigation structures such as check gates, turnout gates, etc. While canal structure operability vs design compares the original design of the irrigation system vs the actual use of the structure. The *environmental component* indicators include dissolve oxygen content and acidity. Higher DO (i.e. > 6 ppm) and pH content (i.e. >5) mean better quality water. The pH found in most water samples show levels >7 which indicate alkaline conditions and potential sodicity problems if not addressed on time. The results of this analysis show that 58% of the sample IAs rated the irrigation performance as moderate. Only 12% of the sample rated performance as high and the rest, low performance.

For communal irrigation systems, the preliminary evaluation leads to the following findings:

- National and Regional/Provincial Trends

Service area has been growing but at a relatively very slow pace while firmed up service area has been closely following. Given the relatively stable difference between the SA and FUSA, land conversion or growth in permanently non-restorable area does not appear to be a concern. However, the trends in actual irrigated areas during the wet and dry seasons seem to have faltered in 2012. Wet and dry seasons irrigation intensities never reached the 80% mark and even declined by about 20% in 2012.

With the rise in equity schemes, the amortization collection decreased and became a less significant source of income. Despite this trend, amortization collection efficiency drastically declined, making this a serious concern.

- Characterizing the sample CIS

The 66 CIS are saddled with technical issues and problems that affect their performance. The sample CIS in this study have run-of-the-river type dams which are quite old, with exposed rock cores, damaged spillways, and sediments almost at the crest level. The sluice gates and intake gates which were initially made of steel have been replaced with flashboards, sand bags, or stones and in some relatively larger CIS, with defective lifting mechanisms. These problems contributed to the increase in sedimentation. However, most of the sample CIS have concrete-lined main canals and even laterals. The good conditions of these lined and unlined canal networks are said to be due to the IAs O&M efforts and cleanup mechanisms. Where heavy siltation is experienced due to watershed degradation, the solutions are simply beyond the IAs.

The sample CIS are characterized according to size, technology, “success” or “not successful” and by province. On size, three types are defined: small, medium, large. Based on technology, the CIS are classified as gravity or pump systems. To profile CIS according to some measure of success, a “successful” IA is defined in terms of three criteria: (1) NIA’s functionality rating of very satisfactory to outstanding; (2) IA’s own financial rating of 3 to 4, with 4 as very strong; and (3) IA’s ISF collection performance rating of 3 to 4, with 4 as excellent, and a collection rate of 65% and above. “Not successful” or unsuccessful IAs are defined as all other IAs not classified as “successful”. These categories capture various technical and institutional factors that influence CIS irrigation service.

The experience in small CIS exemplifies “small is beautiful.” Compared to the other classes, the small CIS have the least incidence of inadequate water during dry seasons, siltation and solid waste problems. They also have less problem in irrigation structures and canals compared with the large systems and they reported the highest average cropping intensity and yield. However, they have the lowest collection efficiency and highest count of funding problem. Following the criteria above on “successful” CIS, the small systems have the highest percentage of “successful” IAs compared to the larger systems. The large CIS have the highest incidence of floods during the wet seasons. They also have the highest count of irrigation canal problems and water theft. But, they have the least funding problems.

Contrary to earlier findings, IAs using pump technology in the sample are found to be more successful despite the higher incidence of flooding and funding problems, and low cropping intensities. The disparity is likely due to their adequate water supply even during dry seasons, fewer problems with their irrigation canals and structures, and high collection efficiencies. The pump technology appears to be closely associated with better control of available water and the success of IAs.

The IAs irrigated by gravity have the highest cropping intensity and a low incidence of flooding, but they have more problems with irrigation canals and structures, more severe water shortages, and greater incidence of funding problems and water theft.

As to profile of “successful” IAs, they have adequate and dependable sources of water supply, high cropping intensity, high collection efficiency, and adequate funding. This success profile is obtained despite flooding, siltation, irrigation structures, and water theft problems. Less successful IAs are characterized by inadequate water in the dry season, more problems with irrigation main canal and control structures, low collection efficiencies, and severe funding problems. It is interesting to note that IAs can still be classified as successful despite physical and economic concerns. It seems that water availability is a key factor in high collection efficiency. This finding needs to be validated so NIA can use this result in formulating strategies to improve collection efficiency.

Recommendations

Based on the technical and institutional analyses carried out for national and communal irrigation systems, the following recommendations are in order.

For National Irrigation Systems:

- Given the new insights from sub-national trends which cannot be inferred from national level data, such level of analysis should be scaled up to cover more NIS in Visayas and Mindanao and better understand the situation on the ground and establish some patterns and trends which can be used to formulate relevant policy changes and actions.
- It appears that conversion of irrigated areas is a more serious concern in certain regions. If the rate of land conversion will continue to rise, estimates of design areas should properly take this into account.
- Given the dramatic slowdown in growth or stagnation of wet season irrigation intensity, it is high time that NIA gives attention to the need to invest in drainage and/or collaborate with DPWH to explicitly and more systematically address flooding problems in NIS systems which fall under the turf of the latter and may require bigger technical/engineering solutions.
- As a first step, each NIS should clearly establish size of firmed-up service areas which are flooded during the wet season. For systems where there is a big difference between wet and dry season irrigable area, two FUSA measures should be recognized in order to set more realistic irrigated area targets.
- Collection efficiency improvements appear to correspond to improvements in cropping intensities. If this relationship can be confirmed, the strategy to improve collection efficiency should include improvement in cropping intensities which in turn will require improvement in irrigation service.
- Relative to the medium and large irrigators associations (IAs), the small IAs appear to have the disproportionate share of the problems. Given this disparity, the design of institutional interventions should take into account “size” of IAs according to membership. Special attention should be given to the needs of small IAs and appropriate interventions be designed.
- Irrigators Associations in reservoir systems claimed to be most “successful” based on many indicators when compared with those in diversion and pump systems. In considering types of projects to invest in, government will have to weigh the trade-offs in investing more in reservoir types which will likely mean higher initial capital requirements vs. other type of systems (e.g. pumps). The later type may mean less initial investment but higher O&M after project completion and less likely to be sustainable to operate given volatility in oil prices.
- “Successful” IAs in the sample are characterized as those with adequate water supply, less institutional problems, adequate budget and facilities, machineries and equipment. If we take these factors as indicative of necessary requirements for “successful IAs,” then at minimum, NIA’s system design and eventually service areas should have better estimates of available water. This finding makes necessary more firm and systematic assessment of adequacy and reliability of water that will be available to farmers when an NIS system operates.
- The issue of equity in the delivery of service remains a major concern given the heavily disadvantaged downstream IAs – with inadequate water during the dry season and more water than they need during the wet season. NIA has to come up with a better strategy of addressing this aspect of equity as part of improving quality of irrigation service.

If use of pumps is to be taken as a way to partly address equity concerns especially during dry seasons, the lack of policy on treatment of use of pumps within NIS systems has to be addressed. The use of discount needs to be evaluated and made an official policy rather than leaving too much discretion on the water masters or institutional development officers in the field.

- Performance of irrigators associations using functionality ratings differ by vintage -- pre-NIA systems, 1965-80 and 1981 to 2013 – indicating that contrary to expectations, functionality of “older” IAs maybe more problematic. If functionality ratings can be validated, there may be a strong case for revisiting the institutionalization program. “Old” IAs appear to need more retraining/reorienting/strengthening so they can keep up and become more effective organizations.
- Again, appropriate institutionalization policy has to be designed according to the specific needs of different types of IAs. Irrigators associations in the early NIA years appear to be mostly financially weak. Given this, the capacity building strategy for IAs should explicitly include ways to improve financial strengths and that intervention for IAs should consider not only size (in terms of membership) but also vintage. IAs with systems built between 1981 and 2013 appear to need in addition, more engineering/technical solutions. These observations should be confirmed by further evaluations given two possible scenarios –more recent systems are not built as strongly or we have simply more intense weather and climate contributing to more rapid deterioration or damage to the systems. If the latter would be the case, this finding will provide a strong support for more deliberate climate change resilient systems in terms of design and structures.
- Using an alternative approach to analyzing the sample NIS, the results show that the composite performance has much to improve. This approach establishes an irrigation performance index in terms of five aspects: financial, economic, institutional, technical and environmental factors. If the results can be confirmed, addressing specific aspects of performance with respect to the five areas can lead to possible marked improvement. Given this potential usefulness of the analysis, this approach should be scaled-up to cover more IAs and national systems to validate the initial observations and at the same time refine the measure to be more useful.

For Communal Irrigation Systems:

- Service area has been growing at a very slow pace and preliminary investigation shows that a good number of CIS are already in elevations beyond the 3% slope. This initial finding warrants scaling up of the characterization to cover more IMOs to get a better sense of the location and distribution of the over 9000 CIS nationwide.
- An assessment of the potential and economics of considering areas between 3% and 8% slopes for CIS expansion should be pursued. Using the GIS technology and some modeling, a more systematic identification of irrigable CIS areas should be carried out taking into account water availability, associated environmental damage/watershed degradation.
- The wet and dry seasons irrigation intensities which are generally below 80%, should be further investigated and understood by looking at trends in all provinces/IMOs and more systems. As a first step to this assessment, the firmed up service area (FUSA) has to be examined and the field work should be used to understand why the actual irrigated areas have been falling short in both seasons. The evaluation should be able to establish how much is due

to “non-functional” areas (which will therefore need repair/rehabilitation/restoration) vs. flooded during wet or with inadequate water during dry.

- With the rise in equity schemes, the amortization collection decreased and became a less significant source of income. Despite this, the fact that amortization collection efficiency has declined, is a concern which should be addressed.
- Reservoir systems appear to coincide with most successful group of IAs. If this finding can be validated, consideration of this type of system may well justify the possibly higher investment needs compared to other type of systems.
- The technical issues and problems affecting the CIS performance point to the need to revisit adherence to design and construction guidelines for new development and rehabilitation of CIS. Specifically, the assessment of dependable flow, catchment conditions, sediment discharges and potential of groundwater source should be properly carried out. The trade-off between spending more on capital requirement during the development phase versus higher O&M expenditures after turnover should be carefully weighed.
- If results can be validated by scaling up the evaluation to cover more CIS, appropriate government interventions can be designed according to the priority needs of IAs. NIA can use the results for targeting interventions and allocating the corresponding resources. Small IAs need more capacity building and funding while large IAs need more technical solutions.
- Lastly, while IAs can still be considered “successful” despite physical and economic concerns, it appears that water availability is a key factor in high collection efficiency. NIA’s strategy to improve collection efficiency has to also include addressing the issue of water availability.

INTRODUCTION

This report is a Phase 2 of the 2013 Rapid Assessment of national irrigation systems (NIS) conducted for the Philippine Institute for Development Studies (PIDS) which largely focused on national level data and analysis with six case studies (Inocencio, et al. 2013). This second phase has three components: (i) assessment of national irrigation systems (NIS) regional trends and 22 systems; (ii) rapid appraisal of communal irrigation systems (CIS) at the IMO or province level and a sample of 66 systems; and (iii) characterization the irrigation sector governance structure. This component is tasked with integrating the first two components.

Irrigation development and management in the country has historically been the single biggest item of public expenditure for agriculture, accounting for about a third of the total since the 1960s. In the 1970s and early 1980s, as well as in recent years when world rice prices rose at unprecedented levels, this ratio was even higher at close to half of total public expenditures for agriculture. In recent years, irrigation has taken up from one third to close to half of the Department of Agriculture budget.

Table 1. Budget appropriation by the Department of Agriculture²

	Appropriation for irrigation (P Million)	Share in Department of Agriculture budget (%)
2011	12,790.650	36.8
2012	24,454.052	46.2
2013	27,156.295	42.1
2014	21,182.734	30.9
2015	28,750.441	42.4

Sources: Various General Appropriations Act (GAA).

The National Irrigation Administration (NIA) development program largely focuses on national irrigation systems (NIS) and communal irrigation systems. NIS are irrigation systems supposedly with minimum service areas of 1,000 hectares (ha), the biggest reaching over 120,000 ha. However, a number of NIS fall short of the 1,000 ha threshold size. Management of these NIS systems is by NIA and irrigators associations. There are 231 NIS with a total service area of 813,916 ha. (or 731,186 ha firmed-up service area) as of December 2014. The three largest NIS with massive reservoirs operated in combination with river run off, are gravity irrigation systems which account for about a third of total NIS service area. The remaining two-thirds are mostly run-of-the-river gravity irrigation, except for five medium-sized NIS that pump water from large rivers.

Communal irrigation systems (CIS) are those whose service areas fall below the 1,000-ha threshold. The total service area of CIS continues to be sizeable at about 599,049 ha or a firmed-up service area of 576,859 ha as of December 2014. While many CIS started as private initiatives, most of them have been receiving government support for the cost of rehabilitation and new construction. At least 95% of CIS are gravity systems obtaining water from rivers or streams. However, few have been given funding support for medium sized pumps to also

² The 2015 share is computed as ratio of NIA to DA plus NIA budgets to be consistent with other years. The appropriations for irrigation are only those through NIA.

abstract and distribute water from a river. Most CIS are constructed by NIA, but the irrigator associations are responsible for the management and maintenance of the systems.

While the government started to promote the adoption of pump irrigation in the 1950s, recent data indicate that at least 90% of pump irrigation used by rice farmers have been purchased privately, and even more so for pumps used for non-rice cultivation. The Department of Agriculture's Bureau of Soils and Water Management (BSWM), as well as NIA, have occasionally distributed small pumps to rice farmers for free and sometimes on credit, especially during periods of drought when the surface irrigation systems have unusually low actual irrigated areas. In relative terms, government subsidy for the use of small pump or individual irrigation systems has been nominal.

OBJECTIVES

The project aims to evaluate the effectiveness and efficiency of the government's irrigation program. It focuses on technical, physical, and institutional aspects of performance of both national (NIS) and communal irrigation systems (CIS), and selected cases led by other project proponents. Specifically,

Component 1: National Irrigation Systems

This component analyzes trends in NIS secondary data and examines 22 cases to help understand and explain the trends and state of national irrigation service provision from the points of view of providers and beneficiaries. Specifically:

1. Analyze the trends and patterns of performance indicators across different types of systems in terms of ratios of actual irrigated areas to service and firm-up service area, cropping intensity, collection efficiency, operation and maintenance (O&M), and farm productivity based on system level and aggregated data, and
2. Analyze the factors affecting the trends and patterns of performance across NIS and within selected NIS using secondary data, key informant interviews and focus group discussions, geographic information system (GIS), and other techniques. This analysis requires collection of secondary data at the different levels of NIA – Central Office (CO), Regional Irrigation Office (RIO), Irrigation Management Office (IMO) and selected NIS cases.

Component 2: Communal irrigation systems

This component provides preliminary evaluation of investments in CIS. This component undertakes CIS analyses from secondary data and cases to help understand and explain the trends and state of irrigation service provision from the points of view of providers and beneficiaries. Specifically:

1. Characterize the CIS at national and provincial levels, examine the trends and patterns of performance indicators in terms of ratios of actual irrigated areas to service and firm-up service areas and cropping intensity, collection efficiency, and farm productivity based on national and provincial level data, and

2. Undertake preliminary analysis of factors affecting the trends and patterns of performance of CIS at the national and provincial levels and within selected CIS in 11 IMOs/provinces (out of 60 total as of July 2015) using secondary data, key informant interviews and focus group discussions, GIS, and other techniques. This analysis requires collection of secondary data at the different levels of NIA particularly the CO and the IMO and site visits to selected CIS cases.

This component is tasked with integrating the findings of both the NIS and CIS technical and institutional assessments of performance. The aim is to establish technical and institutional factors constraining the NIS and CIS systems from performing well and delivering quality service. These factors may relate to inefficiencies in the development and management of the systems, from planning and design, to project evaluation/selection, construction, operation and maintenance, and rehabilitation. A separate study component covers the entire irrigation sector governance aspect.

FRAMEWORK OF ANALYSIS AND METHODOLOGY³

The study applies a rapid assessment approach following Burt and Styles (1998) and the MASSCOTE (Mapping Systems and Services for Canal Operation TEchniques) (2007) rapid appraisal procedure (RAP) taking into account availability and access to technical data on the systems and what can be realistically measured during the relatively short visits and ocular inspections.⁴

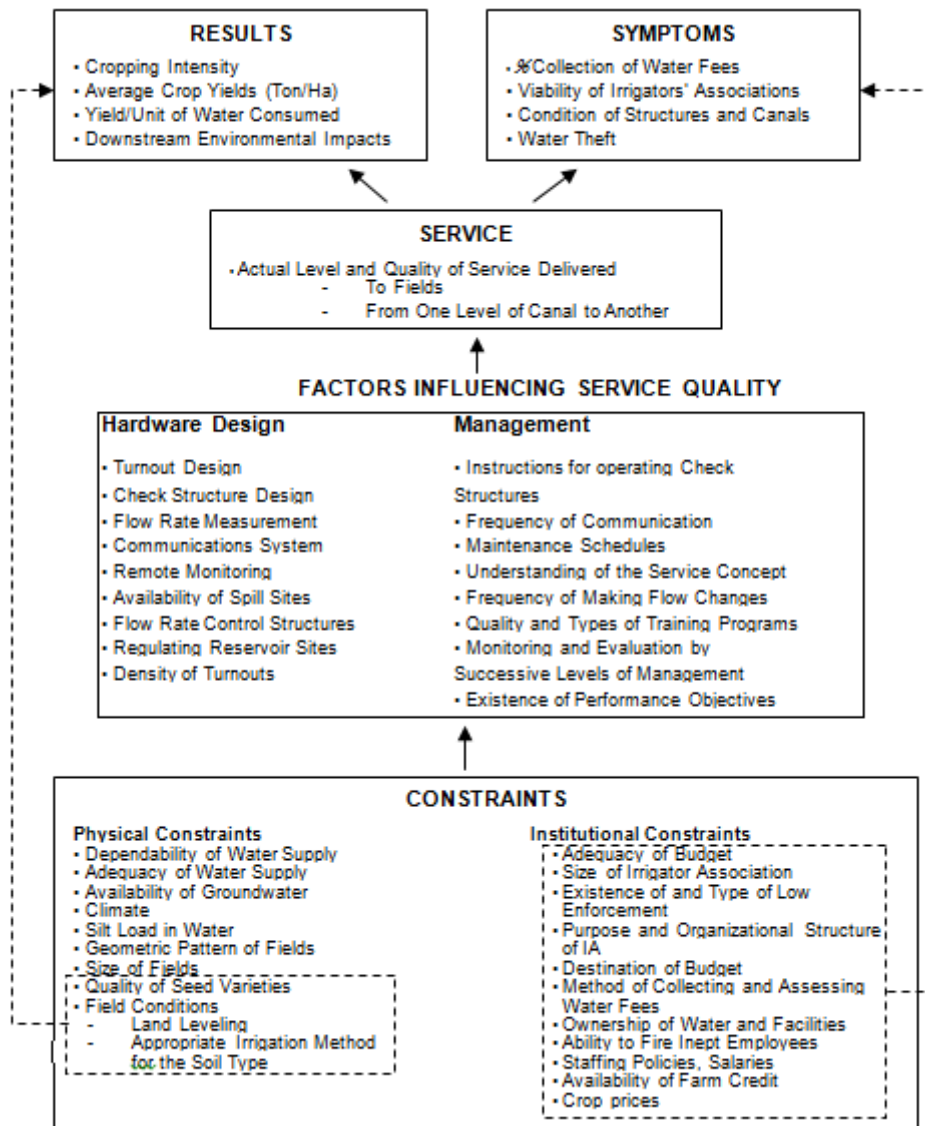

Figure 1 shows some of the major inter-relationships that affect outputs from irrigation projects/systems. It is important to distinguish "results" from "causes" and "symptoms". For instance, strong IAs maybe thought to eliminate most of the problems in irrigation systems/projects. However, this framework takes strong IAs as a *result* and not a *cause*. A scenario for the existence of a weak IA is where the irrigation project authorities expect the IA to collect water fees, distribute water, and maintain a water distribution network. Yet, the IA has little or no say in how the fees are spent and the water arrives at the IA area is inadequate and untimely (i.e. poor water delivery service). In this scenario, the weak IA is a *symptom* and not a *cause* of poor water delivery service.

The framework shows that many factors will impact project/system outputs and that the strength of an IA is dependent on both *institutional* and water delivery service factors. It describes a rapid appraisal process that takes into account the various *hardware design* and *management* factors that affect service. Consequently, the *physical, technical* constraints that include aspects of water supply and sources, and *institutional* constraints that include capacities of parties involved, influence availability and flexibility of irrigation service.

³The RAP approach draws heavily from Burt and Styles (1998).

⁴ The MASSCOTE framework aims to map the entire services area into manageable cost-effective units to better serve users. The framework maps the service to users by taking into account the perturbations, the opportunities for water management improvement, and the costs. This mapping in turn serves as an input in formulating strategies for water management service delivery, canal operation, and modernization. The NIS and CIS studies only limit themselves to the use of some relevant and applicable parts of the RAP.

Figure 1. The Rapid Appraisal Procedure (RAP)

Sources: Burt and Styles (1998) and MASSCOTE (2007).

The RAP examines external inputs such as water supplies and outputs like water destinations (e.g. evapotranspiration or ET, surface runoff, etc.). It provides a systematic examination of the *hardware* and the *processes* used to convey and distribute water internally to all levels within the project (i.e. from the source to the fields).

The RAP *outputs* include *external* and *internal* indicators. Basically, external indicators examine inputs and outputs of the whole project/system, while *internal* indicators examine processes and hardware within the project/system. The *internal* indicators also identify key factors related to water control throughout a project/system. They define the level of water delivery service provided to users, examine specific hardware, and check up on management techniques and processes used in the control and distribution of water. The *external* indicators include ratios or percentages comparing project inputs and outputs to describe performance,

measures of forms of efficiencies related to budgets, water, yields, etc. However, these indicators do not provide insight in how to improve performance.

The fieldwork asked questions to management in the RIO/IMO offices, systems operators, and IA officers/farmer beneficiaries, and observes or critically examines them. Questions for provincial/IMO/system offices probe on information/readily available data on general project/system conditions, water supply location, ownership of land and water, budgets, operation as described by office staff, and stated water delivery service at various levels in the system. In the field, RAP includes observing the state of the canals and structures from head works to main canals to laterals to field level, discussing operations of cross regulator and inlet, and performing key informant interviews (KIIs) with NIA staff/irrigators association officers/members responsible for system management/co-management and water distribution.

Scope of the Study

For the NIS component, 22 systems in 14 provinces in Luzon are covered: (1) Bonga Pump 2 and (2) Nueva Era RIS in Ilocos Norte; (3) Banaoang Pump Irrigation System (PIS) in Ilocos Sur; (4) Magapit PIS and (5) Solana PIS both in Cagayan; (6) Visitacion RIS also in Cagayan; (7-8) Magat River Integrated Irrigation System (MRIIS) in Isabela; (9-10) Ambayoan-Dipalo RIS in Pangasinan; (11-13) Upper Pampanga River Integrated Irrigation System (UPRIIS) in Nueva Ecija and parts of Tarlac, Pampanga, and Bulacan; (14-16) Tarlac-San Miguel-O'Donnell River Irrigation System (TASMORIS) and selected operational TGIS systems; (17) Pampanga Delta RIS; (18) Angat-Maasim RIS in Bulacan; (19) Balayungan friar land irrigation system (FLIS) in Cavite; (20) Libmanan-Cabusao PIS in Camarines Sur, (21) Caguray IS in Mindoro Occidental, (22) Dumacaa in Quezon. The sampling frame represents Regions 1 to 5 national systems, with a total firm-up service area (FUSA) of 440,785 ha (as of December 2014). The selected NIS represent about 47% of the Regions 1 to 5 firm-up service area (FUSA) or 28% of overall total NIS FUSA.⁵

For the CIS component, 11 provinces/IMOs in Luzon are covered, with total firm-up service area of around 180,328 has, representing 31% of the total. The selected IMOs were drawn from the top 20 provinces in terms of total FUSA except for Laguna because it was selected to optimize the overlap with the NIS sample provinces. Specifically, the selected provinces/IMOs include the following: (1) Laguna (part of Laguna-Rizal IMO); (2) Ilocos Norte; (3) Cagayan (part of Cagayan-Batanes IMO); (4) Isabela; (5) Nueva Vizcaya; (6) Benguet (part of Abra-Benguet -Ifugao-Mt. Province IMO); (7) Pangasinan; (8) Nueva Ecija (part of Bulacan, Aurora, Nueva-Ecija IMO); (9) Pampanga (part of Pampanga-Bataan IMO); (10) Camarines Sur; and (11) Occidental Mindoro. Of these provinces, Camarines Sur (with 43,730 has) and Pangasinan (29,783 has) have the largest CIS areas (NIA 2014).⁶

⁵ UPRIIS and MRIIS have FUSA of 119,640 ha and 85,176 ha., respectively, as of December 2014. These two largest systems already represent around 28% of the total FUSA for NIS.

⁶ NIA has 60 IMOs nationwide each headed by a Division Manager. The IMOs consist of 40 clustered provinces; and the 9 district offices, and two dam and reservoir divisions of UPRIIS and MRIIS. The IMOs are responsible for the construction and rehabilitation of irrigation projects and systems in one or a cluster of provinces. They also implement the operation and maintenance (O&M) plans of irrigation systems in collaboration with the farmer-beneficiaries (<http://www.nia.gov.ph>).

For each selected province/IMO, six sample CIS systems were drawn using the 2013 NIA Inventory file that serves as the sampling frame. This file contains system size, technology, source of water, and percentage of operational/non-operational FUSA. The CIS sample represents small (i.e. 50 ha and below), medium (i.e. above 50 to 100ha), and large (i.e. above 100 ha) systems. Selection of CIS is also based on the type of technology, whether gravity or pump. In consultation with the NIA Irrigation Development Officers (IDOs) at each IMO, “success” and “failure” cases were included in the sample. Accessibility of the system was also considered.

Data Collection

Primary and secondary data were collected from the central and field offices. Primary data were collected during technical field visits, and qualitative information gathered from key informant interviews (KIIs) for the institutional and governance aspects of irrigation service. Secondary data were collected from the different NIA offices such as NIA-Central, Regional, Irrigation Management Offices (IMOs), and the offices of each selected NIS. Additional secondary data were gathered from other the government agencies. Relevant documents, appraisal, implementation/completion, project performance audit reports, annual/yearend reports, technical studies, policy notes, and river basin master plans were reviewed to characterize the current state and distribution of NIS and CIS and to evaluate trends and patterns of performance indicators.

Specifically, secondary data/reports, whenever available, included the following:

- List of NIS/CIS under the IMOs and available data including functionality survey results;
- Technical data (i.e. physical state, service area, irrigation efficiency, source of water, access to and availability of water, year constructed and start of operations, construction cost, rehabilitation cost, other major investments, yield, cropping calendar, cropping intensity; rainfall and other climatic data;
- Status of IAs (i.e. profile/institutional report of IAs, source of funding, financial status/viability, program of works (POWs) for all available years, and national irrigation system performance (NISPER) and communal irrigation system performance (CISPER); and
- Assistance provided by NIA to CIS/IAs; assistance provided by other agencies to CIS/IAs.

For each selected NIS or CIS case, the proponents met with the IMO Division Managers, NIS Managers, and the system personnel. Where available, technical references including feasibility studies, technical drawings, network maps were obtained. A review and analysis of the maps, including technical specifications, canal layout, location and functions of irrigation structures, and irrigated and built-up areas were conducted.

Key informant interviews (KIIs) of NIS or CIS staff and IAs (e.g. IMO, System managers, IDOs/operations staff, and IA president/officer/member) were conducted. Information on socio-economic characteristics of farmer-members, institutional capacity of IA, problems and constraints in managing the NIS canals/laterals/CIS by the IAs were generated from the KIIs. The status and current conditions of the main canal, selected secondary, and tertiary canals

were initially determined through KIIs and complemented by ocular observations during the walk-throughs.⁷

Walk-throughs and actual measurements were collected for a subset of the sample NIS and CIS to gauge the physical conditions of the systems (i.e. current vs. designed dam/reservoir capacity; length and efficiencies of lined vs. unlined canals; legal and illegal turnouts, including functionality; for pump systems: fully, partially operational, or non-operational pumps; among others). Depending on the size of the IS, one secondary lateral was selected: (a) near the dam or headgate, (b) in the middle, or (c) at the tail end of the system. If the NIS is relatively small, only one lateral near the headgate and one at the tail end had been selected. These structures/facilities are photographed and geo-tagged for proper referencing. Conveyance losses were measured on selected main and lateral canals, and where applicable, compared for lined and unlined canals. For the CIS, at least two systems per IMO/province were selected for the walk-throughs. One lateral each near the headgate and at the tail end were selected for technical evaluation.

Data Analysis

This study carried out trend analysis and use case studies to provide in-depth analysis. To accomplish this goal, technical and institutional evaluations are carried out applying some RAP approaches. Application of the RAP framework allows development of *internal* process indicators and *external* indicators. The generation of *internal process indicators* requires information listed in the "**Constraints**", "**Factors Influencing Service Quality**", "**Service**", and "**Symptoms**" in Figure 1. The *external indicators* require some of the information contained under "Physical Constraints" (e.g. water supply, climate) and "Results".

The following measures can be considered as among the *internal* indicators:

- Service area (SA) (proxy for *hardware*)– total area that a completed national or communal system can potentially irrigate;
- Firmed-up service area (FUSA) (proxy for *hardware*) – Service Area less converted areas and permanently non-restorable areas; this is further broken down into operational/functional vs. non-operational/functional; functional service area is the actual area irrigated in the wet season plus the area submerged in the said season but irrigated in the dry season; non-operational/functional service area is the difference between FUSA and operational/functional service area, mainly due to water shortage and dilapidated facilities;
- Programmed service area (dry season, wet season) (proxy for *management*) – FUSA less non-operational area that can be irrigated given “expected/estimated” available water in the dry season and less areas that will potentially be flooded during the wet season;

While the following maybe considered a combination of *internal* and *external indicators*:

- Actual irrigated area (dry season, wet season) – Programmed area which were planted and reported in the verified list of irrigated planted area (LIPA);

⁷ Refer to the inception report for the KII and guide questions for NIS staff at different levels and NIS/CIS IAs.

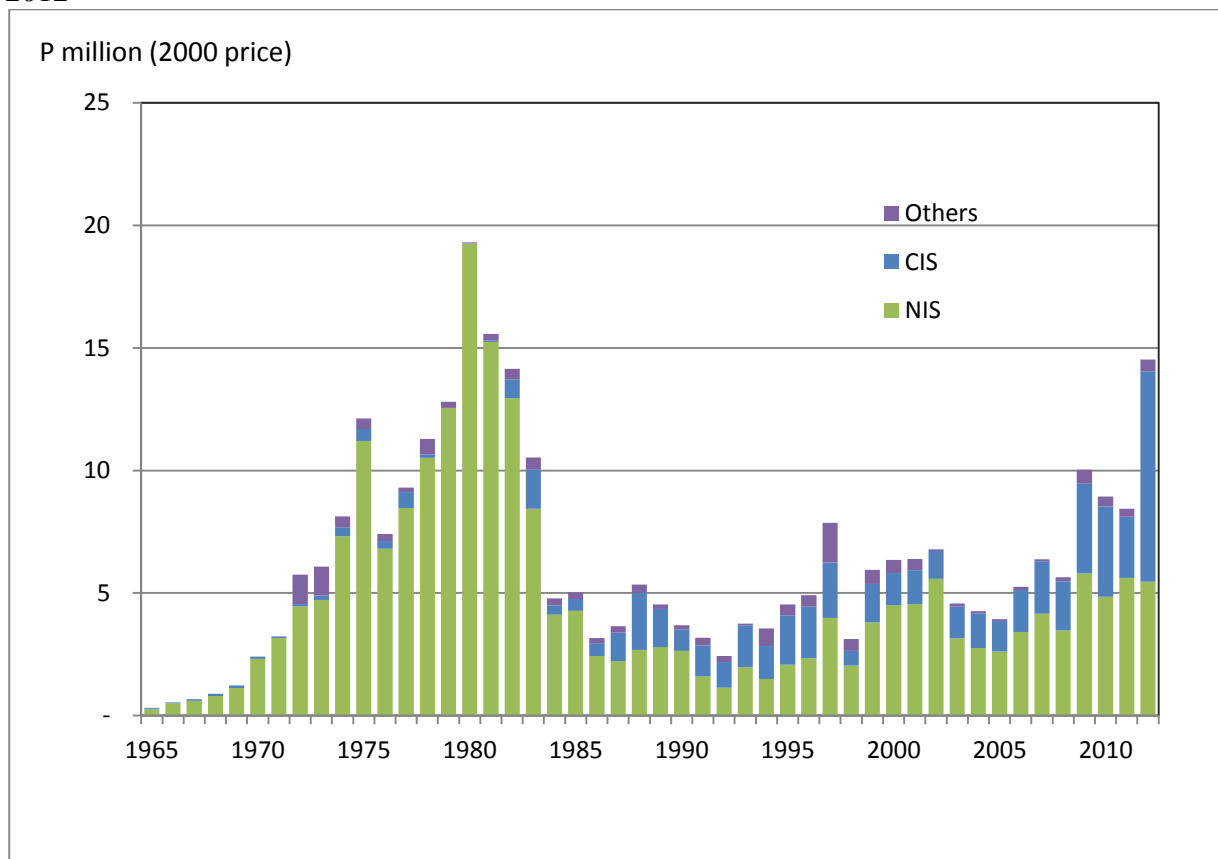

- Benefitted area (dry season, wet season) – irrigated areas which harvested at least 40 cavans/ha.
- Cropping intensity (*result*) – sum of actual irrigated wet and dry seasons divided by FUSA (before 2004, SA is used)
- Irrigation intensity (*result*) – actual irrigated wet (or dry season) divided by FUSA (before 2004, SA is used)
- Collection efficiency (*symptom*) – current collected irrigation service fee (ISF) divided by current collectible;
- Viability (*symptom*) – total system income divided by reported total O&M expenses.

In addition to the above performance indicators, some ratios are used to characterize the *institutional constraints* captured by capacities of the systems in terms of manpower, level of operation or functionality, financial structure, and productivity of the systems (*result*).

TRENDS IN NATIONAL IRRIGATION INVESTMENTS AND PERFORMANCE

Irrigation investment remains the most important policy instrument that government uses to increase productivity in agriculture and to achieve its food staples sufficiency objective. Figure 2 presents the trends in total public expenditures for irrigation in 2000 prices. Over the past four decades, irrigation investments have peaked in the late 1970s to early 1980s and rose again in more recent years.

Figure 2. Irrigation investment trends for national and communal irrigation systems, 1965-2012

Sources: NIA Yearend Report, various years.

The increase in world rice prices in the 1970s together with the introduction of modern rice varieties suited to irrigated conditions raised the marginal rates of returns for irrigation investments. As world commodity prices decline, yields of modern rice varieties leveling off, and the cost of irrigation expansion increase, public expenditures declined. Investment shifted from new development to rehabilitation projects, which were reported to give higher returns to investment.

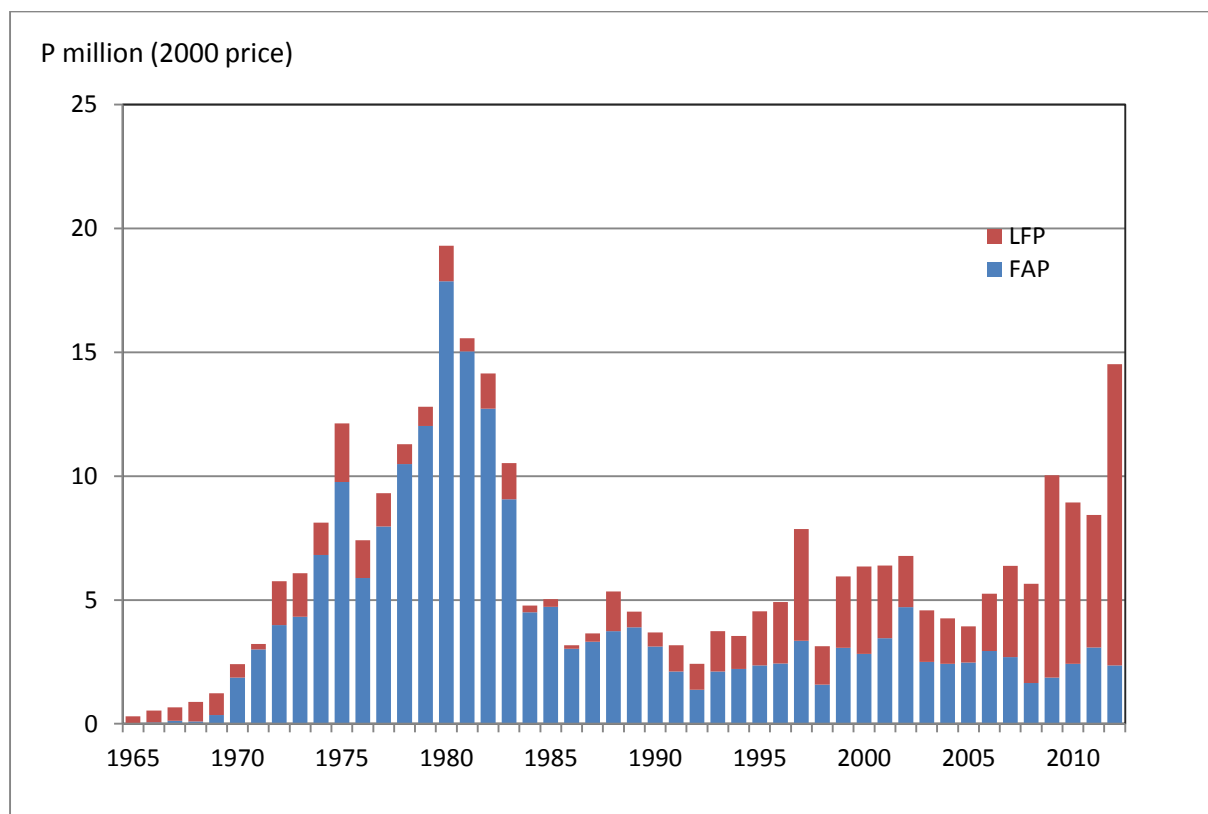

The rise in investments in 2008 was as a response to the increase in world rice prices in 2007. This trend continues with the present administration's food self-sufficiency program. More systematic analyses indicate that levels of public investments respond to short-run changes in

world rice prices as these affect marginal rates of returns to irrigation investments and adoption of rice self-sufficiency instead of consideration of long-term benefits and costs

There are also discernible shifts in investments from largely NIS to more CIS in early 2000 and in more recent years (Inocencio and David 2013). These changes were consistent with the delayed enforcement of the provisions in AFMA (supposedly to begin in 1997) to give more attention to smaller systems and promote participation of LGUs in developing CIS.

The funding source also has shifted from predominantly foreign in the 1970s to the 1980s to local in more recent years (Figure 3). This pattern is reflective of the country’s development strategy at that time where foreign funding was a key element. That period was characterized by a debt-driven growth. The poor fiscal position of the country in early 2000 led it to foreign funding for irrigation projects. The recognition of the need to reduce foreign exchange risks, directed borrowings back to local sources. This fiscal policy had implications on the quality of projects and implementation. Foreign funding appeared to have certain implementation rules and standards at the start of the project up to completion. Local funding however, appears to have fewer requirements and less stringent rules and accountability.

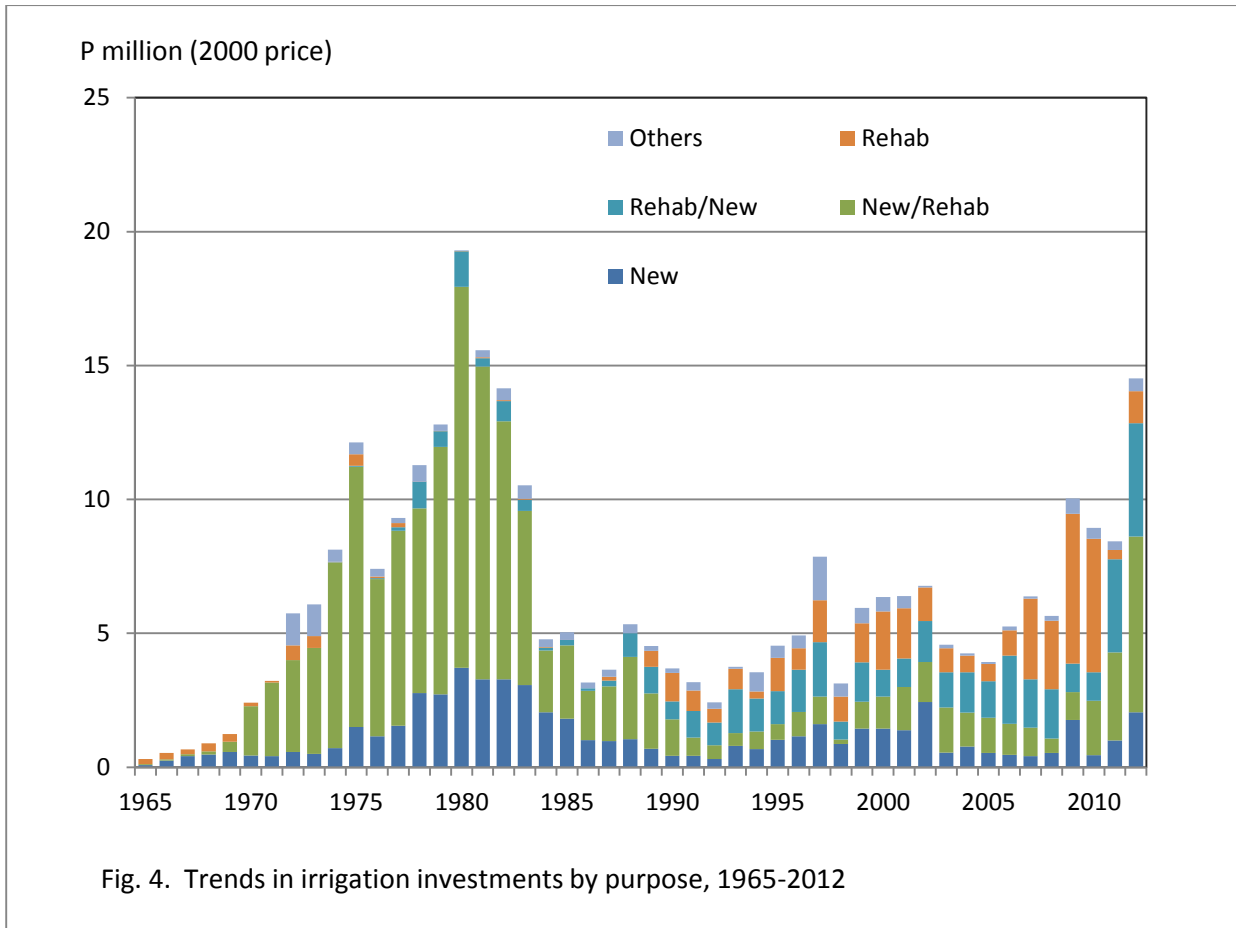

Figure 3. Trends in irrigation investments by source of funding, 1965-2012

Sources: NIA Yearend Report, various years.

Looking at investment by purpose (Figure 4), the 1970s and early 1980s were dominated by new projects with some rehabilitation components. Donor evaluation studies in the late 1980s indicated that rehabilitation projects have higher rates of return (Jones 1995). This was also the period in which donors began to invest more in institutional strengthening relative to construction projects.

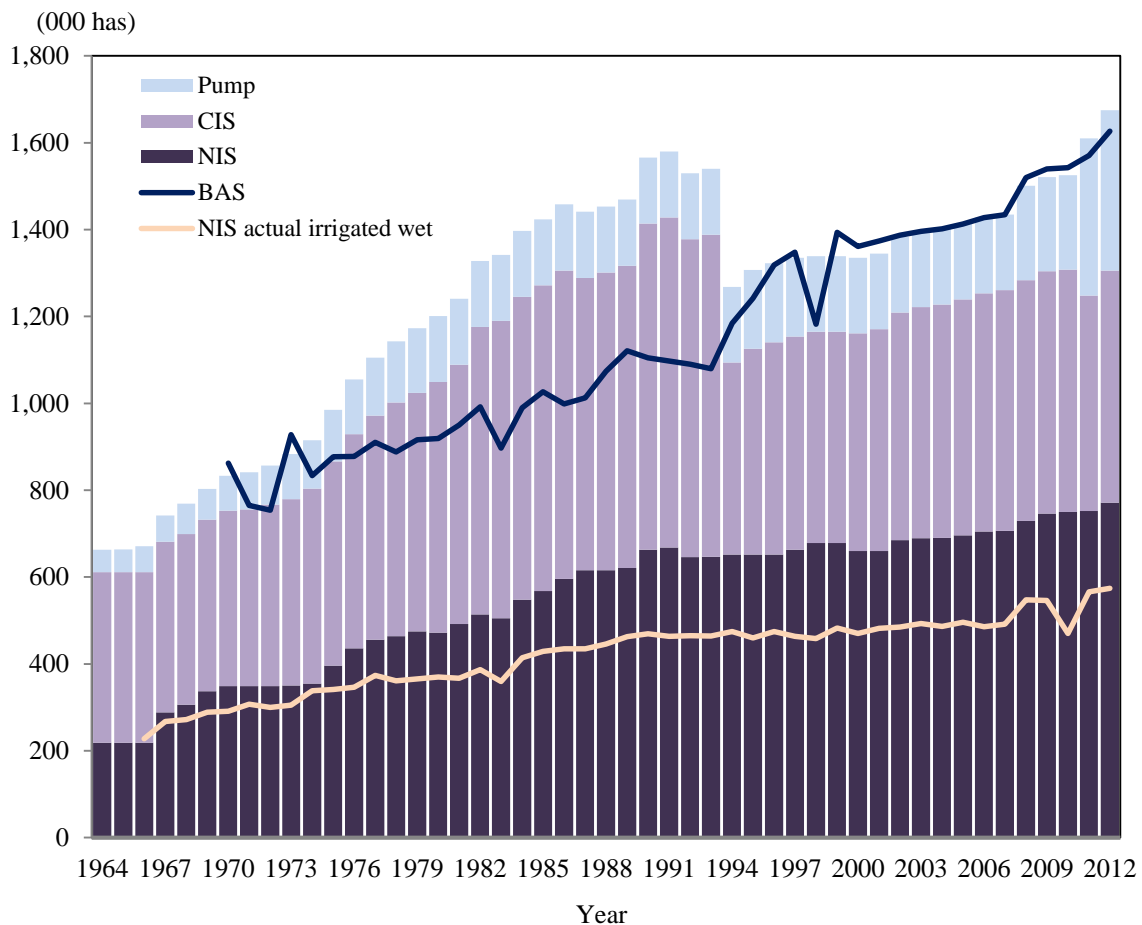

Figure 4. Trends in irrigation investments by purpose, 1965-2012

Sources: NIA Yearend Report, various years.

Trends in irrigation service areas indicate continuously rising service areas although the rates of increases seem to be slowing down in the last decade (Figure 5). The NIA data would be seemingly consistent with those of BAS if the former's correction of CIS data in 1994 is extended back to the mid-1970s. Noteworthy is the trend in actual NIS irrigated area (wet season) which appears to grow even on much lower rate relative to the NIS service area. Also, interesting to note that private pumps appear to be increasing with discernible growth in early 2000.

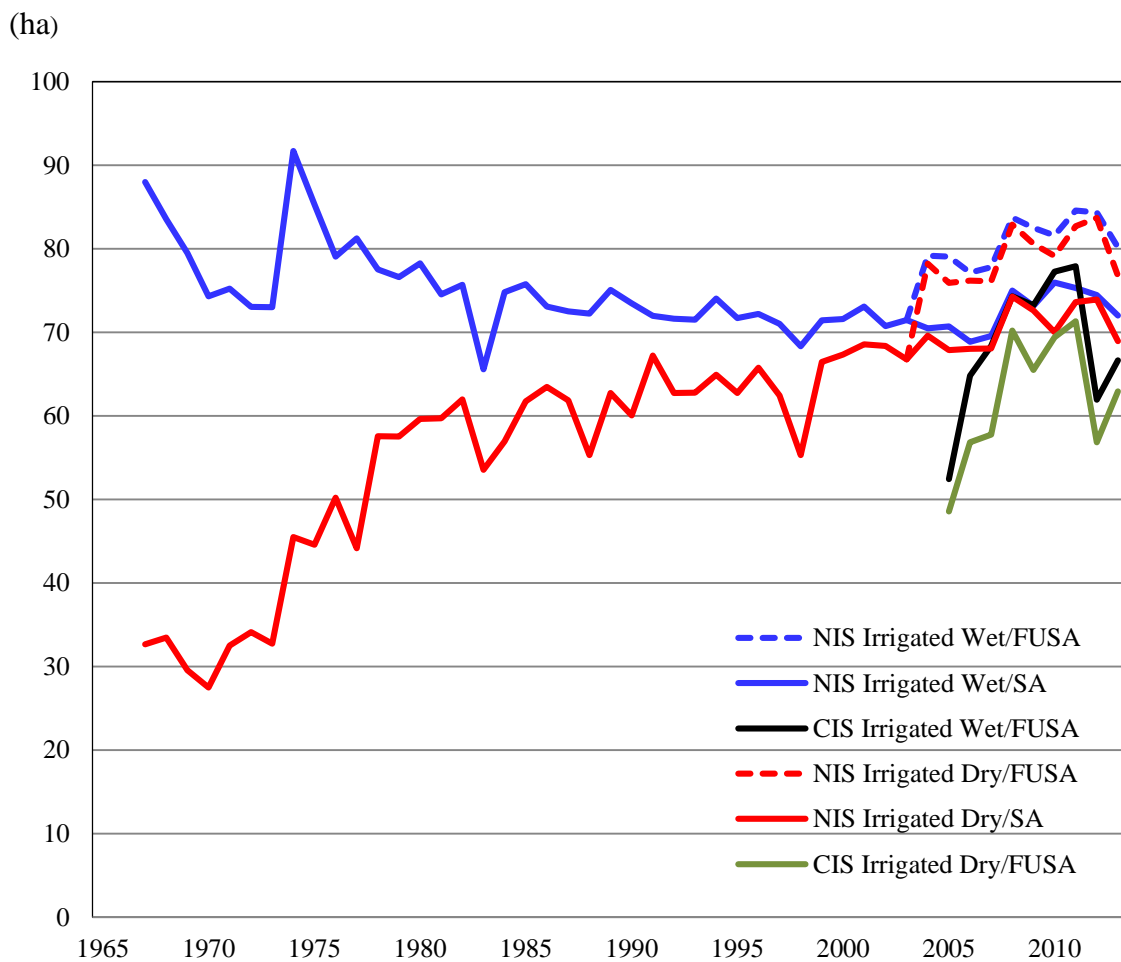

Figure 5. Trends in NIA NIS, CIS & Pump service areas, Actual NIS irrigated area (wet season), and the BAS-PSA estimates of irrigated rice crop area (second semester), 1964-2012 (000 has).

Sources: NIA-SMD NISPER and CISPERS data, various years.

Figure 6 shows the trends in irrigation intensities for NIS and CIS, wet and dry seasons. The trends for CIS show the same pattern for wet and dry seasons, with the first generally higher than the latter, Using the irrigated area to FUSA measure, the NIS intensities are much better than those of the CIS. What is striking is that the NIS intensities using the SA are seemingly in contrast with a declining wet season versus a rising dry season trend. Yet, if the FUSA definition is used, the contrast seems to diminish with both wet and dry intensities rising closely to each other. The correction in FUSA with converted lands and permanently non-restorable areas removed from SA, shows improved performance which does not differ much between seasons.

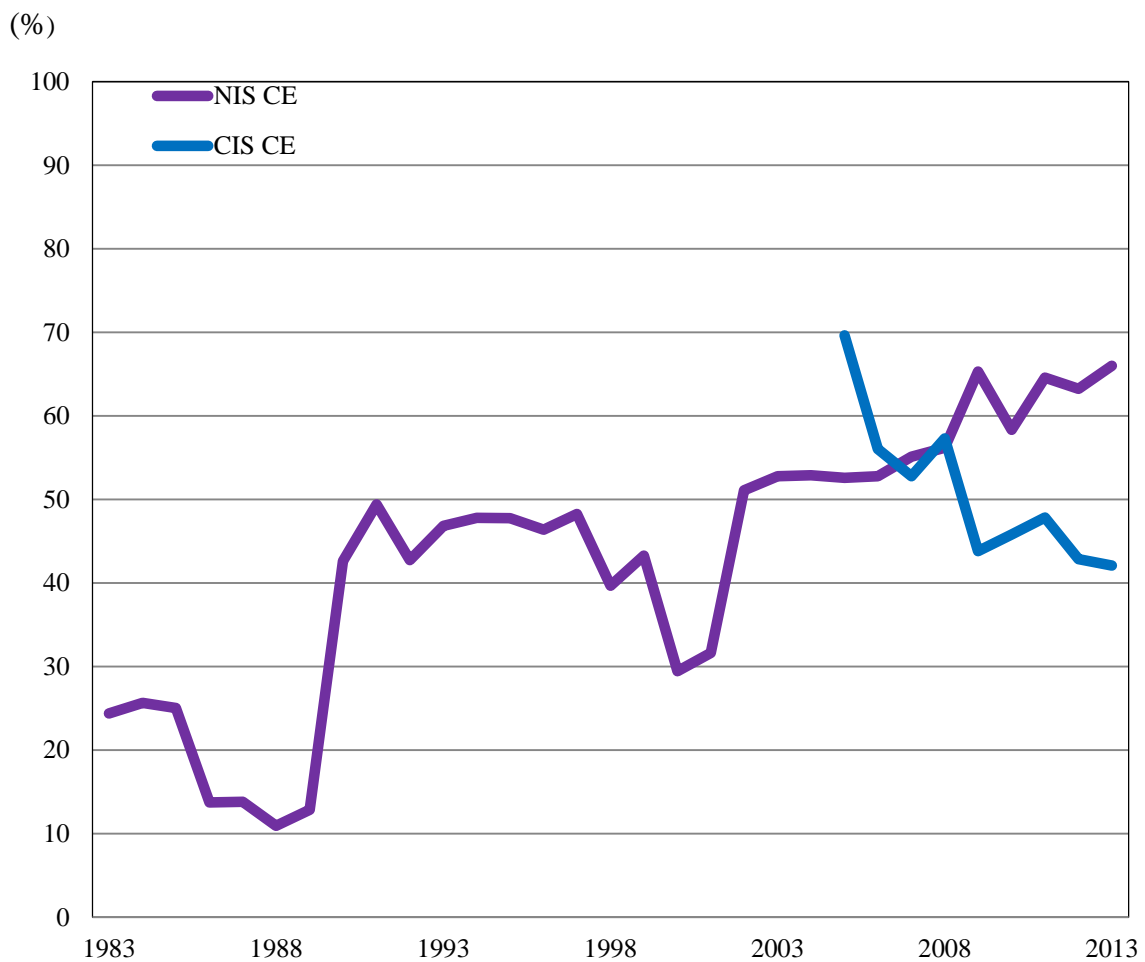

Figure 6. Trends in Irrigation Intensity in NIS and CIS, Philippines, 1965-2013

Sources: NIA-SMD NISPER and CISPER data, various years.

The collection efficiencies (**Figure 7**) defined for NIS as the rate of current ISF collection ratio to current collectible, while for CIS, current amortization payment ratio to current collectible, show opposite trends. The collection efficiency for NIS has been below 50% until the early 2000. It started rising in 2003 to over 60 percent in more recent years. The ISF collection is used for O &M of the systems and to partly cover the operations costs of the IMOs and the RIOs. For the CIS, the amortization collection rate has been declining since 2004 which should be alarming given the declining share to total revenues from CIS. This pattern could mean much reduced effort in collection and/or less effective collection strategy.

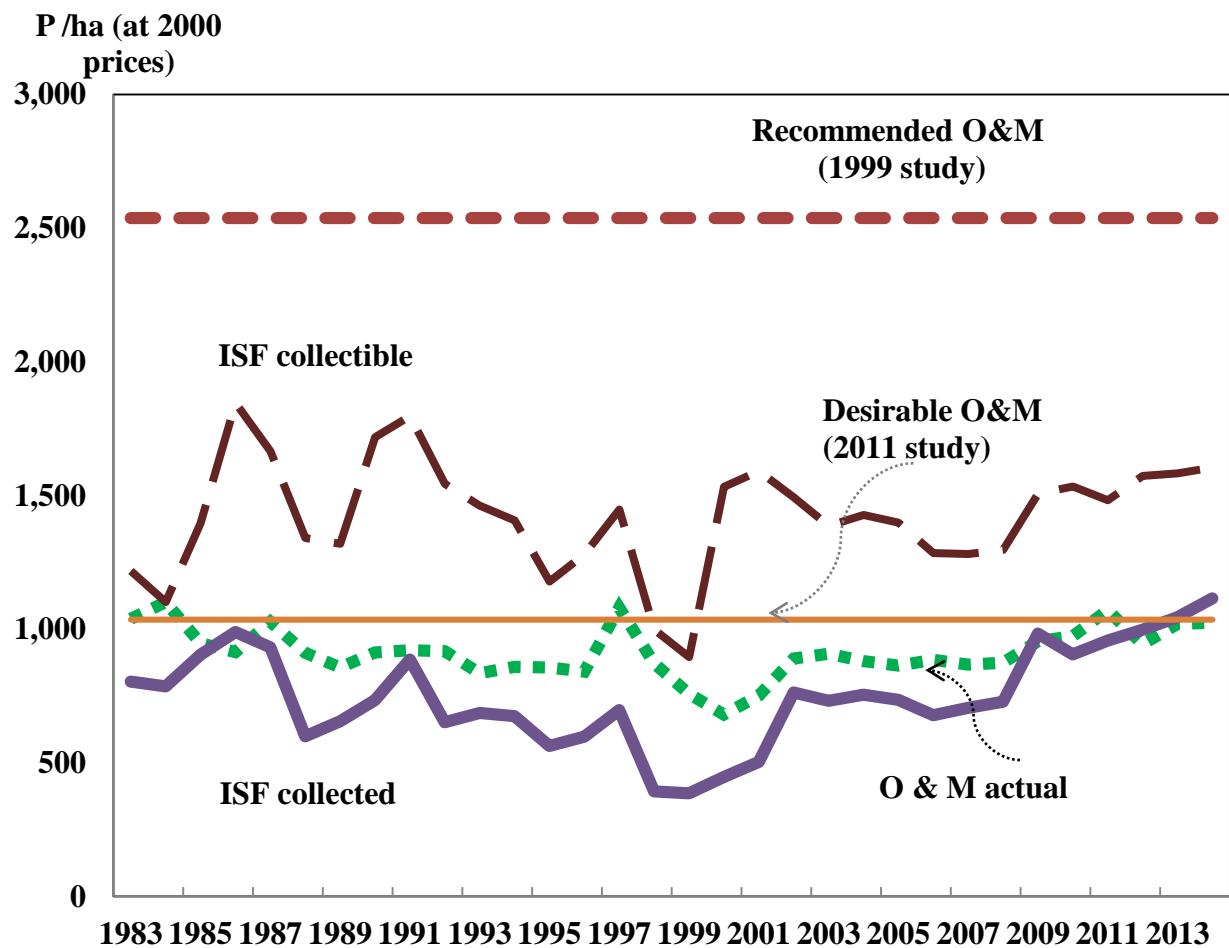

Figure 7. Trends in Collection Efficiency in NIS and CIS, Philippines, 1965-2013

Sources: NIA-SMD NISPER and CISPER data, various years.

Figure 8 shows the trends in actual cost of NIS operation and maintenance (O&M) compared to recommended/desirable levels and to irrigation service fee collectible and collections o at 2000 prices. There are a few key observations: (1) an old recommended O&M is much higher than current collectible ISF implying that even with a 100% collection efficiency, the ISF will not be able to properly cover the O&M; (2) the actual O&M appears to be pegged to the actual ISF collected. These observations may help explain why despite the increasing investments in irrigation development, firm up service areas, actual irrigated and irrigation intensities hardly improved over time.

NIS REGIONAL TRENDS AND SYSTEM PERFORMANCE

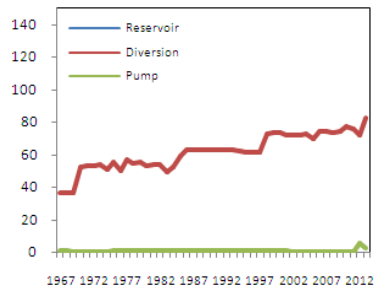

This section presents system level and regional trends put together from NIA-SMD data to broadly explain the national trends. While Figure 9 shows trends in key national performance indicators, Figures 10 to 13 report regional trends in selected performance indicators.

Trends in regional service area (SA) indicate that the national growth has been coming from four regions – Regions 2, 3, 10 and 12 (**Figure 10**). By type of scheme, the growth in Luzon is in reservoir type while that in Mindanao, diversion type.

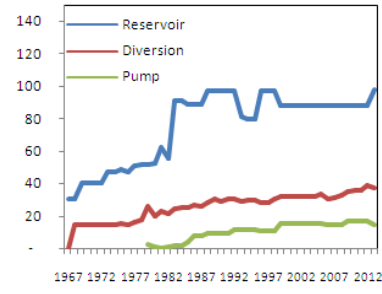

The NIS are classified into three types of schemes: run-of-the-river diversion, storage or reservoir, and pump irrigation. A diversion scheme draws water under controlled conditions directly from the flow of rivers or streams while a storage or reservoir scheme involves the construction of storage dams to impound water and released as needed to be drawn from a diversion dam downstream. According to NIA, the reservoir projects are usually multi-purpose and may serve power generation, flood control, fishery and recreation functions. Pump projects lift water from underground or from rivers and streams. These schemes maybe used in some storage or diversion systems to lift water to irrigate areas in higher elevation or pump groundwater to supplement available surface water supply. As of 2012, reservoir type accounts for 31% while diversion schemes, 63%. The rest of the areas are accounted by pump-systems. The reservoir schemes are largely found in Regions 2 (i.e., MRIIS) and 3 (i.e., UPRIIS) while most of the pump systems are in Regions 2 and 5. Over time, much of the expansion appears to have been in diversion and small reservoir schemes. Diversion schemes will be more vulnerable during dry seasons and also to higher water stress resulting from decreased rainfall and extended dry spells.

Figure 11 shows the regional trends in O&M expenditures and O&M per ha. According to Shepley, et al. (2000), the recommended cost of O&M per hectare that will cover the average direct costs of water scheduling and gate operations, canal cleaning labor, gate repairs/greasing and locks, use of hand held radios and equipment rental is at least double the current level of ISF charged in run of the river diversion and reservoir systems (Inocencio, et al 2014). The actual spending on O&M/ha at the field level is even significantly less than the collectible ISF in the wet and dry seasons, as ISF collection rate on current account has averaged only about 50% in the 1980s and 1990s, and rising to slightly higher than 60% over the past decade. The Shepley, et al. study found that about 40% of the time of ditch tenders is devoted to ISF collection, rather than to O&M. In fact, a more recent study on ISF indicated that the system operations staff spend as high as 80% of their time for ISF collection (Cabluyan, et al. 2014). Except for four regions, regional real O&M expenditures have been almost constant (CAR and Region 1, Regions 7 and 9) or even declining (Regions 6, 10 & 13, and slightly, Regions 4 and 5 and AMRIS). Real O&M per ha follow the same pattern of decline or hardly changing in the last three decades. Given these trend, the dismal states of many systems and likely poorer performance can only be expected. The poor performance is confirmed by the trends in regional (wet and dry season) irrigation intensities (**Figure 12**).

Figure 12. Trends in irrigation intensities in national irrigation systems by region, 1967-2013.

Sources: NISPER, NIA-SMD, various years.

In terms of explaining the national trends, CAR, Regions 1 and 4 appear to be consistent for both wet and dry irrigation intensities. As to the increasing trend in dry season irrigation intensity, almost all regions seem to be consistent with the exception of Regions 5 and 6 which have more flat lines and Region 3 because of the big drop in the early 1990s because of the Mt. Pinatubo eruption impact.

The regional trends in collection efficiency in **Figure 13** show generally poor performance except for Regions 2 and 11. In recent years, however, several regions (Regions 4, 7, 8, 10/13, and 12/ARMM) and MRIIS are starting to show improvements. The consistent poorly performing regions and system (CAR/Region 1, Regions 3, 5, 6 and 9, AMRIS) appear to be also those which suffer from low irrigation intensities.

What is notable is the trend in benefitted to actual irrigated area (Figure 9c) indicating increasing exemptions (for areas harvesting below 40 cavans/ha) over time at around 10%. Since 2008, exemptions for wet season irrigated area have been higher, even reaching as high as 20% in 2011.

Table 2 shows additional indicators to help characterize NIS capacity and resources and productivity of systems and these figures serve as the benchmark for the regional trends. With the rationalization and food self-sufficiency agenda, it is interesting to note that at the national level, NIA is still to fill-up about 40% of its approved plantilla under the RatPlan, as of December 2014. . Since 2010, one plantilla staff is on average responsible for an increasing service area, at 424 ha as of December 2014. If the daily staff would be considered, the coverage decreases by 86. It appears that the daily staff is on average covering 17 to 20% of service area in the last five years.

Region 1 – Ilocos

For Ilocos, six systems have been visited (see **Figures 14 to 18**). Three of these systems are small and the rest are medium-sized. One is relatively recent. Except for Ambayoan –Dipalo, performance data for the 4 other systems are patchy (especially Tables 3 to 6). What seems apparent is that firmed-up service area appears to be much lower than service area indicating substantial land conversions and/or large permanently non-restorable areas.

Bonga 2 Pump Irrigation System

Bonga 2 started as a communal irrigation system (CIS) to be fully turned over to the IAs upon full payment of amortization. However, with the failure of the IA to manage the system and fulfil obligations to NIA and electric company, a tri-partite body comprising the local government unit (municipality), NIA and IA was formed to help the system recover. The municipality takes care of collection and management of finances while the IA is responsible for pump operation and maintenance and water distribution. Despite being included in the NIS roster, Bonga 2 is operated like a CIS.

Looking at the performance indicators for Bonga 2, it is difficult to establish any pattern due to insufficient data (**Figure 14**). However, data show that the decline in irrigation intensity, coincides with the decreases in collection efficiency. The irrigation service fee (ISF) is the sole source of income which is supposed to cover O&M expenses and amortization payment to NIA (**Table 3**).

Madongan

Madongan is a medium size system with an initial service area of 3,200 ha in 2001 which decreased to over 1,400 ha in 2012 (**Figure 15**). Both the actual irrigated wet and dry, however, dropped drastically in 2004-2005 and remained constant up to 2012 (Figure 15). The big drop in actual (wet and dry) irrigated areas from 2004 onwards was due to the major damage in head structure caused by typhoon Igme. Specifically, the left side of the system was seriously damaged and became non-operational while in the right-side, the siphon #1 was silted and was partially operational (David, et al. 2012). The damage to overflow dam had been severe, reducing actual irrigated area to about 20% of the design. Yabes (2008) attributes the big drop in service area to typhoons and the lack of NIA funds for repairs (before Igme, there was Feria in 2001).

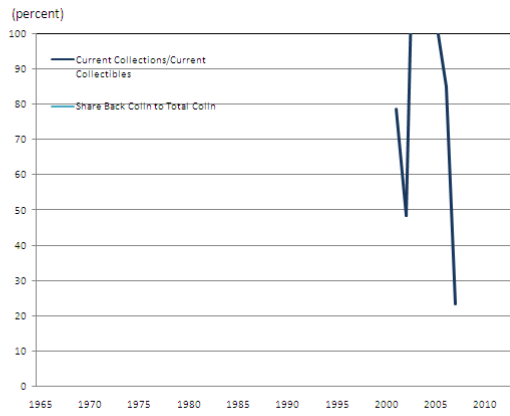

Despite the 100-year flood design, the severe damage to Madongan was attributed by David, et al. to: (a) error in estimating the design flood, (b) shifting hydrographs due to watershed degradation, and (c) poor construction standards. Even before the typhoon, a large discrepancy between design area and irrigated area was noted by David, et al. (2012) and cited a number of technical concerns to explain the discrepancy.

For this system, the irrigation service fee (ISF) is the main source of income which is supposed to cover O&M expenses and amortization payment to NIA (**Table 4**).

Nueva Era

Again, there is not enough data for Nueva Era to establish any pattern. Like Madongan, the system was also badly damaged by typhoons especially Igme. After typhoon Igme, the system was heavily damaged and silted and was not operational which explains the drastic declines in performance (ratios to current collectibles of current collections and total collections, with irrigation intensity, have downward trends in **Table 5, Figure 16**). Total ISF collections as part of total income and collection efficiency correspondingly drastically declined.

Banaoang

Banaoang in Ilocos Sur is a newly completed system, thus data only started in 2010. So far, a declining trend for service area and irrigated wet are reported while the ratios to current collectibles to total current collections and share of current to total collections trend upward. With already small farms, farmers were not willing to give up land for right of way or were not willing to pay for irrigation service. Due to this, the realized service area has been much lower than the designed area.

The same decreasing pattern can be seen for both O&M cost per service area and per FUSA. Lastly, both irrigation intensity and viability index trend downward (**Figure 17, Table 6**).

Ambayoan-Dipalo

Service area of Ambayoan-Dipalo dropped from 10,800 ha. to 2,445 ha. in 1974. It then recovered and settled at 6,300 ha since 1988. Irrigated areas during wet seasons generally showed a downward trend after 1976 while dry seasons fluctuated through the years with a slightly upward trend.

The system has a low collection efficiency never reaching above 50%. While, the collection efficiency as well as the ratio of ISF collections to collections and total income seemed to increase slightly in the later years. Shares of back account collections generally showed an increasing trend from 1989 to 2008. Cropping intensity as ratio of the sum of irrigated wet and dry area to either irrigated wet or dry area showed an upward direction over time reaching up to 157% in 2013. On the other hand, O&M cost per service area followed a downward path after its peak in 1992. Viability index rose from 33% to 131% in 2013 (**Figure 18**).

Table 7 shows additional indicators to profile these two systems. The coverage area per staff spiked to 578 ha per staff in 2013. This relatively big coverage per staff might hinder the staff from providing the necessary services to their assigned areas. The gaps between irrigated area and FUSA during dry season ranged from 62% to 75% are higher compared to wet season which only ranged from 18% to 43%. These gaps are likely caused by lack of water supply and defective facilities. But, despite of these gaps, benefited to irrigated area showed high ratios across the year averaging at 97% during wet seasons and 94% during dry seasons.

Most of the total income comes from current account collections averaging at 57%, followed by the other income like equipment rentals at 23% and then, by back collections at 17%. The system has very low collection efficiency and viability index compared to other systems averaging only at 19% and 62%, respectively.

Region 2 Cagayan Valley

Magapit Pump Irrigation System (PIS)

The service area of Magapit PIS has been increasing over time. In 2012, it more than tripled its size from 3,523 has in 1986 to 11,875 ha. Actual irrigated areas during wet and dry seasons also correspondingly increased (**Figure 19**).

Collections and income ratios fluctuated over the years (**Table 8**). Shares of current and back collection to total collection moved symmetrically at opposite trends from each other. Ratios of irrigated area to FUSA during wet season fluctuated towards 50% while during dry seasons it fluctuated towards 100%. The ratio of benefited area to irrigated area during wet season seemed to stabilize in the later years while dry season showed a slightly downward trend. Cropping intensity fluctuated towards 150% from 1993 to 2012. O&M cost per service area also showed steep movement over the years having peaks up to PhP 4,672/ha in 1991 and dips up to 417 in

2012. Viability index exhibited an increasing trend starting at 39% in 1986 and ending at 115% in 2013.

Filled-up plantilla position was constant at 53% from 2010 to 2013. FUSA to filled-up plus daily staff also had minimal changes, ending at 306 ha. per staff in 2013. The ratios of actual irrigated areas to FUSA are much lower in the wet seasons, averaging 45%, compared to dry seasons which average of 89%. This pattern is likely caused by calamities or floods during the wet season.

Collection efficiencies in terms of ratios of ISF current account and total ISF (current plus back accounts) to total income do not show any clear trend. The ISF collections comprise 73% of total income over the years. Viability index, despite its fluctuations, generally followed an upward trend peaking at 254% in 2012.

Visitacion Irrigation System

Visitacion in Cagayan is an interesting case because it was a communal system which has been converted to an NIS. Apparently, funding constraints led to the slow pace of development of irrigation facilities of Dagupan CIS. In addition, the inadequate staff of NIA resulted in the poor social condition of water users because of the disorganized IA which led further to the deterioration of irrigation facilities. This condition motivated the IAs, with strong support from the LGU of Sta. Ana to pursue the conversion of Visitacion CIA into an NIS. The thinking was that, with the conversion, the funding problem would be addressed and the system will be restored to its fully operational condition and fully developed.

Collection efficiency tends to fluctuate through the years with no clear trend while the other collections and income ratios appear to be stable (**Figure 20**). The ratios of benefited to irrigated areas do not show any clear trends. Cropping intensity, on the other hand has been increasing and reached 122% in 2013. The same trend is observed with the O&M cost per SA and viability index (**Table 9**).

There is no data on filled-up plantilla positions of Visitacion. In the last 5 years, no land conversion has been reported with FUSA equal to SA. But ratios of actual irrigated area to FUSA show relatively low averages of 50% during the wet season and about 30% in the dry season. These low irrigation intensities are essentially due to the poor physical state of the irrigation system, defective facilities and lack of water supply.

The ISF current account collection accounts for the system's income averaging at 99%. The cropping intensity has an increasing trend despite drops in various years. Viability index also exhibits the same upward trend from 103% in 2004 to 193% in 2013.

Solana-Tuguegarao Pump Irrigation System

The service area of Solana-Tuguegarao barely increased from 2009 onwards (**Figure 21a**). FUSA remained constant over the years. But with the increase in service area in 2009, the gap between FUSA and SA increased to 12 % indicating land conversions and uncovered permanently non-restorable areas.

Actual irrigated area started increasing around mid 2000s. These changes are consistent with the installation of a new pump house in March 2002 under the Water Resources Development Project (WRDP) Fund. This project was completed in 2003 and became operational during the wet season crop in 2004.

The ratio of actual irrigated area to FUSA in wet season has a higher average over the years compared to dry season. But, in terms of ratios of benefited area to irrigated area, dry season crop did better indicating substantial areas during wet being exempted –either because of damage from calamities or pests and diseases.

The ISF accounts for much of the system's income averaging 87% over the years although its share to total income dropped in 2009 and 2013 as other incomes like equipment rental increase during these years (**Table 10**). Collection efficiency has sharp fluctuations exhibiting drops below 50% over the years. Starting in 1997, the share of current collection to total collections, on the other hand, seemed to stabilize at 100%. Cropping intensity fluctuated over the years but showed an increasing trend in the later years. O&M expenditure per ha has been increasing over time starting at PhP. 2,611/ha in 1990 and PhP 12,669/ha in 2013. The same is true even for the O&M over FUSA. In terms of viability of system (revenues exceeding O&M expenditures), the system appears to be generally not viable except in 2009 and 2012.

Magat River Integrated Irrigation System (MRIIS) Division 2

Figures 22a to f show trends in key performance indicators for MRIIS 2. Service area is among the largest of national systems at 23,241 ha until 2013 and when it increased to 25,718 ha. Actual irrigated areas showed modest increases as they already approach the firmed-up service area, indicating the system is almost fully operational. Aside from the share of ISF collection to total income and collection efficiency which showed an upward trend in later years, ratios of collections and income fluctuated towards the same level in earlier years. Cropping intensity as a ratio of irrigated wet plus dry over FUSA generally has an upward trend despite dips in various years. O&M cost per service area and O&M cost per FUSA moved with the same upward trend. Viability index has a downward trend and exhibiting drops below 100%.

Looking at the ratio of filled-up plantilla positions to approved plantilla and firmed-up service area, the coverage area per staff has increased from 225 ha in 2004 and increased to 399 ha in 2013 (**Table 11**). The gaps between actual irrigated areas in both wet and dry seasons and FUSA over the years do not exceed 5%. Inadequate and/or defective facilities account for these gaps. The ratios of benefited areas to irrigated areas across the years averaged 96% during dry season and 91% in the wet season indicating little crop damage by calamities and crop infestations.

Magat River Integrated Irrigation System (MRIIS) Division 4

MARIIS 4 service area and firm-up service area have hardly changed over time until 2013 when service area increased to 24,000 ha (**Figure 23**). Actual irrigated areas generally exhibited an upward trend over the years.

The ratios of ISF current collection to total income moved in an upward trend starting in 2006 (**Table 12**). The same upward pattern is observed of its collection efficiency reaching up to 83% in 2013.

Shares of current and back collection to total income moved across the years in more or less the same level they started. Benefited area during wet season moved through the years with more dips compared to dry season. This might be due to occurrence of calamities like typhoons and flooding during wet seasons. Cropping intensity as a ratio of irrigated wet plus dry to FUSA has an upward trend. O&M cost per service area as well as the O&M cost per FUSA exhibited peaks and dips in various years but generally has an increasing trend. Viability index fluctuated over the years with a slightly decreasing trend exhibiting dips below 1.0 in various years.

The ratio of filled-up plantilla positions to approved plantilla fluctuated as the plantilla positions varied annually. The coverage area per staff has a slightly increasing trend reaching 342 ha per staff in 2013. The gaps of irrigated areas and FUSA reached 10%. This is likely due to defective or inadequate facilities. Ratios of benefited area to irrigated area during wet season are much lower averaging only at 87% compared to the 96% during dry season. This might be due to occurrence of calamities like typhoons during wet seasons.

Despite the dips in various years, the ratios of ISF collection to total income as well as collection efficiency have been increasing over time. Viability index, on the contrary, fluctuated downward with dips reaching up to 0.74 in 2008.

Region 3 Central Luzon

Angat-Maasim River Irrigation System (AMRIS)

Angat-Maasim in Bulacan has an unchanged service area (**Figure 24**). However, it may be important to note the big dips in areas for irrigated dry and wet from highs of almost 30,000 has. to below 15,000 has. in 1990 and 2005 respectively.

No clear trend with the collections and income ratios can be established (**Table 13**). In 1998, shares of back to total collection and total collections to current collectibles peaked at about 90%. On the other hand, shares of current to total collections, total ISF collections to total income, and current collections to current collectibles dipped and recovered slightly after. It seems interesting to note that all measures seem to converge towards 50% in 2013. Cropping intensity as ratio of the sum of irrigated wet and dry area to FUSA does not fall below 150%. O&M cost per service area was declining from about PhP1,700 per hectare in the 1980s to less than PhP1,000 per hectare in 2013. On the contrary, viability index constantly rose to almost 1.5 in 2013.

Filled-up plantilla position was constant at 39% from 2008 to 2013. FUSA to filled-up plus daily staff also had minimal changes, increasing slightly to 203 ha per staff in 2013. Though irrigated areas in the wet season is lower back in 2004 with a 30% gap, it has closed the gap by half with the irrigated dry as it increase to 83% in 2013.

Ratios to total income of ISF current account and total ISF and collection efficiency appear to have a downward tread. On the other contrary, ISF back account ratio to total income and viability index both increased across the years.

Pampanga Delta River Irrigation System (PDRIS)

Pampanga Delta's service area has been pegged at 8000 ha over the years with a slight increase in 2013 (**Figure 25**). Actual irrigated area in the dry season has been increasing over the years, reaching over 5,000 ha in 2013. On the other hand, wet season actual irrigated area has been generally low with over 2,000 ha in 2010 and only 433 ha in 2012. There is also no clear trend for the share of total ISF collections to total income, though it started at near 100% with a general downward direction (**Table 14**). Cropping intensity as ratio of the sum of irrigated wet and dry area to FUSA in Pampanga Delta is generally increasing with downward dips in 2010 and 2012. O&M cost per service area was increasing before 2005, however as data for O&M cost per FUSA became available, it followed its downward trend. Viability index dropped greatly in 2003, but it has recovered and has averaged at about 1.0.

FUSA per staff, which includes both filled-up and daily staff, averages at around 262 has. This relatively stable movement is also seen for FUSA per service area averaging at around 72.

Irrigated wet per FUSA averaged at about 10% with peak at 32% in 2011. On the other hand, actual wet irrigated area over FUSA remained more than double the dry ranging from 34% to 52% in 2013. This gap may be due to defective or inadequate facilities like lack of drainage.

The ratios of ISF current account to total income, total ISF to total income, and collection efficiency follow downward but fluctuating trends from 97%, 97%, and 94% respectively in 2003 to 83%, 87%, and 52% respectively in 2013.

Tarlac Groundwater Irrigation System (TGIS)

Given the interest in the viability and sustainability in deepwell irrigation, the TGIS was selected. However, there is hardly any information on the TGIS at the Central Office. Going to the field office, we found that data for the systems under the TGIS hardly exist except for the personal notes of the irrigation development officer (IDO) in-charge of amortization payments. The TGIS is actually 72 CIS systems which have been clustered and listed as among the NIS which partly explains the lack of data.

So, in place of the TGIS, the team decided to cover TASMORIS instead. Highlights of the interviews of IA officers from three TGIS systems are in **Annex 1**.

Tarlac-San-Miguel O'Donell River Irrigation System (TASMORIS)

TASMORIS's service area has a generally declining trend starting at about 20,000 has. and dropping to 5,000 has. from the 1960s until 2009 (**Figure 26**). However, it recovered in the later years reaching 15,000 has. in 2013. The same trend can be observed for irrigated areas during both wet and dry seasons. Movement of collections ratios have no clear trend, but all measures experienced a huge dip in the early 2000s. Cropping intensity as ratio of the sum of irrigated wet and dry areas to either wet or dry generally falls below 150%, but starting in 2006 rose above 150%. TASMORIS' viability index generally has an upward trend.

Only 15% of plantilla positions are filled up likely due to either lack of funds or qualified applicants (**Table 15**). FUSA per filled-up position increased more than twice in five years with 596 ha as coverage per staff in 2013. This large coverage and lack of resources may hinder the staff from properly working on their assigned area.

The ratio of irrigated area during the wet season to FUSA almost always remained double the ratio during the dry season from 2004 through 2013. This gap may be due to defective or inadequate facilities like lack of drainage.

Ratios to total income of ISF current account, ISF back account, and total ISF were relatively stable, along with collection efficiency. On the other hand, viability index fluctuated greatly with a peak of 147 in 2008 and low point of 42 in 2013.

Upper Pampanga River Integrated Irrigation System (UPRIIS), Division 2

Figure 27a shows UPRIIS Division 2 service area has a slightly declining trend experiencing significant dips in 1994 and 2005. It dropped from 25,327 ha in 1976 to 24,000 has. in 2013. Irrigated areas also had big dips in various years especially during dry seasons. But, starting in 2004, they moved in a more or less stable manner following FUSA's trend. The share of total ISF to total income fluctuated across the years but stabilized starting in 2002. As share of back collection increased, share of current collectible to total collections fluctuated downward. Collection efficiency and total collections to current collectibles had an upward movement. Cropping intensities had drops over the years but seemed to smoothen out in the later years. O&M costs over service area (SA) followed the same pattern stabilizing at ₱1000 starting in 2003. Viability index fluctuated and exhibited an upward trend in the later years.

With the reduction of plantilla positions in 2009, the filled-up position per plantilla ratio has remained above 90% (**Table 16**). With this, FUSA per filled-up staff including daily staff average at around 350 ha in the past five years. UPRIIS's FUSA generally increased over time as well as its irrigated area closing the gap between FUSA to only 307 has. in 2013. Ratios of benefited area to irrigated area had fewer fluctuations compared to wet seasons averaging across the years at 97% and 90%, respectively. ISF current accounts make up majority of the total income averaging at 83% over the years, followed by back account collections at 12% and the rest from other incomes like equipment rentals.

Upper Pampanga River Integrated Irrigation System (UPRIIS), Division 3

UPRIIS Division 3 service area averaged at about 27,000 ha until the early 2000s (**Figure 28**). Despite its big drop in 2008, its trend has been increasing. This rising trend is followed by the FUSA and actual irrigated areas during both wet and dry seasons.

Table 16 shows the shares to total income of current, total ISF collections, and back collection. These measures appear to be moving together over time. However, after 2005, share of back to total collection moved opposite the rest until 2013 (**Table 17**). It is interesting to note that cropping intensity moved similarly with irrigated area in the dry season, where downward fluctuations were prominent until the late 1990s. O&M costs over service area (SA) averaged below ₱1000 and the same is true even for the O&M over the firmied-up service area (FUSA). Viability index fluctuated but appears to be generally increasing.

From 2008 with only 24% of its plantilla positions filled-up, the ratio increased in the succeeding years reaching 107% in 2013. The FUSA to filled-up plantilla in the past five years averaged at 400 ha/staff while the ratio to both plantilla and daily staff averaged at o 300 ha/staff.

The FUSA is increasing over time. Actual irrigated areas in both wet and dry seasons do not have a clear trend. The ISF current account ratio to total income slightly fluctuated over the years, with highs from 2008 to 2010. A similar pattern can be seen for ISF back accounts to total income ratio, with highs from 2004 to 2006. Total ISF collections comprise most of total income while collection efficiency averages at about 50%.

Upper Pampanga River Integrated Irrigation System (UPRIIS), Division 4

Figure 29 shows the service area for UPRIIS 4 fluctuated across the years, with 20,000 ha in the 1960s and mid-2000s, and ending 2013 back to 25,000 has. Irrigated area during the wet season dominated the dry season's until 2005 where the former was consistently outnumbered. Irrigation intensity had similar movements with dry actual as it continued with an upward trend in recent years. On the other hand, shares to total income of current and back collections appear to move in opposite directions. O&M costs per service area decreased after 1997 to PhP500 per ha in 1999. However, the average O&M remains below PhP1,000 although has been increasing after 2010.

Filled-up positions for plantilla started with 23% in 2008 and improved significantly ending 2013 with 86% (**Table 18**). FUSA covered by staff, both for filled-up and daily staff, were at 486 has in 2013 despite variable fluctuations in previous years.

Ratios of irrigated wet and irrigated dry to FUSA appear to move in similar directions and have little to no gap across the years. ISF current account as part of total income did not change variably unlike ISF back accounts as part of total income, which experienced a decline after 2007 but recovered back in 2011. Collection efficiency is slightly higher at around 60%. However, viability index is lower than the others at 180 percent.

Region 4A CALABARZON

Cavite Friar Lands (Balayungan RIS)

While the system actually visited was Balayungan, the trends reported in this section pertain to the entire Cavite friar land irrigation system (FLIS). Cavite FLIS' service area has been decreasing over time (**Figure 30**). It started at 15,000 ha in 1967 and was at 13,500 ha in 2013. The actual irrigated area during wet season declined over time increasing the gap between the service area by 8,725 ha in 2013. During the dry season, even with the slightly increasing trend of actual irrigated area, the gap is bigger at 9,545 ha in 2013. This gap is mainly due to the lack of water supply and aggravated by inadequate and/or defective facilities. The ratio of benefited area to irrigated area has been consistently rising during dry seasons while decreasing in the wet seasons.

Collection efficiency fluctuated above 50% despite dips in several years. Contributions of back account collections averaged 17% over the years. Cropping intensity as ratio of the sum of irrigated wet and dry areas to either irrigated wet or dry seemed to increase over time reaching up to 183% in 2013. O&M cost per service area displayed steep variations through the year but levelled out starting 2002. Viability index showed no clear trend over the years.

In 2012, the staff had been reduced to 32 from 74, increasing the coverage area per staff to 265 ha from 115 ha (**Table 19**). During the wet season, the gap between irrigated area and FUSA ranged from 23% to 44%. While during dry season, the gap is even bigger ranging from 52% to 72%.

These gaps are probably caused by lack of water supply and aggravated by defective facilities. But, despite these gaps, benefited to irrigated area showed high ratios of 91% during wet seasons and 99% during dry seasons.

About 77% of the total income comes from current account collections while 17% from back account collections. Collection efficiency showed no clear trend throughout the years but has a relatively high average at 73% compared to other systems. The viability index also displayed no clear course averaging at 96% over the years.

Dumacaa-Hanagdong-Lagnas

The service area of Dumacaa-Hanagdong-Lagnas has been stagnant over the years at about 3,300 ha from 1994 to 2013 (**Figure 32**). The actual irrigated areas during wet and dry seasons have been almost stagnant with minor declines in 1980 and 1998. The ratio of benefited area to irrigated area as well as the ratio of irrigated to FUSA exhibited minimal fluctuations except for sharp dips in 1981, 1982, 1988 and 2001.

The ratios of collections to collectibles and income, on the other hand, exhibited sharp fluctuations throughout the years. But, despite these fluctuations, collection efficiency and share of current collections to total collection depicted an increasing trend.

In spite of fluctuations over the years, cropping intensity appears to be increasing. O&M cost per service area tend go towards PhP1,000 per ha. after its drop to PhP518 per ha. in 2000. Viability index rose from 56% in 1998 to 253% in 2013.

Even with the reduction of plantilla positions from 51 to 12 in 2012, the coverage area per staff of 229 ha is still relatively low compared with the other systems (**Table 20**). Ratios of benefited area to actual irrigated areas showed relatively high averages at 94% during wet season and 97% during dry season.

Sixty percent (60%) of the total income are obtained from current account collections. This source is followed by back accounts collections averaging at 35% and other income at 5%. The collection efficiency averaged only at 51% but rose in the later years. The viability index has been fluctuating over the years but t showed an upward trend in the later years and reached 253% in 2013.

Region 4B MIMAROPA

Caguray RIS

Starting in 1988, the service area of Caguray remained constant at 3,308 ha (**Figure 31**). The actual irrigated areas, however, fluctuated over the years and had been generally low during dry seasons. This is mainly due to inadequate water made worse by defective facilities. The ratio of benefited area to irrigated area also followed the same trend and reaching below 50% in various years.

The ratios of collections and income showed sharp fluctuations with no clear trends (**Table 21**). Cropping intensity as ratio of the sum of irrigated wet and dry areas to either irrigated wet or dry area whichever is bigger generally falls below 150%. O&M cost per service and viability index wavered throughout the years exhibiting no clear directions.

Despite the fact that only 47% of plantilla positions are filled up, the average area per staff is only 142 ha which is much better compared with the other systems. There is a big gap between actual irrigated areas and FUSA especially during the dry seasons where the ratios average 17%. This phenomenon is consistent with the ratio of benefited areas to actual irrigated areas during dry seasons averaging only at 75% compared to the 95% during wet seasons. Inadequate of water and inadequate or defective facilities are the likely causes of these gaps.

Majority of the income comes from collections of current account averaging at 78% and followed by other income at 15%. Collection efficiency averaged only at 55% across the years exhibiting no clear trend. The viability index also showed no clear trend averaging at 99% through the years.

Region 5 Bicol

Libmanan-Cabusao

The service area of Libmanan-Cabusao has been generally decreasing from 3,427 ha to 2,195 ha in 1986 (**Figure 33**). However, irrigated areas during both wet and dry seasons showed no clear trend.

The collection and income ratios exhibit steep variations with no clear trends. Same sharp fluctuations are observed with the ratios of benefited to irrigated area, irrigated to FUSA and cropping intensity. O&M cost per service area, on the other hand, has a clear downward direction from Php3,263 per hectare in the early 1980s to less than Php500 per hectare in 2013. On the contrary, viability index despite its dips in various years tend to have a slightly increasing course from 35% in 1983 to 83% in 2013.

The filled-up plantilla positions remained constant at 22% from 2009 to 2013 (**Table 22**). FUSA to filled-up plantilla plus daily staff also has hardly changed, increasing slightly to 366 ha per staff in 2013. The ratio of irrigated area to FUSA averaged only around 53% to 56%. This is likely due to defective facilities and inadequate equipment like main irrigation pumps.

The ratios of ISF current account and total ISF fluctuated through the years following the movement of collection efficiency. The ratios of benefited area to irrigated area sharply declined in 1999 and 2013 reaching below 50%. The O&M cost to SA generally appeared to have a downward direction dropping from Php3263/ha to Php422/ha. in 2013. Despite low levels in various years, the viability index seemed to have a slightly increasing trend starting from 35% in 1983 and ending at 83% in 2013.

ANALYSIS AND CHARACTERIZATION OF THE SAMPLE NIS

This study examines 22 NIS cases by province, size (large, medium, small), technology (gravity type vs pump type), location (upstream, midstream, downstream), vintage, and by some measures of “success”.

For vintage of systems, the sample is classified into three periods: pre-NIA, 1965-1980, 1980-onwards. For size, the sample systems (and effectively the IAs) is classified into large, medium and small according to their firm-up service area (FUSA). IAs with FUSA size of above 5,000 ha are classified as large. IAs falling between 1,000 and 5,000 ha FUSA are classified as medium while those with FUSA below 1000 ha are classified as small.

Then following NIA’s loose definition of successful IAs, the sample IAs is classified into “successful” and “less successful”. The first group are those that satisfy the following criteria: NIA’s functionality survey rating of very satisfactory to outstanding, IA’s own financial rating of at least 3, with 4 as very strong, IA’s ISF collection performance rating of 3 to 4 with 4 as excellent and/or having a collection rate of 65% and above. On the other hand, “less successful” IAs are defined as those which satisfy the following criteria: NIA’s functionality survey of poor to satisfactory, IA’s own financial rating of 0 to 2 with 4 as very strong, IA’s ISF collection performance rating of 0 to 2 with 4 as excellent and/or having a collection rate below 65%.

These typologies capture various technical and institutional aspects of providing irrigation service by national systems. Pump systems will have different challenges from reservoir and diversion systems. Size of IAs based on firm-up service area will likely be correlated with complexity of design, and operation of physical structures and facilities, and the corresponding type of management. Vintage entails different technical and institutional concerns between relatively old vs. newer systems. “Successful IAs” entail institutional factors at play but also probably technical aspects contributing to such performance.

By Province

The characterization of the sample NIS according to province is captured in various tables (**Tables 23.1 to 23.18**).

The IA sample of Bulacan reported lack of facilities like farm-to-market roads (FMRs) and high occurrence of calamities like pest infestations as key concerns. On the brighter side, the IAs have relatively high functionality ratings, reported the minimum count of irrigation structure problems and moderate occurrence of siltation problem.

The Cagayan sample IAs did not report inadequate water supply as a problem. All the IAs claimed high collection efficiencies. However, these IAs are characterized by the following as problems in decreasing order: low yield due to pest infestation, lack of facilities/infrastructure like solar driers

and FMRs, deteriorated lateral canals, siltation problems, and institutional problems like water theft.

The Camarines Sur sample is saddled with of inadequate water supply, lack of machineries and equipment like pumps, low functionality survey ratings, financially weak IAs and high occurrence of poor structure design. On the plus side, the IAs have minimal problems in their irrigation canals and irrigation structures, no occurrence of siltation problems and lack of facilities.

The Cavite sample reports high counts of FMR problems, institutional problems like water theft and lack of discipline among members, low functionality survey ratings, high percentage of financially weak IAs, low buying price of produce, occurrence of siltation, headwork and lateral canal problems.

The hierarchy of prevailing problems of Ilocos Norte IA sample is as follows (in decreasing order): inadequacy of water supply, lateral canal problems and siltation problems. On a positive note, the IAs did not report institutional problems as key concerns, FMR problems or lack of facilities. A high collection rate is reported.

Ilocos Sur sample IAs does not consider inadequacy of water supply during dry seasons as a key concern, and reported moderate count of irrigation canal problems, minimal siltation problems, moderate institutional problems like lack of safety policies and training and generally have high collection efficiencies. But, half of these IAs have problems with the main and lateral canals.

The dominating negative features of NIS systems reported by the Isabela sample IAs are as follows (in decreasing importance): irrigation main canal, lateral canal and control structure problems, institutional problems like lack of policies and water theft, crop production problems due to calamities and pest infestations/diseases and occurrence of siltation. But, all sample IAs reported adequate water supply, no occurrence of flooding, very high IA functionality ratings and very strong financial position.

The Nueva Ecija sample IAs reported adequate water supply, no occurrence of siltation problems, minimal problems in their irrigation structures, low counts of problems in their FMRs and lack of facilities, and minimal occurrence of flooding. Furthermore, they only have slight institutional concerns like few hard headed members and water theft.

Mindoro Occidental sample IAs consider inadequate water supply especially during dry season as a key problem, followed by very high siltation problems and high occurrence of headwork and canal problems. However, the IAs have not reported flooding, calamity/pest infestation problems and problems with lacking facilities, machineries and equipment, as important concerns.

Most of the Pampanga sample IAs have control structure problems like damaged or vandalized check gates. They also encounter several institutional problems, like water theft and delinquent members and flooding problems due to low level areas acting as catch basins in the wet season.

The Pangasinan IAs generally exhibit many irrigation structure problems, especially headwork and control structures, inadequacy of water supply, siltation problems, deteriorated FMRs, and lack of machineries (e.g. backhoe for dredging works).

IAs sample from Quezon showed the following problems in decreasing order: inadequate water supply, irrigation canal problems, institutional concerns like water theft, and solid waste deposits in canals. Given the problems, majority of these samples are considered less successful IAs.

The Tarlac IA samples experience the following predominant problems, in decreasing severity: water supply inadequacy, solid waste in canals, and siltation problems. On the contrary, these IAs do not experience flooding, have only slight irrigation structure problems, and relatively high collection efficiencies.

Table 23.1. NIS IA Profile, Cropping Information and Financial Aspects by Province

Provinces	No. of IA sample	Ave. of No. of Members	Ave. of No. of Farmers-Landowner-operator (%)	Ave. of No. of Farmers-Tenant (%)	Ave. of No. of Farmers - Lessees (%)	Does IA have water permit? By Size

Characterizing the NIS sample according to size provide some useful insights (**Tables 24.1 to 24.19**).

The 64 IA NIS samples are not well distributed by size, as defined above. Small sized IAs come from only one province. These IAs reported the highest incidence of water scarcity in the dry season, flooding in the wet season, canal problems (e.g. lateral canals), and siltation/solid waste problems. These IAs are financially weaker compared to the medium and large ones.

Medium-sized systems/IAs come second in severity of water scarcity in the dry season and siltation problems. They have the highest count of problems of irrigation headwork and main canal. They also have the highest count of lacking facilities or damaged FMRs. On the other hand, they have reported flooding and the lateral canal and control structures problems as their least concerns. In terms of gravity, institutional problems comprising of water theft, lack of discipline and conflict among members, lack of policies and weak policy enforcement have been identified. These are followed by inadequacy of water and irrigation structure condition problems.

Large systems/IAs indicated adequate water supply, least occurrence of siltation problems, lowest count of irrigation headwork and main canal problems, minimal occurrence of flooding and adequacy of budget. Furthermore, they have a high percentage of “successful” IAs compared with the small and medium size IAs. On the flip side, they come second in terms of lateral canal and control structure problems, lack of facilities/infrastructures and institutional problems like lack of policies and weak enforcement of their laws. In this sample IAs, institutional problems have the highest count, followed by irrigation structure problems and lastly, production problems caused by calamities/pest infestations.

By Technology

Tables 25.1 to 25.19 provide the profiles of the NIS sample in terms of technology: gravity, reservoir and pump.

There are three types of irrigation technologies, irrigation by gravity, use of pump technology, and reservoir systems. IA samples irrigated by gravity experience the most severe water supply shortage in the dry season. Other problems they experience include flooding, irrigation headwork and control structure problems, deteriorated FMRs, and having several financially weak IAs. On the contrary, IAs irrigated by gravity have the least irrigation canal and institutional problems, and second for siltation problems.

IA samples that use pump technology have adequate and dependable sources of water, do not experience flooding problems, and have higher collection efficiencies compared to the gravity system IAs. However, these IAs also have the highest incidence of siltation problems lateral canal, and institutional problems. The most prevalent problem among this group is the poor condition of their lateral canals, accompanied by problems induced by lack of machineries and equipment (e.g. backhoe and back-up pumps).

Reservoir systems appear to be the most successful of the three technologies. In general, the sample IAs had adequate water supply, low count of siltation problems, with more financially strong IAs, high functionality survey ratings, and high collection efficiencies. On the contrary, they also have the most number of deteriorated FMRs and the worst main canal conditions. Other problems are institutional, and those caused by calamities and/or pest infestations.

Table 25.1. NIS IA Profile, Cropping Information and Financial Aspects by "Technology"

By Location

Following earlier studies (Cablayan, Inocencio, et al 2014), location of the IAs relative to the main canals of the NIS (upstream, mid-stream, downstream) is a key factor influencing performance. **Tables 26.1 to 26.19** show the IAs profiles by location.

Downstream IAs in the sample are characterized by high count of siltation and/or solid waste problems, water supply shortages, flooding in the wet season, damaged FMRs, financially weak IAs, and low ratings of water delivery service (i.e. in terms of adequacy and timeliness). In addition, other problems include institutional, crop production and irrigation canal problems. On the positive side, downstream IAs have no issues with their irrigation headwork and control structures.

Midstream IAs are almost the opposite of the downstream IAs. They have the least solid waste/siltation problems, no flooding problems, low count of damaged FMRs, main canal, and lateral canal problems. Despite lacking machineries and equipment, they face the least problems brought by the deficiency. However, midstream IAs showed the most irrigation control structure problems, least number of facilities/infrastructure, and the most institutional problems.

Prominent attributes of upstream IA group are low incidence of water supply shortage and solid waste/siltation problems and a high percentage of financially strong IAs. This group also experienced the following problems, in order of decreasing severity: , irrigation structure problems (e.g, irrigation canal), institutional problems, cropping problems due to calamities/ pest infestation, and inadequate machineries and equipment.

Table 26.1. NIS IA Profile, Cropping Information and Financial Aspects by "Location"

Location	No. of IA sample	Ave. of No. of Members	Ave. of No. of Farmers-Landowner-operator (%)	Ave. of No. of Farmers-Tenant (%)	Ave. of No. of Farmers-Lesseees (%)	Does IA have water permit? By Vintage

Tables 27.1 to 27.19 report the profile of the sample NIS according to vintage covering the pre-NIA and post NIA eras.

IAs with systems built before establishment of NIA generally have few irrigation structure problems, sufficient machineries and equipment, and adequate water supply. However, they lack facilities, lateral canal problems, and have the lowest ratings in NIA's functionality surveys, indicating poor management performance.

IAs constructed between 1965 and 1980 predominantly have irrigation headwork and control structure condition problems, problems brought about by lack of machineries and equipment, financially weak IAs, lack of water supply, damaged FMRs, cropping problems due to calamities/pests. On the other hand, they have the least occurrence of institutional problems and siltation/solid waste problems.

Generally, IA systems built from 1981 to 2013 are financially strong, successful, experience the least flooding, have adequate water supply, and have FMRs in good condition. However, they also exhibit the most and lateral canal problems, siltation problems, and institutional problems.

Table 27.1. NIS IA Profile, Cropping Information and Financial Aspects by "Vintage"

Vintage	No. of IA sample	Ave. of No. of Members	Ave. of No. of Farmers-Landowner-operator (%)	Ave. of No. of Farmers-Tenant (%)	Ave. of No. of Farmers-Lesseees (%)	Does IA have water permit? By “Success”

The characterization of the sample according to a measure of “success” is reported in **Tables 28.1 to 28.19**.

The NIA IA Functionality Survey classifies the IA into either successful or less successful, where data collected from the field are few. In the samples, successful IAs generally have adequate water supply, few institutional problems, high functionality survey ratings, sufficient budget, and fewer problems due to lack of facilities, machineries and equipment. Despite these good attributes, these IAs still exhibited cropping problems due to calamities/ pest infestation, severe siltation problems, and condition problems for main canals, lateral canals, and control structures

On the other hand, less successful IAs experience water shortage in the dry seasons, irrigation headwork problems, problems due to lack of facilities, machineries and equipment, inadequate budget, and low ratings in functionality surveys

Table 28.1. NIS IA Profile, Cropping Information and Financial Aspects by "Success"

Classification	No. of IA sample	Ave. of No. of Members	Ave. of No. of Farmers-Landowner-operator (%)	Ave. of No. of Farmers-Tenant (%)	Ave. of No. of Farmers-Lesseees (%)	Does IA have water permit? (answer: no)	Does IA have water permit? (answer: yes)	Does IA have water permit? (no answer)	No. of Crops Irrigated: rice only	No of Crops Irrigated: rice and other crops	No. of IAs paying SF/DCC/ amortization

Technical and Institutional Issues and Concerns across the 22 Sample NIS

Tables 29-31 show the summary of technical/environmental and institutional issues and concerns across all the 22 NIS cases. This table reports siltation, damaged irrigation canals and control structures, double pumping and high operation costs when private pumps are used when NIS water is inadequate or not timely. For the environmental concerns, the high pH which can potentially result in sodicity and lack of data are dominant. For the institutional concerns, water theft, scheduling and distribution appear to be the more common concerns.

Overall Irrigation Performance Assessment⁸

In the initial development of Irrigation Performance Index (IPI) using PCA based on a small sample size of 64, results show that performance ranged from low to high level with majority of the IAs (37/64) having moderate level of performance as reflected in the IPI of the different NIS cases analyzed. The key indicators that affect the performance of NIS consist of Financial, Economic, Institutional, Technical and Environmental factors.

Within the *financial component*, the key indicators that posed significant contribution as computed by the PCA are: 1) IA's rate on their financial strength – this could imply the financial capability of the IA which could be critical in the organization's development; 2) Collection efficiency – a higher collection efficiency would mean higher capacity to pay the ISF and consequently more incentives for the organization; and 3) Collection delinquency – this indicator posed a negative relationship with the overall CPI since a higher delinquency would decrease the performance index of the IAs. This is expected since more uncollected ISFs would mean less incentive and could imply a very low capacity to pay.

Within the *economic component*, the indicators Annual yield and Annual gross profit posed significant contribution to the overall impact. Increase in the annual yield could also be consequent to the increase in the annual profit. An increase in any of these factors also indicates an increase in the overall CPI.

The significant indicators for the *institutional component* includes: 1) Effectiveness of policies; 2) Flexibility index rating; 3) Reliability index rating; and 4) Satisfaction rate on farm to market road availability. All institutional component indicators are based on satisfaction rating of IAs towards the policies implemented by NIA.

The *technical component* indicators include Canal structure's ease of operability and Canal structure's operability vs the design. Canal structure's ease of operability pertains to how easy it is to operate the structures such as check gates, turnout gates, etc. While Canal structure's operability vs design pertains to the comparison between the original designs of the irrigation system vs the actual use of the irrigation structure.

⁸ This section is drawn from Clemente, et al. (2015).

Finally, the *environmental component* indicators show that the Dissolve Oxygen content and acidity (indicated by pH content <5) posed significant effect to the overall CPI. Higher DO (i.e. > 6 ppm) and pH content (i.e. >5) means better quality of water. However, the pH found in most water samples show levels >7 which indicate alkaline conditions and can pose some sodicity problems in water quality if not addressed on time.

This impact assessment on performance is from the point of view of IAs and will have to be complemented or validated by technical data. However this initial assessment already provides some indication how an NIS is performing based on the overall index.

The results indicate that only 12% of the 64 sample IAs consider their systems' performance as "high" based on the five areas of irrigation service performance while 58% rated their systems' performance as "moderate" and the rest of the systems, low performance. These results indicate opportunities to improve overall irrigation service performance.

COMMUNAL IRRIGATION SYSTEM PROVINCIAL OR IMO TRENDS

To put the CIS institutional and technical assessments of 64 sample cases in perspective, trends in provincial or IMO data are analyzed. The national CIS trends are used as benchmark (**Table 32**, **Figure 34**).

Figure 34 shows the national trends in CIS performance. Service area has been growing but at a relatively slow pace while firmed up service area has been closely following. Given the relatively stable difference between the SA and FUSA, land conversion or growth in permanently non-restorable area does not appear to be a concern as it peaked at 10% but down to 4% in 2013. However, the trends in actual irrigated areas during the wet and dry seasons are much lower than the FUSA and faltered in 2012. In fact, the wet and dry seasons irrigation intensities never reached the 80% mark and even declined by about 20% in 2012.

The decline in collection efficiency has been steady and substantial from about 70% to just over 40%. The decrease in back account to collectible ratio is even more drastic. And yet, the share of actual current amortization to total income has been largely reduced indicating amortization collection has drastically dropped (Table 32). One explanation has to do with the reduction in the CIS staff due to the RatPlan which started in 2008 and confirmed by the drastic declines in the ratios of FUSA to plantilla staff even if the daily staff would be added. Another possible explanation is the remoteness of many CIS and the lack of operating funds which may have limited the efforts and effectiveness of NIA in collecting. A basic issue is that there is no incentive for NIA to collect because whether the IAs would pay the amortization or not, the CIS staff are paid salaries.

The O&M per ha had been declining since late 2000 although appear to be increasing again from 2012 (**Figure 35**). This pattern appears to be consistent with the observations of poor system maintenance

Figure 36 shows the regional trends in service area indicating where the developments had been in the last eight years. Hardly any change can be observed except in two regions – CAR and Region 1 and region 5 since 2012. Eye catching is the sharp decline in Region 2 which may be explained by the conversion of many CIS to NIS. Looking at the IMO or Provincial trends, it looks like the decline in Region 2 is largely happening in Cagayan, followed by Isabela and Nueva Vizcaya (**Figure 37**).

The regional trends in O&M and O&M per ha show a telling picture (**Figure 38**). Except for CAR & Region 1, Regions 2 and 8, the rest of the regions show declining spending on O&M/ha. **Figure 39** shows the trends for the sample IMO-Provinces clearly indicating where O&M spending are relatively better particularly in Region 2.

Interestingly, irrigation intensities are seen to be increasing in Regions 2 and 9 from 2012 onward, and generally in Regions 3 and 8 (**Figure 40**). The sample IMO-Provinces however, show only Pangasinan and Nueva Ecija as seemingly consistent with the increasing regional patterns in Regions 2 and 3 (**Figure 41**).

Figure 42 shows which regions show dismal collection efficiencies with below 50% or generally declining trends. It appears that the Mindanao CIS are doing far better. Among the IMO sample, Isabela and Nueva Vizcaya are doing better (**Figure 43**).

CAR

Benguet (part of Abra, Benguet-Ifugao-Mt. Province IMO)

Both service area and irrigated area had increasing pattern (**Figure 44**). While the ratio of total amortization to total income has a slightly increasing trend, total collection to collectibles and collection efficiency have no clear trend (**Table 33**). There is a small gap between and the irrigated areas in both wet and dry seasons. Minimal fluctuations are also observed between the ratios of benefited areas to irrigated areas. O&M cost per SA has a declining trend. In contrast, the viability index has been increasing over time. Cropping intensities have been showing nominal increases from 2012. .

In 2012, the coverage per plantilla jumped from 350 has. per staff in 2011 to 573 has. (Table 33). But, despite this increase, the coverage per staff is still better compared to other systems.

There is just a small gap between irrigated areas across the years reaching only 9% during wet season and 18% during dry season. This gap is mainly due defective facilities and inadequate water supply.

An average 62% of the total income over the years comes from equity. This is followed by equipment rental at 26% and then, amortization at 9%. Cropping intensity followed a stable trend. Viability generally had an upward trend.

Region 1 Ilocos

Ilocos Norte IMO

Figure 45 shows that Ilocos Norte's CIS service area dropped from 20,111 ha in 2005 to 7,124 ha in 2007 with FUSA following the same trend (Figure 30). But after 2007, it slightly increased. The gap between FUSA and the irrigated area is mainly due to lack of water supply especially during dry season. Amortization payments and collection efficiency have downward trends from 2006 to 2011 but started increasing in the later years. The cropping intensity and viability index generally have an increasing trend over the years.

Even if the filled-up plantilla positions are augmented by the daily staff, 76% of the plantilla positions are not yet filled up **Table 34**). One major reason for this is for cost reduction of overhead but this would result in a large coverage per staff of about 1,000 ha.

Figure 45. Trends in key performance indicators, Ilocos Norte IMO, Region 1, 2005-2013

d. Cropping intensity, (actual irrigated wet + actual irrigated dry)/FUSA

e. O&M per ha

f. Viability index

Sources: NIA-SMD CISPERS data, various years.

During wet season, the gap between irrigated area and FUSA ranges from 1% to 23%, while during dry season, the gap is bigger ranging from 22% to 71%. This gap is mainly due to lack of water supply in the dry season.

Majority of the total income comes from equity reaching up to 74% followed by CIS back amortization ranging from 5% to 85% and then, CIS current amortization ranging from 2% to 30%. The equity scheme had been chosen by the IAs because they received financial support from LGUs. Viability and cropping intensity generally have an upward trend.

Pangasinan IMO

Pangasinan's CIS service area dropped from 79,398 has. in 2005 to 21,854 ha in 2008 with FUSA following the same trend (**Figure 46**). But, it has a slightly increasing trend in the later years. There a big gap between FUSA and the irrigated area. This is probably due to lack of water supply especially during dry season where the gap almost tripled. Amortization payments and collection efficiency have a downward trend. Despite few dips, cropping intensities more or less moved at the same level. However, viability index generally have an upward trend over the years.

Even if the filled-up plantilla positions are augmented by the daily staff, the coverage per staff for CIS only is about 1,016 ha (**Table 35**). This is relatively big coverage per staff and without necessary resources the staff may not be able to properly cover their assigned area.

During wet season the gap between irrigated area and FUSA ranges from 19% to 85%. While during dry season, the gap is even bigger ranging from 46% to 90%. This gap is mainly due to lack of water supply.

About 64% to 90% of the total income comes from equity while 6% to 21% comes from amortization. Viability is not affected by the decreasing trend of amortization due to the increasing trend of equity generated.

Region 2 Cagayan Valley

Cagayan (Cagayan-Batanes IMO)

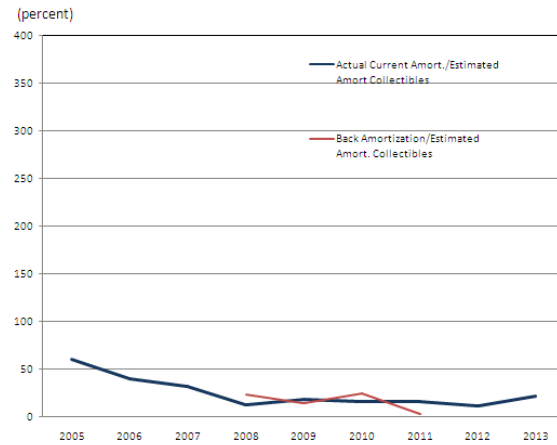

With minimal data, no clear trend can be seen on the Cagayan province CIS. But, the service area and actual irrigated area appeared to have increasing trends. Notable is the large gap between actual irrigated area and FUSA (**Figure 47**). This gap reached up to 34% in 2005 and is likely due to inadequate and/or defective facilities aggravated by lack of water supply. The ratios of collections and collection efficiency appeared to have a downward trend. Cropping intensity on the other hand, seems stable while the viability index is decreasing (**Table 36**).

Almost half of the income of the province is derived from amortization and the other half from equity payments.

Isabela IMO

Isabela CIS service area and irrigated area both had the same increasing trend across the years but dropped significantly in 2013 (**Figure 48**). It is interesting to note that as the SA drooped in 2013 O&M cost reached its peak. This drop is probably due to defective facilities like silted canals and lack of water supply. The ratios of total collections to collectibles, amortization to total income, collection efficiency and back amortization to collectibles had no clear trends. Over the years, cropping intensity increased to 200% despite dips in various years. The viability index, on the other hand, recovered at a lower index after it decreased in 2011 and 2012.

About 79% of the plantilla positions are not filled up yet as of 2013 (**Table 37**). But with the reduction of FUSA by more than half in 2013, the coverage per staff was also reduced from 3,643 ha to 1,464 ha. Yet even with this reduction, the coverage per staff is still large which consequently could result in a poor service.

The gap between irrigated area and FUSA reached 48% in wet season and 55% in dry season. This gap is likely due to defective facilities and/or lack of water supply.

The income consisted of equity collections followed by amortization and then, equipment rental. Cropping intensity generally moved toward 200% in spite of drops in various. Viability index, however, followed a declining trend with significant dips in 2011 and 2012.

Nueva Vizcaya IMO

Nueva Vizcaya IMO's service area and irrigated area slightly increased over the years but dropped significantly below 15,000 ha in 2013 (**Figure 49**). Inadequate water supply and defective facilities is the probable cause of the gap between irrigated area and FUSA. Amortization payments and collection efficiency generally have increasing trend over the years. The share of total amortization to total income dropped to 18% in 2013. This might be due to maintenance work since equipment rental peaked at 71% in the same year. The cropping intensities followed stabilized pattern in the later years with a slightly increasing trend. While viability index, on the other hand, fluctuated and seemed to have a downward trend.

Sixty-nine percent (69%) of the plantilla positions are not filled up yet (**Table 38**). With the reduction of FUSA by almost half in 2013, the coverage per staff was also reduced from 3,446 ha to 1,760 has. But, even with this reduction, the coverage per staff is still large that would consequently affect the quality of serve.

The gap between irrigated area and FUSA during both wet and dry season reached 22% and 19%, respectively. Defective and inadequate facilities coupled with lack of water supply are likely the reasons for this gap.

In the later years, majority of the farmers opted to pay amortization with the decrease of equity payments. Cropping intensities slightly fluctuated over the years while viability has a declining trend.

Region 3 Central Luzon

Pampanga (Pampanga-Bataan IMO)

Pampanga's CIS service area drastically dropped in 2008 as O&M/ha reached its peak due to a major O&M work (**Figure 50**). But, it gradually recovered over the years. The irrigated area is also increased reaching above 5,000 has. Many opted to pay equity reaching more than 50% of total income from 2008 up to 2010. Cropping intensities fluctuated across the years but generally had an upward trend. Viability index, on the other hand, did not improve over the years due to declining collection rate.

Table 39 shows that only 43% of plantilla positions are filled up due to lack of funds or lack of qualified applicants but probably more of the first. On average, each staff covers a bigger service area of about 398 ha. This is relatively a big coverage and without the necessary resources, NIA will be likely unable to deliver the expected service.

Although the irrigated area is increasing over time, there is still about 62% gap between irrigated wet and FUSA (Firmed-up Service Area) and about 50% between irrigated dry and FUSA in 2013. The difference in gap might be due to defective or inadequate facilities like lack of drainage.

CIS current amortization ranged from 1% to 31% of the total income while the CIS back amortization ranged between 3% and 32%. There is a big decline in amortization collection efficiency from 26% in 2005 to only 7% in 2013.

Nueva Ecija (Bulacan-Aurora-Nueva Ecija IMO)

Nueva Ecija's CIS service area almost doubled its size in 2012 but dropped back in 2013 (**Figure 51**). But, it gradually recovered over the years. The irrigated areas during wet season almost have the same areas as FUSA. But during dry season in 2008 to 2012, it falls down. The share of CIS current amortization to the total income is very minimal with a decreasing collection rate in the later years. Despite fluctuations, cropping intensities move smoothly between 2008 and 2012. Viability index generally increased over the years.

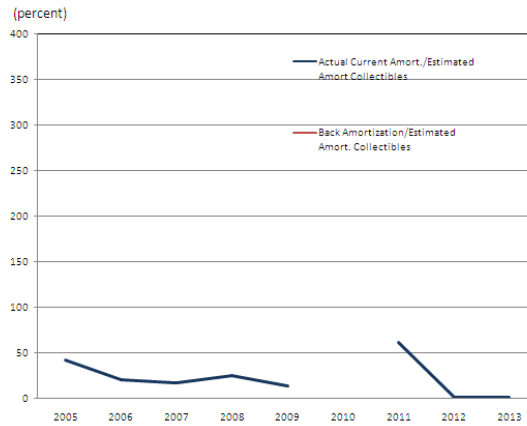

About 56% of plantilla positions are not filled up yet might be due to lack of funds or lack of qualified applicants but probably more of the first (**Table 40**). Aside from the NIS coverage of NIA staff, about 586 has. more for CIS is added to the staff's responsibility. This is relatively big coverage per staff and without necessary resources the staff may not be able to properly cover their assigned area.

More areas are irrigated during wet season by up to 37% more. This is mainly due to lesser available water during dry season.

Majority of the systems in Nueva Ecija opted to pay equity ranging from 68% to 99% of total income while CIS current amortization only ranged from 1% to 5% of the total income. There is a big decline in amortization collection efficiency from 20% in 2005 to only 1% in 2013.

Region 4A CALABARZON

Laguna (Laguna-Rizal IMO)

The service area and irrigated area of Laguna-Rizal CIS exhibited an upward trend over the years (**Figure 52**). There is little gap between FUSA, SA and the irrigated area probably owing to sufficient water supply of the system. Ratios of amortization payments, collections and collection efficiency peaked between 2007 and 2008 with the drastic reduction of the estimated amortization collectible. Cropping intensities fluctuated through the years but moved towards increasing values in the later years. Viability index had a slight increasing trend over the years.

The filled-up plantilla is only 42%. But, in spite of this, the coverage area per staff has a fairly good ratio of only 475 ha (**Table 41**)

The ratios of benefited area to irrigated area during wet season are generally lower compared to dry season ratios. This is probably due occurrence of calamities and flooding during wet season.

Sources: NIA-SMD CISPERS data, various years.

The total income comes from equity averaging 25% across the years followed by equipment rental at 24%, CIS current amortization at 19% and then, equipment rental at 15%. Viability index dipped in 2012 but generally have an upward trend.

Region 4B MIMAROPA

Occidental Mindoro IMO

Occidental Mindoro CIS service area has more or less stable movement over the years as well as its irrigated area. FUSA, on the other hand, fluctuated with dips in 2008 and 2010 (**Figure 53**). The gap between FUSA and the irrigated area is probably due to lack of water supply and defective facilities. Share of amortization to total income dropped as equity payments increased. Collection efficiency fluctuated across the years reaching its peak in 2013. O&M cost per SA and FUSA had moved in a stable pattern over the years. The ratios of benefited area to irrigated area generally have an upward trend. The upward trend is observed with both cropping intensities and viability index.

In 2012, 88% of the plantilla positions are filled up, reducing the coverage per staff (**Table 42**). But even with the reduction, the 610 ha per staff in 2013 is still a relatively large area to cover considering distance and remoteness of some CIS and limited resources to support IMO activities.

Sources: NIA-SMD CISPER data, various years.

The gap in irrigated area and FUSA is higher during dry season ranging from 33% to 66% compared to the 14% to 53% during wet season. The ratios of benefited area to irrigated area fluctuated during wet and season due to calamities and inadequate, respectively.

The total income consisted of the amortization repayment averaging over the years at 35% and followed by equity payments averaging at 30%. Viability and cropping intensities generally showed an upward trend.

Region 5 BICOL

Camarines Sur IMO

The service area of Camarines Sur CIS has increased over the years reaching around 40,500 ha in 2013 (**Figure 54**). The irrigated area during both wet and dry seasons followed the same pattern. The gap between FUSA and the irrigated area is probably due to defective facilities. Ratios of total amortization collections to total, total collections to estimated collectibles and collection efficiency had no clear trend but tend to converge to 50% starting in 2010. After 2008, benefited areas during wet and dry seasons tend to equalize. The cropping intensities reached a peak in 2007 but generally had a stable movement through the years. The viability index, on the other hand, generally has an increasing trend over the years despite its fluctuations.

Dry Yield (cavan/ha)	84	84	82	82					

Sources: NIA-SMD CISPER data, various years.

Even with the plantilla positions filled-up to up to 75%, each personnel still have a very large coverage of 2,699 ha per staff (**Table 43**). The reduction of staff might be due to lack of funds. But, this large coverage per staff would consequently diminish the quality of their service.

During wet and dry seasons, the gap between irrigated area and FUSA ranged from 17% to 64% and 20% to 64%, respectively. This gap is might be due to defective and/or inadequate facilities.

Majority of the total income comes from amortization repayment averaging up to 38% over total income across the years. This is followed by equity payments averaging at 29%. Cropping intensities generally had a stable movement despite few fluctuations across the years. Viability index, on the other hand, had some fluctuations but generally followed an upward trend.

CHARACTERIZING THE SAMPLE CIS

The 66 communal irrigation systems (CIS) sample are characterized according to size, technology, “success” or “failure” and by province. On size, three types are defined: small, medium, large, based on the size of the firm-up service area (FUSA). IAs with FUSA of 100 ha or more are classified as large while those with FUSA between 50 ha and 99 ha. are classified as medium. IAs with FUSA below 50 ha are classified as small. Based on technology, the CIS are classified as gravity or pump systems. To profile “successful” or “failed” CIS, “success” is defined in terms of three criteria: (1) NIA’s functionality survey rating of very satisfactory to outstanding; (2) IA’s own financial rating of 3 to 4, with 4 as very strong; and (3) IA’s ISF collection performance rating of 3 to 4 with 4 as excellent and/or a collection rate of 65% and above. “Unsuccessful” or “less successful” IAs are then defined as those which are not “successful” or with NIA’s functionality survey rating of poor to satisfactory, with own financial rating of 0 to 2 , and ISF collection performance rating of 0 to 2 or a collection rate below 65%.

By province

To establish patterns according to province, the provincial profiles of the sample CIS are reported in **Tables 44.1 to 44.7**.

Benguet IA samples have more successful IAs than less successful ones. Generally, Benguet has the highest cropping intensity and collection efficiency does not experience water shortage in the dry season or flooding problems, and have minimal siltation problems. However, they do have moderate problems in funding and in the condition of their headwork and old piping structures. They also have the least number of facilities, such as water storage, among the IAs from 11 provinces.

Cagayan is one of the 3 provinces that only have less successful IAs. Their IA samples have high incidence of water supply shortages especially on dry seasons, severe condition problems of canals, very high siltation problems, low cropping intensity, low collection efficiency, and high occurrence of water theft.

For Camarines Sur, half of the sample IAs are considered successful and the other half, less successful. Of the 11 provinces in the study, Camarines Sur IAs have the highest average yield, high dependability, adequate water supply, and , fewer funding problems. On the contrary, they have the most number of lateral canal problems, moderate occurrence of flooding, and, slight siltation problems. They also lack facilities and equipment like farm-to-market-roads and backup pumps.

IAs from Ilocos Norte are also considered as less successful. The sample IAs have the highest count of water inadequacy, funding problems, and the most problems with the lateral canals and control structures. In addition, the CISs have relatively low cropping intensity and low average yield.

The IAs of Isabela have the least access to production credit, high siltation, and inadequate water supply. They also have high counts of irrigation headwork structure problems and main and lateral canal problems. Despite these constraints, Isabela has more “successful” IAs than less successful ones, likely due to good management performance, resulting in high functionality ratings, and relatively good levels of collection efficiency.

Of the Laguna IAs visited, only one would qualify as “successful”. The rest are “less successful.” high cropping intensities, adequate of water supply, and good levels of collection efficiency, Laguna IAs have the most flooding problems, funding problems, and condition problems for lateral canal and control structures. In addition, their management rating is not very good, resulting in lower functionality survey ratings.

Nueva Ecija has many less successful IAs, attributed to having low collection efficiency, inadequate water supply during dry seasons, high siltation and funding problems., water theft, and problems with headwork and lateral canal conditions. On the positive side, most of the sample IAs have good management performance resulting in high ratings.

IAs in Nueva Vizcaya are less successful IAs. Despite having high average cropping intensity and yield, these IAs exhibit high counts of canal and headwork problems, inadequate water supply, high count of siltation problems, low collection efficiency, and several funding problems.

Occidental Mindoro has the largest amortization rate among the 11 provinces. Their IAs have minimal funding problems, good levels of collection efficiency, and do not experience siltation problems. However, their “less successful” IAs dominate the “successful” ones. This disparity is likely due to inadequate water supply especially during the dry season, very low average yield, low cropping intensity, flooding problems, problems with irrigation canals and headwork structures, water theft, and lack of facilities (e.g. FMR, solar driers, canal extensions and STWs).

Pampanga IAs have the same percentage of successful and less successful IAs. They experience both minimal water shortages in dry seasons and flooding in wet seasons. All sample IAs have high ratings in the functionality surveys, indicating very good management performance. Albeit the good ratings, Pampanga IAs have high siltation problems, low average collection efficiencies, and problems with the condition of their canal and control structures.

Pangasinan IAs have a higher percentage of successful IAs compared to less successful ones. Their IAs have not experienced flooding and funding problems, and have high collection efficiencies, and good functionality ratings. However, they still experience water supply shortages during the dry seasons, low average cropping intensity, problems with physical conditions of irrigation canals, water theft, and slight siltation problems.

Notes: Cropping intensity 1 = (Wet actual + Dry actual irrig)/FUSA

Cropping intensity 2 = (Wet actual + Dry actual irrig)/Wet actual (except in cases where actual dry season irrigated is bigger)

By size of system

The CIS sample has been categorized and characterized according to three sizes: small, medium, and large as shown in **Tables 45.1 to 45.7**.

Compared to medium and large CIS, the small CIS have the least incidence of inadequate water during dry seasons, siltation and solid waste problems. The small CIS have the least problem in their irrigation structures and canals compared to the large systems. They come second to the medium size CIS on incidence of water theft. The small CIS report the highest average cropping intensity and yield. However, despite this favorable profile, they have the lowest collection efficiency and highest count of funding problem. Following the criteria above on “successful” CIS, the small systems have the highest percentage of “successful” IAs compared to the larger systems.

Medium-sized CIS have the lowest average cropping intensity and yield. They have the highest incidence of inadequate water supply during dry seasons and siltation problems. They have the highest count of irrigation headwork and control structures-related problems. On the other hand, they have the highest collection efficiency and least incidence of floods and water theft. The medium CIS have the second highest percentage of successful IAs.

Large CIS have the highest incidence of floods during the wet seasons. They also have the highest count of irrigation canal problems and water theft. But, they have the least count of funding problems.

By technology

The CIS sample is also characterized in terms of usage of pump vs. gravity systems (**Tables 46.1 to 46.7**).

Contrary to the common findings, IAs using pump technology in the sample have more successful IAs despite having higher amortization rates, incidence of flooding and funding problems, and low cropping intensities. The disparity is likely due to their adequate water supply even during dry seasons, fewer problems with their irrigation canals and structures, and high collection efficiencies.

On the other hand, IAs irrigated by gravity have the highest cropping intensity and a low occurrence of flooding. However, when compared to IAs using pump systems, they have more problems with irrigation canals and structures, more severe water shortages, and greater incidence of funding problems and water theft.⁹

⁹ Of the 66 sample IAs, only one IA with a reservoir scheme does not have much data to allow comparison with the other schemes.

By “success”

The profiles of the CIS sample in terms of some “success” measure are reported in **Tables 47.1** to **47.7**.

Despite flooding, siltation problems, problems with irrigation structures, and water theft, successful IAs as defined above generally have adequate and dependable sources of water supply, high cropping intensity, high collection efficiency, and adequate funding.

Less successful IAs are characterized by inadequate water in the dry seasons, more problems with irrigation main canal and control structures, low collection efficiencies, and severe funding problems.

Technical Assessment¹⁰

There are technical issues/problems that generally confront the IAs and the performance of their CIS (**Tables 48 to 50**). Most run-of-the-river type dams are quite old, with exposed rock cores, damaged spillways, and with sediments almost at the crest level. Most of the sluice gates and intake gates usually made of steel are now replaced with flashboards, sand bags, or stones and in some relatively larger CIS with defective lifting mechanisms. These problems also contribute to increased sedimentation. On a positive note, most CIS that were visited have concrete-lined main canals with some up to the laterals. In general, the good conditions of the lined and unlined canal networks are due to the IAs having good O&M and cleanup mechanisms. In some cases, heavy siltation experienced is due to watershed degradation and requires major policy/governance solutions.

Structures found in CIS include cross regulators, check gates, drop structures, division boxes and farm turnouts. Some of which are well-maintained, while others have deteriorated with control structures not functioning well or as originally intended. For example, some cross or check regulators initially intended to measure discharges lack staff gages that measure water levels and have missing or uncalibrated rating curves. Other miscellaneous or appurtenant structures commonly found in all CIS are road and thresher crossings, end checks, and service roads, where most service roads are rough roads with most dams accessible only by walking or by motorcycles.

As in most irrigation systems, there are no specific drainage canals at the CIS. Normally, the downstream farm ditches receive the excess water from paddies, which in turn would be used to irrigate downstream areas in some CIS. With water distribution downstream being from paddy to paddy, not having an individual farm ditch for each paddy, result in large application losses.

Sedimentation is one of the main problems that cause canal deterioration and decrease in water yield in dry seasons. Identified sources of sediments are (a) sidehills, (b) drainage/creeks, (c) side slopes of irrigation canals, and (d) catchments. Lahar is the major source of sediments for some CIS in Pampanga. Several operational lapses (e.g. full opening of intake gates and closing of sluice gates to maximize water intake even during high sediment inflows), contribute to increased sedimentation. For example, defective lifting mechanisms or the replacement of steel sluice gates permanently by flashboard or concrete maximize water inflow into the system but also effectively increase sediment inflows. Given the high sedimentation rate, IAs regularly clean the canals, especially since CIS canals are smaller and more manageable compared to NIS. Thus, the IAs rated low silt level and undesired seepage grade in their canals. .

One of the major reasons for low performance by irrigation systems is the lack of water during dry seasons. The sources of water for the CIS visited are lakes, rivers, creeks, springs, ground water, runoff, or a combination of these sources. Some rivers are large and have adequate flows that can irrigate even during the dry seasons, while some rivers have very low dry season flows. Most creeks have adequate flows for small areas during wet seasons but are either very low or have no flow during dry seasons. Only 22 of the 66 surveyed CIS (33%) have river sources capable of

¹⁰ This section is drawn from Luyun (2015) Final Report.

providing irrigation during dry seasons. Eight rivers have published historical records that showed low dependable flows. Four of these rivers are very large and can provide water for large NIS, thus, irrigation is assured at least 80% of the time with only siltation and hardware problems remaining. However, water source is a major problem for majority of the CIS that tap water from less dependable small rivers, creeks, springs, and runoffs.

Groundwater remains a viable option, especially for areas where the surface water sources (i.e. creeks) have low dependable discharges during the dry seasons, and are underlain by good shallow aquifers. Despite having to use STW pumps and engines that lead to additional fuel costs, groundwater is reliable even in intense drought periods or El Niño episodes, and farmers have control of irrigation schedules and flows. In times of water shortages or when the area to be irrigated is higher from the source, STWs and LLPs (3"x 3" or 4"x 4" centrifugal pumps) are commonly used. They are usually driven by 8 – 12 Hp water-cooled diesel engines. With respect to rehabilitation, the rehabilitated areas averaged at about 140,000 ha per year from 2006-2013, which is double of the 1992-1996 rate. Despite massive efforts and funding, the increase in irrigation area is minimal at just about 40,000 ha per year.

In terms of water delivery performance, on average, the IAs appear to be satisfied given that their rating for their CIS are highly flexible, reliable, and equitable. Around 40% of the IAs practiced AWD technology.

The operation and maintenance of CIS is turned over to IAs upon project completion. Based on the KIIs, most of the IAs claim that they receive sufficient water at the right time. Moreover, the IAs rated themselves high in terms of water distribution, maintenance of canals, and control structures. However, improvements may be necessary since delays are still commonplace.

The expansion of irrigated agriculture, through the development of new areas or the rehabilitation of old ones, is necessary for food security. New irrigable areas come from small scale systems like CIS, STWs and SWIPs, all of which have low gestation periods, offer low investments, quite efficient, and are easy to manage.

CONCLUSIONS

There is value in looking at sub-national trends given insights which cannot be inferred from national trends. Using secondary data from the Central and regional offices of NIA and the systems, complemented by key informant interviews and ocular inspections, this study establishes key institutional and technical constraints to improving performance of both national and communal irrigation systems.

Specifically, for national irrigation systems, we found the following:

- National and regional trends in NIS. Service area growth has slowed down in the last decade and growth has been concentrated in just four regions. Firmed up service area difference with service area indicate on average a land conversion rate or declared permanently non-restorable area of about 10%. Most NIS systems are diversion systems and the few operational pump systems available are in five regions (Regions 1, 2, 3, 5 and 13).

Cropping intensity only slightly increased over the years. In fact wet season irrigation intensity appears to have largely slowed down. In Luzon, some increases in dry season irrigation intensities can be seen while wet season intensities appear to have stagnated. However, in Mindanao, similar increasing patterns for both wet and dry seasons irrigation intensities are observed.

Collection efficiency has only noticeably improved in two (the rest of Region 2 and Region 4) regions only in Luzon and in MRIIS and slightly in UPRIIS while worst in Region 6. The Mindanao regions appear to have been performing better in terms of this indicator, consistent with the corresponding improvements in cropping intensity. Aside from this, possibly other factors maybe at play given dramatic performances in Regions 2 and 11 and in MRIIS and higher cropping intensities in the rest of Mindanao.

- NIS Cases: States and Patterns. Of the 22 NIS cases, six are from Ilocos, five from Cagayan (including 2 MRIIS), seven from Region 3 (including 3 UPRIIS), three from Regions 4a and 4b, and one from Region 5. The sample also included four pump systems.¹¹ Except for UPRIIS and MRIIS, the rest of the systems are diversion/gravity type.

The performance of the NIS cases are analyzed in terms of size of IAs (defined as large, medium, small based on their FUSA), technology (diversion/gravity, pump, reservoir), location (upstream, midstream, downstream of the main canals), vintage (before 1965, 1965-80, 1981-2013), and by some measures of “success” which largely capture institutional and financial/economic aspects of irrigation system management by IAs/NIA. “Success” is measured similarly as NIA loosely defines it -- based on functionality ratings and active and functional IA organization, high collection efficiency and payment of ISF to NIA. These typologies capture various technical and institutional aspects of providing irrigation service by

¹¹ Part of UPRIIS and MRIIS systems are served by pumps.

national systems. Pump systems will have different challenges from reservoir and diversion systems. Size of IAs based on firmed-up service area will likely be correlated with complexity of design, and operation of physical structures and facilities, and the corresponding type of management. Vintage entails different technical and institutional concerns between relatively old vs. newer systems. "Successful" IAs entail institutional factors at play but also probably technical aspects contributing to such performance.

There is disparity between small and large IAs. The small IAs reported the highest incidence of inadequate water during dry seasons, flooding during wet season, high counts of canal problems especially lateral canals, and siltation/solid waste problems. The large systems/IAs indicated adequate water supply, least occurrence of siltation problems, lowest count of irrigation headwork and main canal problems, minimal occurrence of flooding and adequacy of budget. These IAs also have a high percentage of "successful" IAs compared with the small and medium size IAs. This apparent advantage of large IAs may be linked to their degree of influence by virtue of their size and ability to access funds which result in favorable physical states of their systems, which in turn led to their success.

Reservoir systems appear to have clear advantages over the other types of schemes. And while pumped systems are shown to be doing well, these systems are in fact heavily subsidized. The IA sample irrigated by diversion system (gravity) reported the highest count of inadequacy in water supply especially during the dry season. The IAs which used pump systems have the highest counts of siltation, lateral canals and institutional problems. Despite these concerns, these IAs reported adequacy and dependability of water supply even during dry season, no flooding problem, and higher collection efficiencies compared to the situation of IAs with diversion/gravity system. The IAs in reservoir systems claimed to be most successful of the three groups. This group reported adequate water supply, lowest count of siltation problems, largest percentage of financially strong IAs, very high IA functionality ratings and high collection efficiencies.

Downstream IAs are heavily disadvantaged over the rest of the IAs. The sample has the following characteristics: highest count of siltation and/or solid waste problems, highest count of lack of water supply, highest occurrence of flooding during wet seasons, highest count of damaged farm-to-market roads, highest percentage of financially weak IAs and lowest ratings of water delivery service in terms of adequacy and timeliness. The upstream IAs on the other hand, reported the least incidence of water supply problems, lowest count of solid waste and/or siltation problems, highest irrigation structure problems, highest count of lack of machineries and equipment and a high percentage of financially strong IAs. Irrigation canal problems were ranked first in the list of problems, and followed by institutional problems and then by calamities/pest infestation causing production problems.

Profiles of IAs and irrigation systems differ by vintage. This measure splits the sample into three periods which coincide with the distinct trends in irrigation investment and development. Interestingly, the pre-NIA systems are characterized as those with the least irrigation structure problems, concern for lack of machineries and equipment and inadequacy of water supply. However, the IAs in these systems have the lowest functionality ratings. Systems constructed

between 1965 to 1980 have the following attributes: highest count of poor headwork and control structures condition, highest concern of lack of machineries and equipment, highest count of financially weak IAs, highest count of lack of water supply, and highest incidence of damaged FMRs. Yet, these systems have the least siltation/solid waste problems relative to systems from the other periods. Prevalent problems in decreasing order include: inadequate of water during dry seasons, poor conditions of lateral canal and control structures. The IAs with systems built between 1981 and 2013 reported the highest count of main and lateral canal problems. They also have the highest incidence of siltation problems and the largest count of institutional problems. However, this group has the largest number of financially strong IAs, the highest count of “successful” IAs, the least occurrence of flooding, with adequate water supply and least damaged FMRs. This observation seems ironic as it implies that IAs can still be financially strong and “successful” despite technical and institutional problems.

Profiling IAs according to “success” or failure, indicates distinct differences between these groups. “Successful” IAs in the sample are characterized as those with adequate water supply, less institutional problems, adequate budget and facilities, machineries and equipment. However, these IAs experience higher incidence of siltation and problems with physical state of main canals, lateral canals and control structures. The hierarchy of problems of successful IAs are as follows in decreasing order: lateral canal condition problems, institutional problems, crop production problems due to calamities/pest infestations and damaged irrigation structures. The “less successful” IAs have the higher count of inadequate water during dry seasons, irrigation headwork problems, lack of facilities, machineries and equipment, with inadequate budget and lower IA functionality ratings, indicating poor management performance. In order of importance, inadequacy of water comes first, followed by institutional problems, and then by the lack of irrigation facilities/infrastructures, machineries and equipment.

Using an alternative approach to analyzing the sample NIS performance, the results show that irrigation performance has much to improve. This approach establishes an irrigation performance index (IPI) measured in terms of five aspects: financial, economic, institutional, technical and environmental factors. The *financial factors* include: 1) IAs rating of their financial strength – financial capability of the IA is critical in the organization’s development; 2) collection efficiency – a higher collection efficiency means higher ISF shares by IAs and better incentive; and 3) collection delinquency – a higher delinquency decreases the performance index. Financially strong IAs can carry out better O&M and repairs so that irrigation systems can deliver good/sustainable irrigation service. The *economic factors* include average annual yields and gross profits of IA members which would be indicative of benefits that reach beneficiary farmers. Higher annual yields can lead to higher annual profits. Also, higher incomes can mean farmer members would be better able to pay ISF resulting in IAs financial strength. The *institutional component* includes: 1) effectiveness of policies; 2) flexibility index rating; 3) reliability index rating; and 4) satisfaction rating on farm to market road. The *technical component* indicators include canal structures ease of operability and canal structure’s operability vs. design. Canal structure ease of operability pertains to the ease in operating irrigation structures such as check gates, turnout gates, etc. While canal structure operability vs design compares the original design of the irrigation system vs the actual use of the structure. The *environmental component* indicators include dissolve oxygen content and

acidity. Higher DO (i.e. > 6 ppm) and pH content (i.e. >5) mean better quality water. The pH found in most water samples show levels >7 which indicate alkaline conditions and potential sodicity problems if not addressed on time. The results of this analysis show that 58% of the sample IAs rated the irrigation performance as moderate. Only 12% of the sample rated performance as high and the rest, low performance.

For communal irrigation systems, we found the following:

This component provides preliminary evaluation of investments in CIS.

- National and Regional/Provincial Trends

Service area has been growing but at a relatively very slow pace while farmed up service area has been closely following. Given the relatively stable difference between the SA and FUSA, land conversion or growth in permanently non-restorable area does not appear to be a concern. However, the trends in actual irrigated areas during the wet and dry seasons seem to have faltered in 2012. Wet and dry seasons irrigation intensities never reached the 80% mark and even declined by about 20% in 2012.

With the rise in equity schemes, the amortization collection decreased and became a less significant source of income. Also, the fact that amortization collection efficiency drastically declined is a serious concern.

- Characterizing the sample CIS

The 66 CIS are saddled with technical issues and problems that affect their performance. The sample CIS in this study have run-of-the-river type dams which are quite old, with exposed rock cores, damaged spillways, and sediments almost at the crest level. The sluice gates and intake gates which were initially made of steel have been replaced with flashboards, sand bags, or stones and in some relatively larger CIS, with defective lifting mechanisms. These problems contributed to the increase in sedimentation. However, most of the sample CIS have concrete-lined main canals and even laterals. The good conditions of these lined and unlined canal networks are said to be due to the IAs O&M efforts and cleanup mechanisms. Where heavy siltation is experienced due to watershed degradation, the solutions are simply beyond the IAs.

The sample CIS are characterized according to size, technology, “success” or “failure” and by province. On size, three types are defined: small, medium, large. Based on technology, the CIS are classified as gravity or pump systems. To profile “successful” or “failed” CIS, “success” is defined in terms of three criteria: (1) NIA’s functionality rating of very satisfactory to outstanding; (2) IA’s own financial rating of 3 to 4, with 4 as very strong; and (3) IA’s ISF collection performance rating of 3 to 4 with 4 as excellent and/or a collection rate of 65% and above. “Unsuccessful” or “less successful” IAs are defined as those which are not “successful.” These categories capture various technical and institutional factors that influence CIS irrigation service.

The experience in small CIS exemplifies “small is beautiful.” Compared to the other classes, the small CIS have the least incidence of inadequate water during dry seasons, siltation and solid waste problems. They also have less problems in irrigation structures and canals compared with the large systems and they reported the highest average cropping intensity and yield. However, they have the lowest collection efficiency and highest count of funding problem. Following the criteria above on “successful” CIS, the small systems have the highest percentage of “successful” IAs compared to the larger systems. The large CIS have the highest incidence of floods during the wet seasons. They also have the highest count of irrigation canal problems and water theft. But, they have the least funding problems.

Contrary to earlier findings, IAs using pump technology in the sample have more successful IAs despite the higher incidence of flooding and funding problems, and low cropping intensities. The disparity is likely due to their adequate water supply even during dry seasons, fewer problems with their irrigation canals and structures, and high collection efficiencies. The pump technology appears to be closely associated with better control of available water and the success of IAs.

The IAs irrigated by gravity have the highest cropping intensity and a low incidence of flooding, but they have more problems with irrigation canals and structures, more severe water shortages, and greater incidence of funding problems and water theft.

As to profile of “successful” IAs, they have adequate and dependable sources of water supply, high cropping intensity, high collection efficiency, and adequate funding. This success profile is obtained despite flooding, siltation, irrigation structures, and water theft problems. Less successful IAs are characterized by inadequate water in the dry season, more problems with irrigation main canal and control structures, low collection efficiencies, and severe funding problems. It is interesting to note that “IAs can still be successful despite physical and economic concerns. It seems that water availability is a key factor in high collection efficiency. This finding needs to be validated so NIA can use this result in formulating strategies to improve collection efficiency.

RECOMMENDATIONS

Based on the technical and institutional analyses carried out for national and communal irrigation systems, the following recommendations are in order.

For National Irrigation Systems:

- Given the new insights from sub-national trends which cannot be inferred from national trends, such level of analysis should be scaled up to cover more NIS in Visayas and Mindanao and better understand the situation on the ground and establish some patterns and trends which can be used to formulate relevant policy changes and actions.

- It appears that conversion of irrigated areas is a more serious concern in certain regions. If the rate of land conversion will continue to rise, estimates of design areas should properly take this into account.
- Given the dramatic slowdown in growth or stagnation of wet season irrigation intensity, it is high time that NIA gives attention to the need to invest in drainage and/or collaborate with DPWH to explicitly and more systematically address flooding problems in NIS systems which may require bigger technical/engineering solutions.
- As a first step, each NIS should clearly establish size of firmed-up service areas which are flooded during the wet season. For systems where there is a big difference between wet and dry season irrigable area, two FUSA measures should be recognized. This will have implications on the calculation of cropping intensity which uses FUSA as denominator.
- Collection efficiency improvements appear to correspond to improvements in cropping intensities. If this relationship can be confirmed, the strategy to improve collection efficiency should include improvement in cropping intensities which in turn will require improvement in irrigation service.
- Relative to the medium and large irrigators associations (IAs), the small IAs appear to have the disproportionate share of the problems. Given this disparity, the design of institutional interventions that take into account “size” of IAs according to membership. Special attention should be given to the needs of small IAs and appropriate interventions be designed.
- Irrigators Associations in reservoir systems claimed to be most “successful” based on many indicators when compared with those in diversion and pump systems. In considering types of projects to invest in, government will have to consider the trade-offs in investing more in reservoir types which will likely mean higher initial capital requirements vs. pumped systems. The later type may mean less initial investment but higher O&M after project completion and less likely to be sustainable to operate given volatility in oil prices.
- “Successful” IAs in the sample are characterized as those with adequate water supply, less institutional problems, adequate budget and facilities, machineries and equipment. If we take these factors as indicative of necessary requirements for “successful IAs,” then at minimum, NIA’s system design and eventually service areas should be matched with adequate water. This finding makes necessary more firm and systematic assessment of adequacy and reliability of water that will be available to farmers when an NIS system operates.
- The issue of equity in the delivery of service remains a major concern given the heavily disadvantaged downstream IAs – with inadequate water during the dry season and more water than they need during the wet season. NIA has to come up with a better strategy of addressing this aspect of equity as part of improving quality of irrigation service.

If use of pumps is to be taken as a way to partly address equity concerns especially during dry seasons, the lack of policy on treatment of use of pumps within NIS systems has to be

addressed. The use of discount needs to be evaluated and made an official policy rather than leaving too much discretion on the water masters or institutional development officers in the field.

- Performance of irrigators associations using functionality ratings differ by vintage -- pre-NIA systems, 1965-80 and 1981 to 2013 – indicating that contrary to expectations, functionality of “older” IAs maybe more problematic. If functionality ratings can be validated, there may be a strong case for revisiting the institutionalization program. “Old” IAs appear to need more retraining/reorienting/strengthening so they can keep up and become more effective organizations.
- Again, appropriate institutionalization policy has to be designed according to the specific needs of different types of IAs. Irrigators associations in the early NIA years appear to be mostly financially weak. Given this, the capacity building strategy for IAs should explicitly include ways to improve financial strengths and that intervention for IAs should consider not only size (in terms of membership) but also vintage. IAs with systems built between 1981 and 2013 appear to need in addition, more engineering/technical solutions. These observations should be confirmed by further evaluations given two possible scenarios –more recent systems are not built as strongly or we have simply more intense weather and climate contributing to more rapid deterioration or damage to the systems. If the latter would be the case, this finding will provide a strong support for more deliberate climate change resilient systems in terms of design and structures.
- Using an alternative approach to analyzing the sample NIS, the results show that the composite performance has much to improve. This approach establishes an irrigation performance index in terms of five aspects: financial, economic, institutional, technical and environmental factors. If the results can be confirmed, addressing specific aspects of performance with respect to the five areas can lead to possible marked improvement. Given this potential usefulness of the analysis, this approach should be scaled-up to cover more IAs and national systems to validate the initial observations and at the same time refine the measure to be more useful.

For Communal Irrigation Systems:

- Service area has been growing at a very slow pace and preliminary investigation shows that a good number of CIS are already in elevations beyond the 3% slope. This initial finding warrants scaling up of the characterization to cover more IMOs to get a better sense of the location and distribution of the over 9000 CIS nationwide.
- An assessment of the potential and economics of considering areas between 3% and 8% slopes for CIS expansion should be pursued. Using the GIS technology and some modeling, a more systematic identification of irrigable CIS areas should be carried out taking into account water availability, associated environmental damage/watershed degradation.

- The wet and dry seasons irrigation intensities which are generally below 80%, should be further investigated and understood by looking at trends in all provinces/IMOs and more systems. As a first step to this assessment, the FUSA has to be examined and the field work should be used to understand why the actual irrigated areas have been falling short in both seasons. The evaluation should be able to establish how much is truly “non-functional” area (which will therefore need repair/rehabilitation/restoration) vs. flooded during wet or with inadequate water during dry.
- With the rise in equity schemes, the amortization collection decreased and became a less significant source of income. However, the decline in amortization collection efficiency is a concern which should be addressed.
- Reservoir systems appear to coincide with most successful group of IAs. If this finding can be validated, consideration of this type of system may well justify the possibly higher investment needs compared to other types.
- The technical issues and problems affecting the CIS performance point to the need to revisit adherence to design and construction guidelines for new development and rehabilitation of CIS. Specifically, the assessment of dependable flow, catchment conditions, sediment discharges and potential of groundwater source be properly carried out. The trade-off between spending more on capital requirement during the development phase versus higher O&M expenditures after turnover be carefully weighed.
- If results can be validated by scaling up the evaluation to cover more CIS, appropriate government interventions can be designed according to the priority needs of IAs. NIA can use the results for targeting interventions and allocating the corresponding resources. Small IAs need more capacity building and funding while large IAs need more technical solutions.
- Lastly, while IAs can still be considered “successful” despite physical and economic concerns, it appears that water availability is a key factor in high collection efficiency. NIA’s strategy to improve collection efficiency has to also include addressing the issue of water availability.

ANNEX 1. SAMPLE NIS KEY INFORMANT INTERVIEWS

Ilocos Norte Irrigation System (Nueva Era, Bonga 2)¹²

IA	Profile	Issues and Concerns
Kadaklan Baldias IA - Nueva Era (upstream)	Crop: Rice Yield: 90 [hyb] (dry); 80 (wet) Total cost: P20,000 ISF: 2550 (dry); 1700 (wet); CE: 80% FUSA: 190	<i>Technical/Physical</i> <ul style="list-style-type: none"> - Constant repair of brush dams - There is a constant need to put up a brush dam in order to store water specially during dry season <i>Institutional/Socio-Economic/Political/Cultural</i> <ul style="list-style-type: none"> - Usual conflict is due to improper use of turnouts and scheduling of water distribution
Caniyogan-Balbalay-Kali Alakay-IA – Banna (downstream)	Crop: Rice and corn Yield: 80 (rice); 4 tons (corn) Total cost: P30,000; P20,000 (corn) CE: 70% FUSA: 181 Model 3	<i>Technical/Physical with Institutional/Political complexities</i> <ul style="list-style-type: none"> - Water supply is difficult in the area due to complex situations: <p>*Initially, the IA constructed brush dams in order to store water. However, due to a dike construction by the DPWH, the water that flows to the brush dam and eventually to the canal is blocked.</p> <p>*Constructed dike was too high that water can no longer flow through the irrigation canal</p> <p>*The design was contested but DPWH said that it was approved by the Mayor. While the Mayor cannot do anything because that the design was by DPWH.</p> <p>*Problem becomes complicated with water source in a different municipality</p> <p>-Proposed to construct an impounding dam, 10 km upstream, which should go directly to Banna</p>
San Nicolas-Laoag Bonga Pump 2	Crop: Rice and corn Yield: 10 tons/ha [hyb] (dry); 6 tons/ha (wet) Total cost: P45,000	<i>Technical/Physical</i> <ul style="list-style-type: none"> -During wet season, the canal is blocked by heavy siltation due to quarrying activities in the area. Therefore, a channeling canal of 3kms was constructed around for the water to flow. -The cost of excavation for desilting is P100k per excavation

¹² IA Profile does not include total planted area thus cannot compute for CI.

	<p>ISF: 7000 (dry); 4000 (wet) CE: 80% FUSA: 250 Stage 3 special case</p>	<ul style="list-style-type: none"> -A river channeling project was proposed worth P20 million but the budget was reduced to P7 million. Since the cost was reduced, it was instead used to restore canals. -Although the restoration of the canal is good, it was inappropriate and farmers would opt to have used it to purchase a back hoe for excavation use instead. -IA is willing to pay for the purchase of heavy equipment (back hoe) even under an amortization scheme -Dilapidation of canals and turnouts are also aggravated by the heavy siltation from the river -The heavy siltation is due to quarrying. It would have been best to implement a designated zone for quarrying <p><i>Institutional/Socio-Economic/Political/Cultural</i></p> <ul style="list-style-type: none"> -High prices of inputs while low prices of harvest <p><i>Initiative/Success stories</i></p> <ul style="list-style-type: none"> -IA is under a tripartite agreement with NIA and LGU *NIA does the construction and repair; LGU manages the collection and fund disbursement; and IA does the operation
--	---	---

Banaoang Pump Irrigation System

IA	Profile	Issues and Concerns
Paing-Taguipuro IA (upstream)	Crop: Rice and corn Yield: 100 (dry); 110 (wet) Total cost: P35,000 ISF: 6375 (dry); 4250 (wet) CE: 85% FUSA: 230 Total Planted Area: 69 CI: 30% Model 1	<i>Technical/Physical</i> <ul style="list-style-type: none"> - Some main canals are not lined - Personal STW pumps are used as back up for times with low water supply - Cost of pump operation is P15,000 <i>Institutional/Socio-Economic/Political/Cultural</i> <ul style="list-style-type: none"> - Low trading price of rice - Typical conflict issue is due to lack of water management knowledge within members
Cabusligan (midstream)	Crop: Rice Yield: 100 (dry); 200 (wet) Total cost: P30,000 CE: 70% Model 1	<i>Technical/Physical</i> <ul style="list-style-type: none"> - Uses 5hp surface pump in elevated areas which costs P60,000 per unit - New hybrid variety has low yield
Capangdanan (midstream)	Crop: Rice Yield: 100 (dry); 120 (wet) Total cost: P30,000 CE: 80% Model 1	
VSPC IA, San Hera De Magsinggal IA, Western Magsinggal IA, Pansaca IA (downstream)	Crop: Rice Yield: 4.5 tons (dry); 5.5 tons (wet) Total cost: P40,000 ISF: 6375 (dry); 4250 (wet) CE: 80% FUSA: 525 Total Planted Area: 216 CI: 42% IMT Model 1	<i>Technical/Physical</i> <ul style="list-style-type: none"> - Need to fix farm to market roads especially during wet season. - Main canal is beginning to be silted which lessens the availability of water - Siltation comes from the river source - Propose to have adequate heavy equipment due to usual dredging needs <i>Institutional/Socio-Economic/Political/Cultural</i> <ul style="list-style-type: none"> - Since the irrigation facility is new, no ordinances are still intended for the

protection of the facilities i.e. no throwing of waste.

- Many farmers are still traditional and do not want to pay the ISF and do not follow the cropping calendar.
- Low trading price of rice
- Farmers cannot comply with the requirements of NFA therefore they are discouraged to sell in NFA
- Sikat saka is not availed by members as of the moment due to requirements

Ambayoan-Dipalo River Irrigation System (2 NIS)¹³

IA	Profile	Issues and Concerns
Salud-San Eugenio (upstream)	Crop: Rice Yield: 40-45 cav/ha Total cost: P25,000 CE: 70% Model 2	<i>Technical/Physical</i> <ul style="list-style-type: none"> - Structures were destroyed during 2014 typhoon - Need construction of good farm-to-market roads - Lining of canals - There are canals that have become shallow due to siltation - Some members use a low lift pump that was provided by LGU
Main Canal Ambayoan Saranay IA (midstream)	Crop: Rice and corn Yield: 80(dry); 100 (wet) Total cost: P30,000 – P35,000 ISF: 2550 (dry); 1700 (wet); 1530 (other crops aside from rice) CE: 70% Model 2	<i>Technical/Physical</i> <ul style="list-style-type: none"> - Low water supply during dry season - NIS and CIS shares the intake to get water with only 25% goes to NIS and 75% goes to CIS - Complete the intake construction of Ambayoan - Concretize canals - Replace old steel gates and regulators - Concretize farm-to-market roads
Kaps Ambayoan IA (downstream)	Crop: Rice and corn Yield: 50 (w/o pump); 138 (w/ pump) – Rice 100 (w/o pump); 170 (w/ pump) Total Cost: P40,000 (w/o pump) – P 70,000 (w/ pump) ISF: 1750 w/ 10% discount for those who used pump CE: 59% Model 1	<i>Technical/Physical</i> <ul style="list-style-type: none"> - Water schedule is too tight (2days and 2nights only) - Members use pump since no other sources of water apart from irrigation - Another major reason is the construction of the ARIIP main canal. The construction traversed trough the laterals which eventually block the pathway of water from main canal to the lateral. - During wet season, the farms are flooded because the ARIIP main canal also blocks the drainage water.

¹³ No secondary data for IA profile.

		<ul style="list-style-type: none"> - Heavy siltation also comes from the unfinished area of the ARIIP - The construction of ARIIP is on hold as of the moment. - Best to provide STW pumps to farmers as supplement for irrigation - Propose to restore intake of Ambayonan river. <p><i>Institutional/Socio-Economic/Political/Cultural</i></p> <ul style="list-style-type: none"> - Cannot successfully complete 2nd cropping because at the same time, upstream farmers already go to 3rd cropping wherein they consume the water intended supposedly for downstream's 2nd crops - Due to tight scheduling, IAs requests for extension of water delivery. This brings a chain reaction wherein the last of the farmers can no longer benefit from the irrigation - NIA's implementation of water delivery schedule is poor. - Water master is not doing its job. In 5 schedules of water delivery, not once did the water master monitor and assisted in the distribution.
SMD – Samahang Magsasakang Gonzalo (upstream)	<p>Crop: Rice and corn Yield: 90 (dry); 120 (wet); Total cost: P30,000 – P35,000 ISF: 1700 CE: 70-95% Model 2</p>	<p><i>Technical/Physical</i></p> <ul style="list-style-type: none"> - Low water supply during dry season due to alternate rotation - Intake in dam should be increased - Availability of back hoe
Carsan Kudungo - San Quintin (downstream)	<p>Crop: Rice and corn Yield: 80-90 (dry) – rice; 100 cav/ha (dry) – corn; 70-80 (wet) Total cost: P20,000 (rice) – P30,000 (corn) ISF: 1700 (wet only) CE: 50% Type 2</p>	<p><i>Technical/Physical</i></p> <ul style="list-style-type: none"> - Main dam in Dipalo is highly silted since the earthquake of 1990 - All canals are highly silted which blocks the water to flow - No check structures (steel gate, culvert, regulator, etc.) - NIA has inadequate heavy equipment

Magat River Integrated Irrigation System (Div II & Div IV)¹⁴

IA	Profile	Issues and Concerns
Bagong Silang IA (upstream) Div 2	Crop: Rice Yield: 120 (dry); 110 (wet) Total cost: P30,000 ISF: 2975 (dry); 2125 (wet) CE: 85%	<p><i>Technical/Physical</i></p> <ul style="list-style-type: none"> - Earth canals are damaged by carabaos when they dip in the water. This eventually causes siltation. - Needs heavy equipment (back hoe and dump truck) for the constant need to repair the canals <p><i>Institutional/Socio-Economic/Political/Cultural</i></p> <ul style="list-style-type: none"> - Low buying of rice while high prices of input
FIA D-2 members IA (midstream) Div 2	Crop: Rice Yield: 130 (dry); 120 (wet) Total cost: P30,000 ISF: 2975 (dry); 2125 (wet) CE: 60%	<p><i>Technical/Physical</i></p> <ul style="list-style-type: none"> - Lateral canals need to be rehabilitated - Earth canals have to be lined
New Life IA (downstream) Div 2	Crop: Rice Yield: 130 (dry); 120 (wet) Total cost: P60,000 ISF: 2975 (dry); 2125 (wet) CE: 62%	<p><i>Technical/Physical</i></p> <ul style="list-style-type: none"> - In low water supplies, members borrow pumps in NIA and DA. Borrowing of pump is on a first come first serve basis. The members will provide for the gasoline. - The total cost of the unit is P14,000 - Labor cost in the area is too high (5000-6000 per ha), which forces the farmers to do “seed-throwing” instead which is an inefficient way of planting - Canals are eroded and highly silted therefore, best to concretize the main canal. - Concretize the farm-to-market roads <p><i>Institutional/Socio-Economic/Political/Cultural</i></p> <ul style="list-style-type: none"> - Water schedules were not followed by some members

¹⁴ No secondary data yet for IA Profile.

<p>Victoria, San Mateo IA (upstream) Div 2</p>	<p>Crop: Rice Yield: 129 (dry); 129 (wet) Total cost: P30,000 ISF: 2975 (dry); 2125 (wet) CE: 85%</p>	<p><i>Technical/Physical</i></p> <ul style="list-style-type: none"> - Canals are eroded and damaged - Request for additional concrete roads for all IAs
<p>Der-An IA (midstream)</p>	<p>Crop: Rice Yield: 150 (dry); 100 (wet) Total cost: P45,000 ISF: 2975 (dry); 2125 (wet) CE: 60%</p>	<p><i>Technical/Physical</i></p> <ul style="list-style-type: none"> - Lateral canals need to be rehabilitated - Earth canals have to be lined - NIA's equipment are inadequate to service the system. This leads to longer response time of NIA to address the farmers' concerns <p><i>Institutional/Socio-Economic/Political/Cultural</i></p> <ul style="list-style-type: none"> - Need regulation on prohibition of animals in the canals
<p>Victory IA (downstream)</p>	<p>Crop: Rice Yield: 100 (wet); 100 (dry) Total cost: P45,000 ISF: 2975 (dry); 2125 (wet) CE: 62%</p>	<p><i>Technical/Physical</i></p> <ul style="list-style-type: none"> - Canals are silted and damaged due to carabaos - Incomplete lining of canals. NIA's efforts are not sufficient due to financial constraints

Solana Pump Irrigation System¹⁵

IA	Profile	Issues and Concerns
Muhara IA – (upstream)	Crop: Rice Yield: 90-100 (dry); 45-50 (wet) Total cost: P20,000 - 30,000 ISF: 6375/ha with 25% discount for those who re-pumped CE: 57-87% Model 1	<i>Technical/Physical</i> <ul style="list-style-type: none"> - Elevation of canal is lower than paddies therefore, surface pumps are needed to draw water - Sediments clog the main canal thus constant clearing is needed - Domestic and commercial solid and liquid wastes are thrown towards the irrigation canals - Water is very limited due to high cost of pump operation (29 million) due to high electricity prices - Irrigation equipment and facilities are damaged when operation is left with farmers - 5 in 2 scheme greatly decreased the yield of farmers
Northern Solana Rice Producer IA (midstream)	Crop: Rice Yield: 120-150 [hyb] (dry); 100-130 [hyb] (wet) Total cost: P30,000 – P35,000 ISF: 6500/ha CE: 80% Model 1	<i>Technical/Physical</i> <ul style="list-style-type: none"> - Rat infestation during dry season - Implementation of AWD is not effective - Concreting of farm-to-market roads - Installation of steel gates and regulator - Desilting of canals
NWSFIA (downstream)	Crop: Rice Yield: 100 (dry); 80 (wet) Total Cost: P40,000 ISF:6375/ha Model 1	<i>Technical/Physical</i> <ul style="list-style-type: none"> - Earth canals need to be lined - Drainage rehabilitation - Due to high level of canal, surface pumps are used. Surface pump costs P20,000 per unit - Pest infestations (eel, rat, tungro)

¹⁵ No secondary data for IA profile.

Magapit Pump Irrigation System¹⁶

IA	Profile	Issues and Concerns
Lal-lo IA (upstream)	Crop: Rice Yield: 120 (dry); 80-100 (wet) Total cost: P35,000 - 40,000 ISF: 3187.50 normally but 2550 for those who re-pumped CE: 98% Model 1	<i>Technical/Physical</i> <ul style="list-style-type: none"> - Silted canals drainage - Drainage water cannot get through since elevation of drainage is lower than the river - Paddies are flooded during wet season due to overflow of river - Herbicides of upland farmers go through lowland paddies - Upland farming contributes to siltation - Canals are heavily silted which also results to clogged drainage - There are salt water intrusion in times of calamities - The root cause of siltation is the Cagayan river, therefore dredging the river is the immediate solution
Camalap IA (midstream)	Crop: Rice Yield: 120 (dry); 60(wet) Total cost: P30,000 – P35,000 ISF: 3187.50 CE: 94% Model 1	<i>Technical/Physical</i> <ul style="list-style-type: none"> - There are illegal turnouts - During wet season, there are areas that are not plantable - River is fully silted therefore the silt flows to the canals during rainy season - Pest infestation - Presence of illegal settlers along canals <i>Institutional/Socio-Economic/Political/Cultural</i> <ul style="list-style-type: none"> - Some members do not follow the water schedule. They open the gate during night time.

¹⁶ No secondary data for IA profile.

<p>Zigiran-Dadan IA (downstream)</p>	<p>Crop: Rice Yield: 120 (dry); 75 (wet) Total Cost: P40,000 ISF: 3187.50 normally but 2550 for those who re-pumped CE: 65-75% Model 1</p>	<p><i>Technical/Physical</i></p> <ul style="list-style-type: none"> - Earth canals need to be lined - Heavy siltation - Inadequate heavy equipment to address siltation - Need to rehabilitate canals - Implement ordinances for irrigation - Need buster pump to pump water from drainage canal
--------------------------------------	---	--

Visitacion Irrigation System¹⁷

IA	Profile	Issues and Concerns
<p>Dagupan IA – USUAC sector (upstream)</p>	<p>Crop: Rice Yield: 200 (dry); 150 (wet) Total cost: P35,000 ISF: 2500 (dry); 1500 (wet) CE: 100% Model 1</p>	<p><i>Technical/Physical</i></p> <ul style="list-style-type: none"> - There is a corner area of an irrigation canal which is very near the river. The water flow has to be carefully regulated because strong flow might damage the canal. Overflow of the canal will lead to merging of water between river and irrigation. This redirects the irrigation water to the river instead of going to the farm area. - There is a link canal from other alternative sources but a check structure has to be installed to prevent too much water gushing in - Farm to market road are damaged and have not been rehabilitated for the last 3 years. - Farm roads are currently under DA. Previously, maintenance of the road is fine under NIA - Proposed to have an impounding dam to avoid water shortage - More investment on heavy equipment as it is urgently needed <p><i>Initiatives/Success Stories</i></p> <ul style="list-style-type: none"> - The IA implements strict rules and regulation. There is a penalty of P500 per violation. - Not planting on the intended cropping calendar is also a violation. Therefore, when farmers do not plant, they will still have to pay P500. Otherwise, no water for next cropping and penalty will be doubled if violation will reach another cropping season.

¹⁷ No secondary data for IA profile.

		<ul style="list-style-type: none"> - Revenues from penalties usually reach 8000 per year - Revenue from collection incentive is 4000 per year
Dagupan IA – CABISIA sector (midstream)	<p>Crop: Rice Yield: 180 ca/ha Total cost: P30,000 ISF: 2550 (dry); 1700 (wet) CE: 70-100% Model 1</p>	<p><i>Technical/Physical</i></p> <ul style="list-style-type: none"> - Farm-to-market roads have deteriorated - Needs mini dam or impounding dam to store water for dry season - Some private owners don't allow NIA to dredge portions of drainage.
Dagupan IA – KAVISYA sector (downstream)	<p>Crop: Rice Yield: 100 (dry); 70 (wet) Total cost: P30,000 ISF: 2550 (dry); 1700 (wet) CE: 80-100% Model 1</p>	<p><i>Technical/Physical</i></p> <ul style="list-style-type: none"> - Difficulty in water delivery due to canals not being lined - Heavy siltation of canals - Damaged roads and difficult access - Needs heavy equipment (backhoe) - There's a need to use surface pumps for water to reach the area - Surface pump operation cost is P8000 per cropping

Pampanga Delta River Irrigation System

IA	Profile	Issues and Concerns
Sto. Nino Candating IA (Upstream)	Crop: Rice Yield: 100-110 (dry); 70-80 (wet) CE: 94% FUSA: 220 ha Program Area: 220 ha Total Area Planted: 158.10 ha CI: 72% IMT Model 2	<i>Technical/Physical</i> <ul style="list-style-type: none"> - Most laterals are earth canals - Experienced pest infestation in 2013 due to 5 in 2 - LGU promised a backhoe but have not materialized
Magcasaup IA (Midstream)	Crop: Rice Yield: 80-100 (dry); 60-70 (wet) Total cost: PhP50,000 ISF: 2550 (dry); 1700 (wet) CE: 91-100% FUSA: 99.30 ha Program Area: 99.30 ha Total Area Planted: 128.07 ha CI: 129% IMT Model 2	<i>Institutional/Socio-Economic/Political/Cultural</i> <ul style="list-style-type: none"> - Farmers only get break-even thus cannot pay the ISF - No provisions or ordinance in the by-laws which holds the officer accountable
San Carlos-Sta.Rita-San Pedro IA (downstream)	Crop: Rice Yield: 80-100 (dry); 50-60 (wet) Total cost: P20,000 ISF: 2550 (dry); 1700 (wet) CE: 60% FUSA: 162.60 ha Program Area: 162.60 ha Total Area Planted: 154.35 CI: 95% IMT Model 2	<i>Technical/Physical</i> <ul style="list-style-type: none"> - There is double pumping of water from drainage - Pump operating cost is P3000 - Need to improve irrigation facilities - Rehabilitation of damaged canals - NIA has no adequate funds for implementation of projects <i>Institutional/Socio-Economic/Political/Cultural</i> <ul style="list-style-type: none"> - Conflict arises due to difficulty in convincing members to pay the ISF

- Reshuffling of management affects prioritization of programs which leads to delay or cancellation
- Funds should go directly to NIA, not to other channels, since farmers have strong linkage with NIA

Initiatives/Success stories

- Improvements were made through lining and desilting of canals funded by congressmen and politicians.

Tarlac Groundwater Irrigation System (TGIS)¹⁸

IA	Profile	Issues and Concerns
TG 86 ISC	Crop: Rice Yield: 80-90 (dry); 0 (wet) Pump cost: 2 drums of diesel per hectare; 1 cavan per hectare (operator's salary)	<p><i>Technical/Physical</i></p> <ul style="list-style-type: none"> - Most areas are flooded during wet season thus, one cropping only - For non-cropping season, farmers go to other areas to do farming labor - Usual conflict is due to distribution schedule <p><i>Institutional/Socio-Economic/Political/Cultural</i> Difficulty in renewing cooperative registration due to administrative requirements</p>
TG 09 Kalibuan ISC	Crop: Rice Yield: 100-130/170[hyb] (dry); 90 (wet) Total cost: P40,000 per hectare [hyb] Pump cost: 200 liters per hectare; P50 per hectare (operator's salary); P150 per member for maintenance and repair of pump	<p><i>Technical/Physical</i></p> <ul style="list-style-type: none"> - Visit and support from NIA declined since 2005 due to cost constraints. Further declined due to Rationalization Plan <p><i>Institutional/Socio-Economic/Political/Cultural</i></p> <ul style="list-style-type: none"> - Farmers tend to be resistant to change such as using hybrid and organic farming. - Values of farmers have to be influenced to be adaptable to change and new technology <p><i>Initiatives/Success stories</i></p> <ul style="list-style-type: none"> - There is an additional income to the IA by using the pump to supply domestic water to households
GT 125 ISC	Crop: Rice and yellow corn Yield: 100-150 [hyb] (dry); 80-100 (wet) Total cost: P30,000 – P35,000 [hyb] Pump cost: 7% of total revenue (rice); 5% of total revenue (corn)	<p><i>Initiatives/Success stories</i></p> <ul style="list-style-type: none"> - One of the most successful irrigation cooperatives. - They were able to complete the payment of the amortization of the pump to NIA. - Used the pump to provide irrigation water to other groups which have insufficient water. - The success of the cooperative was able to construct an additional 300 meters of lined canal, renovate the pump house, and maintain the pump condition
