Old Idea, New Insights: The Ricardian Revival in International Trade

Arnaud Costinot and Dave Donaldson

Two centuries ago, David Ricardo wrote down a simple thought experiment that changed the way economists think about international trade. Suppose the residents of two nations, England and Portugal, differ in their ability to produce two goods, cloth and wine: Portugal is more efficient at both, but its relative advantage over England is weaker in cloth. If these countries are able to trade, what will happen? Who will trade what with whom? Who will gain from the trades? How large will the gains be?

Ricardo’s famous example has been used to answer these fundamental questions of international trade in countless textbooks: England imports Portuguese wine and everyone’s a winner, all the more so the worse the English are at making wine. Until recently, however, Ricardo’s logic has had surprisingly little impact on the way that economists use data from the world around them to answer questions about trade policy. Extending the logic to a realistic economy with many regions and products had seemed somewhere between impractical and impossible. But thanks to a number of recent innovations — most importantly in the seminal work of Jonathan Eaton and Samuel Kortum — this is rapidly changing.

In this research report, we describe some of our recent attempts to connect Ricardo’s 200-year-old idea to the real world.

Ricardian Comparative Advantage and Empirical Patterns of Trade

We begin by asking the most basic of empirical questions: How well do the predictions of a Ricardian model line up with data on trade patterns? In a famous challenge, a mathematician, Stan Ulam, once asked Paul Samuelson to name one proposition in the social sciences that is both true and nontrivial. After much reflection, Samuelson’s reply was: “Ricardo’s theory of comparative advantage.”

The practical content of Ricardo’s theory has received surprisingly little attention due to the challenges of connecting Ricardo’s ideas to data. Together with Ivana Komunjer, we have extended Eaton and Kortum’s quantitative model to study inter-industry Ricardian comparative advantage in a way that is amenable to empirical scrutiny.

The basic prediction of the Ricardian model is that countries should export relatively more in sectors in which they are relatively more productive. Our model captures this simple idea by providing closed-form solutions for relative bilateral trade flows as a function of relative observed productivity. Crucially, the model takes into account the fact that countries will not produce all varieties of every good. Rather, a country will only produce those varieties in which it is relatively more efficient. This implies that differences in observed productivity tend to be smaller than true differences in productivity as a result of a selection effect.

Combining standard data on industry-level trade flows and productivity, we find that countries do indeed tend to export goods where their relative productivity is higher, as this Ricardian model would predict. More precisely, a 1 percent change in relative productivity is associated with a 6.5 percent change in relative exports. There is also support for the notion that...
observed productivity differences are biased by Ricardian selection. We use our estimates to quantify the welfare impact of this Ricardian channel across sectors. Cross-industry differences in technologies generate only a small part of the gains from trade; comparative advantage operates mostly at the within-industry product level.

**Ricardo’s Difficult Identification Problem**

“Ricardo’s difficult idea,” as Paul Krugman once referred to the theory of comparative advantage, contains at its core a fundamental barrier to empirical analysis. Ricardo’s simple example involved a prediction about trade patterns as a function of four productivity numbers—England’s and Portugal’s productivity levels in cloth and wine. But how is an analyst to measure England’s productivity in an activity, such as wine making, which it does not engage in because it can import wine from Portugal? Without knowledge of this missing productivity number, it is impossible to test the model’s predictions about the patterns of trade. Yet the very essence of the model implies that this fourth number should not be observable to an analyst.

This empiricist’s Gordian knot—formally, an “identification” problem—is familiar in selection models throughout economics, but standard solutions have been difficult to apply to the study of international trade. Previous attempts to test the Ricardian theory, including our aforementioned paper, are therefore based on strong functional-form assumptions that impose a particular structure on the distribution of productivity across goods (and varieties of the same good) to allow an analyst to infer underlying productivity differences from observed differences.

In recent research, we have drawn on some unique features of the agricultural sector in order to make progress on Ricardian empirical work despite the identification challenges. The key observation is that this is a setting in which a major scientific focus among agronomists is to predict the productivity, for any crop, that any location could achieve as a function of its environmental conditions. For example, the Global Agro-Ecological Zones (GAEZ) project from the Food and Agricultural Organization aggregates such predictions for all major crops and at a detailed geographical level. The project includes information on 2.2 million parcels of land around the globe. This permits one to “observe” not only the productivity of a land parcel in its current use, but also in all potential uses.

In a first paper, we focused on a direct test of the Ricardian model. On the basis of GAEZ potential yield observations, we calculated the Ricardian model’s predictions about the pattern of production—which crops growers at different locations would choose to specialize in, at prevailing producer prices. These predicted patterns of production have significant power to predict actual patterns of crop production around the world—perhaps surprisingly so, given the many reasons for actual productivities to differ from those predicted by agronomists.

Moving beyond testing, a core interest is in estimating the gains from trade that exist in the world around us. As in all standard trade models, the Ricardian model postulates that regions differ and those differences give rise to potential gains from specialization afforded by the ability to trade. But how large are the differences, and hence how large are the gains? Unfortunately Ricardo’s identification problem again stands in the way. All four of Ricardo’s numbers are needed to evaluate the gains from trade, for either England or Portugal. The key is to estimate just how much more efficient the world is when England doesn’t have to produce any wine. That efficiency boost depends on how bad England is at producing the wine that it doesn’t produce.

In a second recent paper, we again draw on the GAEZ data to measure some of the gains from agricultural trade. In particular, we ask how much of the growth in U.S. agricultural productivity over the period 1880–1997 has come about because of the spatial integration of agricultural markets across the United States. A key challenge to incorporating information from

**Dave Donaldson** is a research associate in the NBER’s Development Economics, Development of the American Economy, and International Trade and Investment Programs, and a professor of economics at MIT. He is a co-editor of the *American Economic Journal: Applied Economics*, an editorial board member of the *Journal of Economic Literature*, the *Journal of International Economics*, the *Review of Economic Studies*, and the *Quarterly Journal of Economics*, and a program director (for trade) at the International Growth Centre.

Donaldson has investigated the welfare and other effects of market integration, the impact of improvements in transportation infrastructure, how trade affects food security and famine. He has been awarded the 2017 John Bates Clark Medal, as well as an Alfred P. Sloan Research Fellowship, and has benefited from support from the National Science Foundation.

Donaldson is a native of Toronto. He received an undergraduate degree in physics from the University of Oxford and a Ph.D. from the London School of Economics. He lives in Boston with his wife, daughter, and three sons.
the GAEZ data in this historical case is that potential yields, for each crop in each location, have changed, in unknown ways, due to technological progress. But under the assumption that those changes do not reverse comparative advantage within any country, we show how to use data from the Agricultural Census since 1880 to infer the unique set of prices and productivity shocks that is consistent with profit maximization and factor-market clearing in any given county and year. These estimated, model-consistent prices correlate well with data on actual state-level prices and show a clear trend toward lower intra-U.S. spatial price dispersion over time. Commodity markets were more integrated in 1997 than in 1880.

But how large are the benefits from this heightened integration? To shed light on this question, we calculate the change in the value of nationwide output that the 1880 economy would have enjoyed if inter-spatial price gaps in 1880 were set to their later (say 1920) level, rather than to the actual 1880 level. The results are surprising. For example, 1880–1920 gains were 79 percent, approximately the same as the gains that we calculate are due to pure within-location productivity gains. Similar statements are true about a later period, 1954 to 1997. Overall, the increasing exploitation of gains from intra-national trade in this context appear to have been a major, and perhaps underappreciated, contributor to aggregate economic growth.

**Comparative Advantage and the Costs of Climate Change**

Together with Cory Smith, we have also applied Ricardo’s logic to study of the consequences of climate change in agricultural markets around the world. There is little doubt that a warming climate will portend lower yields for many crops in many locations. But the aggregate consequences of those millions of micro-shocks will depend on the extent to which farmers can shift their growing patterns from one crop to another, and the extent to which consumers can change the trade linkages that connect them to particular farmers.

To examine these possibilities we build a general equilibrium model of trade, in 10 leading crops, among each of 1.7 million land parcels around the world. Each parcel has its own Ricardian productivity capabilities in each crop, so we have 17 million crop-parcel estimates, and trade occurs subject to trading frictions designed to match world trade flows today. We then shock each parcel’s productivity level in each crop in the manner that climateologists and agronomists believe will arise due to climate change by 2071–2100. This is feasible because the GAEZ project provides their agro-economic predictions both for contemporary climate conditions and also under the expected climate conditions that correspond to each of the scenarios used by the UN’s Intergovernmental Panel on Climate Change.

What are the consequences of this change in the 17 million place- and crop-specific productivities? We find that climate change would generate a large negative productivity shock for many countries around the world and that if there were no reallocations around the world, welfare would decrease substantially. The value of crop output would be predicted to fall by about 40 percent. However, there is enough heterogeneity in these shocks over space that after reallocation according to comparative advantage across crops within each parcel, welfare losses become smaller by a factor of three. Furthermore, there is so much productivity heterogeneity across parcels within countries that there is little to be gained from controlling countries’ capacity to adjust their trade flows internationally.

**Reducing Ricardian Complexity**

The Ricardian world can be a complicated place. The full equilibrium implications of Ricardo’s four numbers, in his simple two-by-two setting, took almost three decades to work out, as John Stuart Mill did in 1844. So what is the Ricardian analyst — let alone the reader — to make of the complexity of a model like that discussed above with 17 million productivity ingredients? In recent work with Rodrigo Adao, we have developed a new methodology for simplifying the empirical use of general neoclassical models, a class that includes the Ricardian model as a special case.

We first establish the equivalence between such models and reduced exchange models in which countries directly exchange factor services, extending an original insight from Charles Wilson in the Ricardian case. This...

called gravity models — like the version
the parametric approach used in so-
tered non-parametrically. To together, these
results offer a strict generalization of
the parametric approach used in so-
called gravity models — like the version
of the Ricardian model developed by
Eaton and Kortum — in which the fac-
tor demand system is isoclastic.

Home Demand as a Source of Ricardian
Comparative Advantage

In more recent work we have
turned to a more basic question: Where
do Ricardo’s cross-country differences
in relative productivities come from?
In models that incorporate increasing
returns, be they of the Marshallian sort
that are external to firms or of the
monopolistic competition sort that play
out through firm entry in differentiated
product markets, the productivity of a
given industry in a given nation rises as
its output increases. This opens up the
possibility, for sufficiently strong aggre-
gate economies of scale, of what Staffan
Linder and Krugman call the “home-
market effect,” in which a region’s home
demand base will become a source of
endogenous Ricardian comparative
advantage.

In work with Margaret Kyle and
Heidi Williams, we estimate the
strength of this effect in the context of
the global pharmaceutical industry.

Building on previous work on the
effect of demographic changes on inno-
vation and product entry by Daron
Acemoglu and Joshua Linn, our
paper establishes that countries that for
demographic reasons are expected to
have high demand for a certain type of
drug are actually more likely to be net
exporters of that drug. We find that the
correlation between predicted home
demand and sales abroad is positive and
greater than the correlation between
predicted home demand and purchases
from abroad, which is strong evidence
for the role of the home market in cre-
ating comparative advantage.

Ricardo’s Rejuvenation

New data sources, new modeling
strategies, and new empirical procedures
have breathed new life into Ricardo’s
200-year-old insights about comparative
advantage and trade flows. This revital-
ized line of work has generated important
insights on a range of applied questions,
including the design of border taxes, the
origins of aggregate productivity gains,
and the expected harm from climate
change. We have recently surveyed many
of these new developments. The impact
of Ricardo’s path-breaking work may be
even greater in its third century than in
its first two.
