# COMPUTATIONAL EXPERIMENTS IN THE FORMULATION OF LARGE-SCALE LINEAR PROGRAMS

ΒY

GERHARD KNOLMAYER

Paper presented at the Workshop on Large-Scale Linear Programming, organized by the International Institute for Applied System Analysis (IIASA) at Laxenburg, Austria

Kiel, December 1980

Professor Dr. Gerhard Knolmayer Institut für Betriebswirtschaftslehre, Christian-Albrechts-Universität zu Kiel Olshausenstraße 40-60, 2300 Kiel Computational Experiments in the Formulation of Large-Scale Linear Programs

#### Abstract:

One of the decisions in the construction of a linear program is upon the formulation which should be used. This paper explains why there is usually a very large number of equivalent formulations and reports on the computational behavior of these formulations. The usual textbook-hypothesis which claims that CPU-time increases with the cube of the number of constraints is falsified; it is shown that the advantage of reducing the number of rows may be overcompensated by an increase in the number of nonzeros.

#### COMPUTATIONAL EXPERIMENTS IN THE FORMULATION OF

## LARGE-SCALE LINEAR PROGRAMS

1. DECISIONS IN BUILDING A DECISION MODEL

Several (meta-) decisions have to be made in the construction of a decision model:

- Which section of reality should be modelled ?
- How accurate should one model this section of reality ?
- Which algorithm should be used ?
- Which people, computer, software should be employed ?
- Which formulation should be used for a given degree of accuracy of the model ?

The implementation of different answers shows these questions will result in different benefits and costs (of the decision model. The ultimate benefit of modelling is to gain insight into reality. In more detail one could distinguish between

Benefit from model accuracy Benefit of the ease of understanding the formulation the solutionthe model.

On the other hand one can partition the costs of decision models into

Costs of model construction Costs of collecting data Costs of manipulating data Costs of computation.

Many computational experiments have been performed in mathematical programming (MP). Most research has concentrated upon the comparison of algorithms and codes. Recently the need for research on a methodology of <u>formulating</u> MP-models has been expressed /18/.

Most computational experiments compare "costs", usually by giving CPU-time. Sometimes costs and benefits are compared, e.g. if the "quality" of solutions obtained is compared to the CPU-time needed for exact and heuristic algorithms. From this point of view one can distinguish the four areas of computational experiments shown in Fig. 1. These areas have been investigated to a very different extent. This paper concentrates on a <u>cost</u>-comparison of equivalent <u>formulations</u> by using a production code for linear programming (LP).

Type of Object of comparison	Cost-Comparison	Cost-Benefit-Comparison
Algorithms (Codes)		
Formulations	X	

Fig. 1: Types of experiments and topic of the paper (  $\mathbf{X}$  )

#### 2. THE NEED TO STUDY EQUIVALENT FORMULATIONS

We define equivalent formulations as models from which identical optimal activity levels can be derived (by using a report writer); the optimal values of the objective functions coincide. Several researchers have compared <u>two</u> equivalent formulations for linear or mixed-integer problems; I make references to the well-known studies of H.P.Williams /17;19/ on (mixed-) integer models and to the confrontation of linear product-mix-models with a "normal" resp. "aggregated" technological matrix /12;14,p.148-157;16,p.27-82/. Such comparisons suffer from the fact that often not only

<u>3</u>

two but plenty of equivalent formulations exist. Especially if MP-models are generated from data bases containing information on every-day-operation the model builder has to decide which of the equivalent formulations should be generated. This decision determines the computational effort for matrix generation and for optimization.

In principle one can define basic relations from the data base as activities of the LP model and connect these activities by balance equations. But often the so emerging model will be unsolvable by production codes due to an enormous number of balance equations. A product-mix-model for a manufacturing firm with 400 final and 10000 intermediate products, with 30000 materials, 300 capacities and an average number of 5 operations for the manufactured products would need 82301 rows and 82400 structurals! Therefore it is desirable to generate a compact models by eliminating balance equations. Fig. 2 shows a small out of the very large number of equivalent LP-models that can be generated from a data base. In Fig. 2 the size of the model is measured by the number of rows. Data manipulation looks highly attractive from the usual textbook hypothesis that CPU-time grows with the cube of the number of rows /cf. e.g. 1, p.83; 3, p.16; 5, p.146; 6, p.181; 15, p.118; 20, p.10/. Few authors claim that CPU-time is influenced by the density of the model /11,p.57;14,p.190/. Oykeliminatize dalance (equations) usually the number of rows is reduced) and the density rises. Therefore rules of thumb are wanted which information about presumable effects of matrix condensation. To support the decisions in model construction two types of experiments are necessary: ow

- Experiments of generating MP-models out of (non-specialized) data bases
- Experiments on the optimization behavior of equivalent formulations.

This paper reports on the second type of experiments.

## 3. THE ELIMINATION OF BALANCE EQUATIONS

## 3.1. THEORY

Let

(1)  

$$c' \quad x \rightarrow \max \ !$$

$$A^{M1} \quad x = b^{M1} > 0$$

$$A^{M2} \quad x = 0$$

$$x \ge 0$$

be a feasible LP with slack and surplus, but without artificial variables. The indices of the constraints i form the set  $M=M1\cup M2$ . Rows i M2 are called balance equations. Let  $M2=M21\cup M22$ . We search for a transformed LP with new variables  $\tilde{x}$ 

(2)  

$$c' T \dot{x} \neq \max!$$

$$A^{M1} T \tilde{x} = b^{M1}$$

$$A^{M2} T \tilde{x} = 0$$

$$T \tilde{x} \ge 0$$

which is equivalent to (1) but computationally more appropriate. The latter requirement might be achieved if

In this case M22 rows can be dropped as redundant,

If the original formulation (1) contains p=|M2| balance equations there are at least  $2^p$  equivalent formulations! To overcome the problems due to this enormous number of equivalent formulations we restrict the discussion to those formulations which arise by a sequential elimination of balance equations. The sequence can be determined heuristically.by some plausible criterium. In the <u>sequential procedure we have</u>

$$\begin{array}{c}
|M22|\\T = \Pi & T\\i=1
\end{array}$$

where  $T_{i}$  is the transformation matrix for the i-th elimination of a balance equation.

It remains to determine Matrices  $T_i$  in such a way that (1) and (2) are equivalent. After elimination of f-1equations there exists a row keM21.so that

$$\overline{A}^{k} = A^{k} \prod_{i=1}^{f-1} T_{i}$$

Let  $\overline{POS(k)} = \{j \mid \overline{a}_{kj} > 0\}$  and  $\overline{NEG(k)} = \{j \mid \overline{a}_{kj} < 0\}$ . These sets are nonempty if there are no null variables.  $\overline{x}_r$  ( $r\epsilon \overline{POS(k)}$ ) can be positive if and only if at least one  $\overline{x}_j$  ( $j\epsilon \overline{NEG(k)}$ ) is positive. This "If-then"-relation allows  $\overline{x}_r > 0$  and  $\overline{x}_s > 0$  ( $s\epsilon \overline{NEG(k)}$ ) implicitly by a "coupled activity"  $\overline{\overline{x}}_u > 0$ . The coefficients of the coupled activity are computed as

$$\bar{\bar{a}}_{iu} = g \left( \bar{a}_{ir} \cdot |\bar{a}_{ks}| + \bar{a}_{is} \cdot |\bar{a}_{kr}| \right)$$

so that variable u has a zero in row k. g is an arbitrary positive factor; in the subsequent text we assume g=1.

<u>All</u> possible activity levels of the prior formulation can be expressed by  $|\overline{POS}(k)|$ .  $|\overline{NEG}(k)|$  coupled activities. After the transformation all variables  $\overline{x}_i$  (*je* $\overline{POS}(k)\cup\overline{NEG}(k)$ ) can be deleted. In the matrix

there are unity column vectors for the untouched activities and two non-zeros in those columns which represent coupled

activities. We have  $T_f^{\geq}$  0 and therefore  $T \geq 0$ .Furthermore we get modified sets

 $\bar{\mathbf{M}}_{21} = \bar{\mathbf{M}}_{21} - \{\mathbf{k}\}$   $\bar{\mathbf{M}}_{22} = \bar{\mathbf{M}}_{22} + \{\mathbf{k}\}$ 

The transformation reduces the number of rows by one. The effect on the number of legitime variables depends on the number of positive and negative coefficients in row k:

 $\vec{n} = \vec{n} + |\vec{P}OS(k)| \cdot |\vec{N}EG(k)| - |\vec{P}OS(k)| - |\vec{N}EG(k)|$ 

Table 1 shows how the number of legitimate (=non-artificial) variables changes with the sign of the non-zeros in the eliminated balance equation. The effects of condensation on model structure are illustrated in Table 2 and Fig. 3 for a refinery model given by Meyer-Steinmann /10,p.390-393/: The points on the right hand of Fig. 3 characterize the original formulation; the effect of sequential data manipulation on problem structure is shown by going to the left. Activity coupling reduces the number of rows far more than e.g. the REDUCE-module of APEX-III.

From an economic point of view one can describe the condensation by the isoquant given in Fig. 4. It might happen that both formulations compared in literature are unsolvable on the system used while some equivalent formulations might be computationally well suited. The isoquant must be read from right to left.

.

In economic theory only the part BC of the isoquant would be regarded as efficient. In this connection the part AB is efficient too because it Atak Aresources to go from A to B. The part CD is explained by the reason that by eliminating a balance equation one or more bounds can become regular rows; this part of the isoquant is inefficient.

As soon as a formulation (2) is reached which is regarded computationally well suited the optimal levels of the activities  $\tilde{x}^{\otimes}$  are determined. The optimal values of the original variables can be computed by

$$x^{\otimes} = T \tilde{x}^{\otimes}.$$

#### 3.2. AN EXAMPLE

Consider a problem in which two final products  $x_1$  and  $x_2$  are produced by using a part, which can be either purchased  $(x_3)$  or produced  $(x_4)$ :

Max. 500  $x_1 + 1000 x_2 - 200 x_3 - 150 x_4$ s.t.  $2 x_1 + 1 x_2 + 1 x_4 \neq 1000$   $4 x_2 + 2 x_4 \neq 2000$   $1 x_1 + 4 x_2 - 1 x_3 - 1 x_4 = 0$  $x_j \ge 0$  all j

The first two constraints represent capacities, the third is the balance equation for the part. The definitions

> X<sub>1</sub> ... quantity of final product 1 produced by using parts purchased X<sub>2</sub> ... quantity of final product 1 produced by using parts produced by the firm

$$\tilde{x}_3$$
 ... quantity of final product 2 produced by  
using parts purchased  
 $\tilde{x}_4$  ... quantity of final product 2 produced by  
using parts produced by the firm

allow the formulation

Max.  $300 \tilde{x}_1 + 350 \tilde{x}_2 + 200 \tilde{x}_3 + 400 \tilde{x}_4$ s.t.  $2 \tilde{x}_1 + 3 \tilde{x}_2 + 1 \tilde{x}_3 + 5 \tilde{x}_4 \leq 1000$  $2 \tilde{x}_2 + 4 \tilde{x}_3 + 12 \tilde{x}_4 \leq 2000$  $\tilde{x}_j \geq 0$  all j.

Formally such a reformulation can be obtained by multiplying the original coefficient matrix with the transformation matrix

$$\mathbf{T} = \begin{bmatrix} 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ 1 & 0 & 4 & 0 \\ 0 & 1 & 0 & 4 \end{bmatrix}$$

We have  $M2=\widetilde{M}22=\{3\}$ ,  $A^{\widetilde{M}22}T=(1\ 4\ -1\ -1\ )$ .  $T=O_{1}$  and  $\overline{\overline{n}}=4+2\cdot 2-2-2=4$ . The optimal solution for the condensed LP is  $\widetilde{x}^{\otimes}=(250\ 0\ 500\ 0)$ '. Optimal levels of the original variables can be determined by  $x^{\otimes}=T\widetilde{x}^{\otimes}=(250\ 500\ 2250\ 0)$ '.

The different paths through the networks in Fig. 5 show that a general series transformation is employed for eliminating a balance equation.

Fig. 6: Flow of information in computational experiments

generator PPPGEN was written in FORTRAN to create LPmodels of product-mix-type. The user specifies the type of model to be created (in-much detail) by setting 16 scalar and 3 vector parameters. One set of parameters generates different LP-problems with very similar but not identical structures by use of random numbers.

15

2. Preprocessing

A FORTRAN-program performs the transformations discussed above. The user controls the order in which the balance equations are selected for elimination by 7 parameters. This selection is based on an estimation of the number of additional non-zeros an elimination might create.

3. Optimization

Optimization was done by the in-core-system BASE-APEX-III using the standard parameters (except LOG=1) on a CYBER 74 under NOS/BE. The reported CPU-time was needed for optimization only. (The maximal deviation of CPU-time due to multiprogramming is only about 1 % on the system used.)

4. Postprocessing

APEX-III produces an FORTRAN-accessible file which was used to determine the optimal levels of the activities in the original formulation. This postprocessing is based on (3) although the matrix T was not computed explicitly.

5. Recording Information about Optimization

The regular OUTPUT-file of APEX-III contains information which is necessary to analyse the optimization behavior. This output-file was read by a program which recorded the structure of the model and the specifics of the solution process.

6. Regression Analysis

The data collected in step 5 were examined by regression analysis. First the exponents of the variables in various regression models were determined by SPSS' module for non-linear regression. The results were used to define transformed variables for a "linear" regression through the origin. Several hypotheses on the dependence of optimization time on model structure were compared by the coefficient of determination,  $R^2$ .

#### 7. Control Experiments to

'A test developed by Hoel /7/) was used to compare the best regression equation against the textbook-hypothesis A more detailed description of the experiments and the program lists are given in /9/.

#### 5. RESULTS OF THE COMPUTATIONAL EXPERIMENTS

Four problem classes and four problem sizes for each problem class have been examined. For each of the 16 cases 5 models were generated. Three problem classes were used to develop an appropriate explanation for the CPU-time observed; problem class 4 was used to control the results. Table 3 shows the approximate structure of the models in largest size. For problems of smaller size the figures in Table 3 have to be reduced by 25%, 50% and 75%.

All 80 formulations were condensed in five steps. In these steps a balance equation was eliminated if not more than a certain number of additional non-zeros were expected to arise. For problem class 3 and largest size Table 4 shows the effects of these condensations. The optimization was done by the procedures CRASH and PRIMAL of BASE-APEX-III. All formulations were optimized using constant field length RFL,100000<sub>8</sub> (=32768 decimal words of 60 bits each). Optimization time was reduced remarkably in the first phases of the condensation but in latter phases the condensation did not pay  $\mathcal{A}_{W}$ .

Table 5: Comparison of regression models for explaining CPU-time in problem classes 1 to 3

The improvement of (6) over (5) is so small that (7) PREDCPU =  $a m^b nz^c$ is regarded as most suitable. For this model the approximate 95% confidence intervals for the exponents are computed in the non-linear regression by SPSS as

Although these intervals for CPU-time.  $26 \leq c = .33 \leq .39$ . Although these intervals are tight they lead to rather wide

 $1.15 \leq b = 1.25 \leq 1.34$ 

The new assumption (5) was compared with the established hypothesis (4) via a test developed by Hoel /7/. This test

<u>18</u>

leads to a linear regression of type

(8) (OBSCPU - ESTHYP) = w . (NEWHYP - ESTHYP)

for additional data. The usefulness of NEWHYP is confirmed if w is significantly positive. Regression (8) gives a coefficient w=1.37 for 111 cases belonging to problem class 4; the 95% confidence interval is w=1.22. The t-value for regression (8) is 15.11. This value can be compared with the one-sided value for 95% and DF=110 which is 1.66. The scattergramm in Fig. 7 shows that in 93 of 111 cases the signs of the differences in (8) are identical. Therefore the new formula (5) predicts significantly better than the established hypothesis (4).

<u>19</u>

6. SUMMARY

An identical LP-optimum usually )car be obtained by many equivalent problem formulations. Data condensation is necessary if large models are generated from data bases containing information about every-day-operations. Most textbooks recommend to reduce y the number of rows as much as possible. Our experiments show that the usual m<sup>3</sup>-hypothesis is misleading and should be cancelled from textbooks. The experiments described above indicate that the number of non#zeros has remarkable influence on computational effort. The rule given by E.M.L.Beale /1,p.83/ that it is normally not worth saving a row by substituting a variable if this adds more than about half a dozen non zeros remains useful in the light of our experimental results. The number of nontzeros may rise if the number of structurals is reduced Taking (into account) the effort for matrix generation one might propose an even easier rule of thumb:

"Eliminate balance equations only if

- the model is so large that the number of rows is a burden
- the number of structurals is reduced by the elimination and the number of non-zpeos rises only slightly."

For product-mix-models this rule suggests to use balance equations for products which have more than one way of preparation (e.g. make or buy; manufacturing variants) and more than <u>one</u> way of utilization (e.g. sell or process). Thus if options are available a "combined" formulation is recommended which differs from both formulations compared in literature. is intermediate bolumen Hease we receive presented in literature.

If the resulting model is still too large the following actions could be taken into mind: cowsidered:

- Nay the problem be solved easien by codes with GUBfacilities and can such a code be made amenable ?

- Should one define in the first (i-1) LP only options which are expected to be optimel and generate for optimization run(i+1) new variables for options which improve the solution of run **5** • These candidates can be determined by the **i**th dual solution.
- Is it possible to develop better algorithms for <u>dense</u> LP-problems ?

If all these questions have to be denied there is an effective "solution constraint" on the LP originally proposed. In this case one must take into account the potential benefits of differently accurate models and judge whether a less accurate model will allow enough insight into the real-world problem that it pays to develop this less accurate model.

## MAIN SYMBOLS

DF ESTHYP	Degrees of freedom CPU-time predicted by the established hypothesis (4)
m	number of rows
Ml	set of indices 1 with b, 0
M2	set of indices i with bi=0 (balance equations)
M21 ⊊ M2	set of indices i for balance equations not eliminated
M22 ⊊ M2	set of indices i for balance equations eliminated
n	number of structurals
nz	number of non-zeros
NEG(k)	set of indices j with a,<0
NEWHYP	CPU-time predicted by the new assumption (5)
OBSCPU	Observed CPU-time
POS(k)	set of indices j with $a_{1,2}>0$
PREDCPU	Predicted CPU-time
R <sup>2</sup>	Coefficient of determination
RFL	Requested Field Length
ISETI	number of elements in a SET
	manaformation matrices
⊥ <b>,</b> ⊥i	Transformation matrices
