Steffen Reinhold

The Institute for Evaluation of Labour Market and Education Policy (IFAU) is a research institute under the Swedish Ministry of Employment, situated in Uppsala.

IFAU's objective is to promote, support and carry out scientific evaluations. The assignment includes: the effects of labour market and educational policies, studies of the functioning of the labour market and the labour market effects of social insurance policies. IFAU shall also disseminate its results so that they become accessible to different interested parties in Sweden and abroad.

Papers published in the Working Paper Series should, according to the IFAU policy, have been discussed at seminars held at IFAU and at least one other academic forum, and have been read by one external and one internal referee. They need not, however, have undergone the standard scrutiny for publication in a scientific journal. The purpose of the Working Paper Series is to provide a factual basis for public policy and the public policy discussion.

More information about IFAU and the institute's publications can be found on the website www.ifau.se

Econometric analysis of the effects of economic conditions on the health of newborns ^a

Gerard J. van den Berg ^b Alexander Paul ^c Steffen Reinhold ^d

December 5, 2018

Abstract

We examine whether economic downturns are beneficial to health outcomes of newborn infants in developed countries. For this we use merged population-wide registers on health and economic and demographic variables, including the national medical birth register and intergenerational link registers from Sweden covering 1992–2004. We take a rigorous econometric approach that exploits regional variation in unemployment and compares babies born to the same parents so as to deal with possible selective fertility based on labor market conditions. We find that downturns are beneficial; an increase in the unemployment rate during pregnancy reduces the probability of having a birth weight less than 1,500 grams or of dying within 28 days of birth. Effects are larger in low socio-economic status households. Health improvements cannot be attributed to the parents' own employment status. Instead, the results suggest a pathway through air pollution.

^aWe thank Anna Sjögren and participants at a seminar at the University of Aarhus and at EEA/ESEM and EALE conferences for useful comments and suggestions. Also, we thank Statistics Sweden and Socialstyrelsen for the use of the micro data registers and Hans-Martin von Gaudecker and Mårten Palme for their efforts in making these data accessible. We thank IFAU Uppsala, in particular Linus Liljeberg and Olof Åslund, for the data on unemployment rates. Financial support from the German Science Foundation DFG Grant RE 3086/1-1 and the European Research Council through Starting Grant No. 313719 is acknowledged.

1 Introduction

A currently expanding literature examines how up- and downturns of the economy affect the health of newborn children. For developing countries, there is strong evidence that recessions tend to increase infant mortality, while booms tend to lower it.¹ In contrast with this evidence, it has been suggested that the effect of the cycle differs in developed countries, with newborn health improving in recessions. The pivotal study by Dehejia and Lleras-Muney (2004), using U.S. state-level data, estimates that an increase in the unemployment rate by one percentage point lowers both the infant mortality rate and the incidence of very low birth weight (below 1,500 grams) by 0.5 percent.

There are several reasons for why babies' health suffers less from recessions in developed countries than in developing countries (see also the discussion in Ferreira and Schady (2009)). First, while spending on public health care has been shown to decline during downturns in developing countries (Cutler et al. 2002; Paxson and Schady 2005), fiscal policy generally tends to be countercyclical rather than procyclical in developed countries (Lane 2003). Second, recessions are often shorter in developed countries, and given the higher level of health spending, marginal reductions are less severe. Third, credit markets are more widespread, allowing mothers to smooth income and thus spending on health care and nutrition.

Studies on effects of economic fluctuations in developed countries on health of the *adult* population confirm that contemporaneous health improves in recessions. Pioneering work by Ruhm (2000) and many subsequent studies provide strong evidence for the procyclicality of the total mortality rate.² Several of the channels linking the business cycle to adult health also apply to babies, both in utero and shortly after birth.³ This includes channels that are related to parental job loss, since downturns

1. See Cutler et al. (2002) for Mexico, Paxson and Schady (2005) for Peru, Lin (2006) for Taiwan and Bhalotra (2010) for India. Baird et al. (2011) using a dataset from 59 developing countries in Africa, Latin America and Asia, find that a 5 percent reduction in GDP per capita increases the number of infant deaths by 1 to 2 per 1,000 children born. A notable exception is Miller and Urdinola (2010), who document that higher world coffee prices raise infant mortality in Colombia in coffee-growing regions. Higher prices lead to higher income but also to lower time-intensive investments in child health, due to increased labor supply.

2. Gerdtham and Ruhm (2006) show that this relationship also holds in a panel of 23 OECD countries. See van den Berg, Gerdtham, et al. (2017) for recent evidence on procyclicality of mortality in the current labor force in Sweden, exploiting regional variation in unemployment rates over time and relating them to outcomes at the individual level.

3. Recently, Page et al. (2018) provided evidence on the cyclical effects on the health of children (aged 0-17 years). They found health to be positively associated with the labor market conditions of men, but negatively with those of women. This supports the view that the business cycle affects health not only in adulthood, but throughout the whole life cycle.

give rise to displacements and lower chances of re-employment. Job loss reduces the available income that can be spent on tobacco and alcohol. Smoking and drinking during pregnancy are highly detrimental to newborns' health. It has been shown that these behaviors are less prevalent in downturns (Ruhm 2000; Ruhm and Black 2002). Further, as a result of job loss, the mother's opportunity cost of time decreases, so she may become more engaged in time-intensive activities that benefit babies' health, such as prenatal care, physical exercise or breast-feeding (Miller and Urdinola 2010), and her exposure to hazardous working conditions decreases. One may also consider channels that are not propelled through actual job loss. First, recessions are associated with less traffic and lower air pollution levels Chay and Greenstone (2003). Air pollution, in turn, has been shown to be an important determinant of newborn health (see Currie et al. (2014) for a review of the literature). Second, while job loss has been associated with stress, lower workloads in recessions might reduce job-related stress for those who do not lose their job, and positive spillovers among parents are likely. There is plenty of evidence that stress affects birth outcomes, in particular during the first trimester of pregnancy (Camacho 2008; Torche 2011; Mansour and Rees 2012; Bozzoli and Quintana-Domeque 2014; Foureaux Koppensteiner and Manacorda 2016). Third, economic upturns are characterized by a shortage of medical staff, resulting in lower availability and quality of prenatal and neonatal care (Stevens et al. 2015).

In the light of the importance of the issues at hand, it is perhaps surprising that there is only little evidence for developed countries. Margerison-Zilko (2010) does an extensive literature search and finds about 15 studies, almost all of which concern aggregate data. One major complication in estimating the effect of the cycle is that women who give birth in a recession may systematically differ from those who give birth in a boom. Dehejia and Lleras-Muney (2004) argue that low-educated women — who do not suffer from skill depreciation — prefer to give birth in recessions when the wage they would receive is low. The authors provide evidence that the fraction of low-educated mothers indeed rises in times of high unemployment, at least for white mothers. The effect is reversed for black mothers, a finding that Dehejia and Lleras-Muney (2004) attribute to credit constraints. In this line of reasoning, low-educated black mothers would also prefer to give birth in recessions, but cannot afford to do so since credit constraints prevent them from smoothing income over time. Salvanes (2013) and Aparicio and González (2014) find that low-educated mothers are overrepresented in recessions.

The composition of newborns has also been studied in the literature on long-run

health effects of conditions at birth. After all, late-life health problems among cohorts exposed to adverse early-life conditions may be affected by selective fertility in the corresponding birth years. Most of these studies do focus on what are now developed countries; however, the birth cohorts are from years in which governmental social safety nets were largely absent. Some studies examine how exposure relates to birth rates or to the composition of newborns in terms of observed characteristics of the families into which they are born, following the line of reasoning that if such a relation exists then it is also more likely that there are systematic differences between exposed and non-exposed in terms of unobserved characteristics of the families. Van den Berg and Modin (2013) provide an overview of those studies (see e.g. Kåreholt 2001; van den Berg et al. 2009; van den Berg et al. 2011). They all conclude that the composition of newborns does not vary systematically over the business cycle.

One approach to deal with compositional changes over the business cycle is to compare babies born to the same mother at different stages of the cycle. Econometrically, this may be achieved by including mother fixed effects in the model equations, which requires individual-level data. Interestingly, when Dehejia and Lleras-Muney (2004), who study the U.S., control for mother fixed effects using a subsample from California, the positive effects on the health of newborns become all insignificant, suggesting that selection had been the main driver. Other studies of developed countries employing fixed-effects identification strategies also fail to establish a significant relationship with the cycle (Salvanes (2013) for Norway and Aparicio and González (2014) for Spain).⁴ Most studies of developing countries find their results unaltered when accounting for selection bias (Paxson and Schady 2005; Bhalotra 2010; Baird et al. 2011).

Van den Berg and Modin (2013) consider individual records from Swedish birth cohorts 1915–1929, where birth weight was recorded at birth by health care workers. Note that at that time, Sweden was not yet a developed economy according to today's standards. They find no relationship between the business cycle and birth weight, both in basic analyses and in fixed-effects analyses with mother-specific fixed effects. Van den Berg, Lindeboom, Popławska, et al. (2017) use family-specific fixed-effects in the analysis of long-run effects of conditions at birth among Dutch birth cohorts around 1850 on individual longevity, and they subsequently examine the distribution of the estimated unobserved family-specific fixed effects over the various birth years. They find no evidence of an association between conditions around

4. In robust specifications with parental and time fixed effects, Aparicio and González (2014) find a negative effect of unemployment only on late fetal death. It is significant at the 10% significance level; however, it vanishes when additionally accounting for province time trends.

birth on the one hand, and the unobserved family-specific “frailty” determinant of longevity on the other hand.

In this paper we utilize population-wide register data from Sweden from 1992 to 2004 to address whether downturns improve newborns’ health. The data include comprehensive register-based information of infant health and conditions around birth, from the neonatal and patient registers. All information is recorded at the individual level and in real time by professional health care workers. We match these data with local-labor-market unemployment rates which provide indicators of the business cycle. Exploiting geographical variation in unemployment within Sweden, we control for variables that may confound a relation between economic conditions and newborns’ health. Moreover, we use identifiers of the mother and father in order to enable comparisons of health outcomes of babies born to the same parents. In this way, we control for the possibility that parents select into pregnancy depending on the state of the business cycle. We find that higher unemployment significantly reduces the incidence of neonatal mortality and very low birth weight. Our point estimates suggest that a one percentage point increase in the unemployment rate is associated with a ca. 10% decrease in these health outcomes, but standard errors are quite large. The effect is entirely driven by the unemployment rate of men. We also find evidence for selective fertility over the cycle, which underlines the importance of controlling for parental fixed effects.⁵

We use merged socio-economic and demographic information about the parents to investigate possible mechanisms underlying the effects. First of all, we consider the role of actual parental unemployment, which is more prevalent in times of recessions. This sheds some light on whether health-enhancing activities — due to lower opportunity cost of time — or reduced smoking and drinking — due to lower available income — drive the estimated effects. We find that parental job loss does not play an important role in mediating the beneficial effects of recessions. As a next step, we investigate whether the effects vary by socio-economic status (SES) of the parents. Low-SES parents tend to be hit harder by recessions. We also find that recessions decrease the occurrence of premature birth. Both observations hint at a pathway through air pollution, which is plausibly reduced in recessions and has

5. Tapia Granados and Ionides (2008, 2011) and Svensson and Krüger (2012) consider time series on mortality and economic conditions at the national level for Sweden. As a by-product of their analyses, they find some evidence for a positive association between infant mortality and national-level indicators of the business cycle. Catalano et al. (1999), studying Sweden and using Norway to control for independent variation in newborn health, find a positive relationship between male unemployment and very low birth weight. Yet none of these papers controls for selection into childbirth.

been shown to disproportionately affect low-SES families and to provoke premature birth in prior work. Our paper also contributes to the literature on birth weight determinants. In particular, the effect sizes on the incidence of low birth weight may be compared to those due to other interventions (Kramer 1987; Currie and Cole 1993; Kaestner and Lee 2005).

This paper is structured as follows: Sections 2 and 3 explain the data and econometric method, respectively. Section 4 presents the results, starting with an analysis of selective fertility. We then report baseline effects on newborn health, followed by a sensitivity analysis, and an investigation into heterogeneity and potential mechanisms. Section 5 concludes.

2 Data

2.1 Unemployment data from the HÄNDEL register

We start this section with a brief outline of some notable features of Swedish society. Sweden has a large welfare state acting as a social safety net. Every citizen has access to the tax-funded public health care sector. Private health insurance and patient cost-sharing only play a tiny role.⁶ Income inequality is among the lowest in the world and consumer credit is widely available. Female labor force participation is relatively high.⁷ Sweden has traditionally had a high level of prenatal and neonatal care, as reflected in one of the smallest infant mortality rates worldwide (World Bank 2016b). We therefore suspect that fluctuations in the quality and availability of medical care over the cycle are rather limited. At the same time, there are reasons to suspect that boom years are not particularly detrimental to health either. Specifically, since overtime work is regulated through collective bargaining agreements, the stress caused by overtime hours in booms is limited.

We should point out that our observation window does not include the 2008 recession and its aftermath. However, Sweden experienced a severe downturn in the early 1990s, with GDP per capita shrinking in three consecutive years between 1991 and 1993 (World Bank 2016a).

For the purposes of our study, we construct a dataset from two sources: monthly unemployment data at the municipality level and, secondly, population-wide ad-

6. See e.g. Tertilt and van den Berg (2015), for a description of the Swedish health care system.

7. According to OECD data, labor force participation among women aged 15–64 years amounted to ca. 78% in Sweden in the period 1990–2004, compared with an OECD average of ca. 58%.

ministrative data on newborn infants and parental characteristics at the individual level. The former are discussed in the current subsection and the latter in the next subsection.

The unemployment data come from the so-called HÄNDEL register created by Swedish public employment offices. HÄNDEL captures all persons in Sweden who register as “openly” unemployed with the employment office. Persons who classify themselves as unemployed in surveys because they are temporarily unemployed (e.g. due to a job change) or expect to be unemployed soon (e.g. due to a short-term contract or the notification of lay-off), but do not register with the employment office, are not included in HÄNDEL. However, Carling et al. (2001) report that more than 90% of the individuals who are ILO-unemployed according to labor force surveys are also registered as unemployed.

From the HÄNDEL registers starting in January 1992, the number of unemployed individuals by month and municipality can be deduced, stratified by gender, age group (18–24, 18–30, 18–40 and 18–64 years) as well as the interaction of gender and age group. These numbers can then be divided by the corresponding numbers of individuals in the population, to obtain the unemployment-to-population ratio. We simply refer to these as “the” unemployment rates. Unfortunately, the registers at our disposal do not allow for observation of the size of the labor force.

If the labor market that is relevant from the individual’s perspective extends to or even centers in a municipality other than the municipality of residence, then the unemployment rate in the municipality of residence is only an incomplete indicator of economic conditions. In fact, an individual can (and might find it optimal for job search to) register with an employment office in a different municipality. To capture spillovers from surrounding areas, we aggregate municipality-level unemployment rates to the local labor market level. This approach also alleviates concerns about measurement error in municipality-level unemployment.⁸ We use the definition of local labor markets provided by *Tillväxtanalys* (formerly Nutek), the Swedish Agency for Growth Policy Analysis (*Tillväxtanalys* 2005). Mainly based on commuting patterns in 2003, this definition divides Sweden into 72 non-overlapping so-called functional analysis regions (FA-regions).⁹ The basic idea is to construct regions

8. For example, measurement error could arise because an individual moves to another municipality without registering with the new employment office.

9. There are two steps in the formation of FA-regions: First, a municipality is defined as independent if the share of commuters to any other municipality does not exceed 20 percent in the working population and the share of commuters to any single municipality does not exceed 7.5 percent. Second, municipalities that are found not to be independent are merged with connected independent ones to form a FA-region. For more details, see ITPS (2008, pp. 195–196).

that include both the place of residence and the place of work for the majority of people. Previous papers using FA-regions are, for example, Eliasson et al. (2012) and Moretti and Thulin (2013). Clearly, the benefits of aggregation to local labor markets must be weighed against the reduced power due to ignoring idiosyncratic variations of economic conditions within smaller regional units. We therefore explore the sensitivity of our results to various degrees of aggregation.

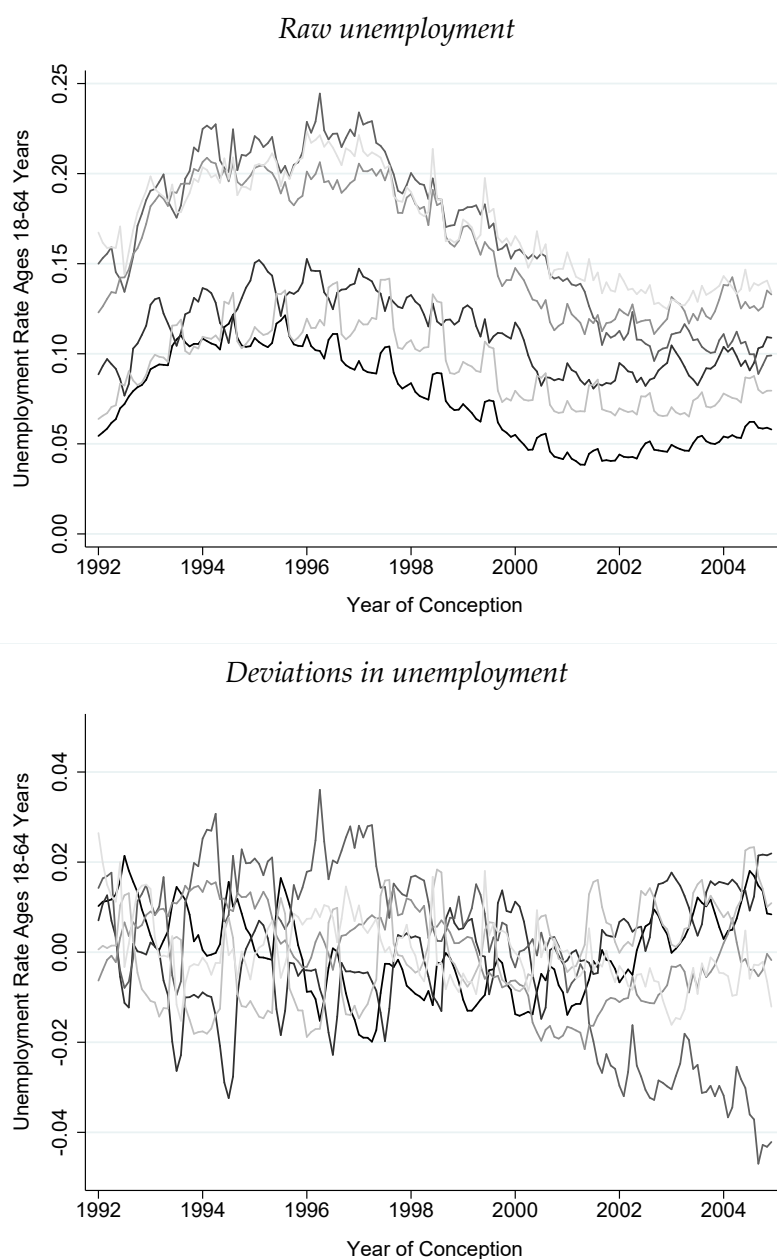

The upper panel of Figure 1 illustrates the evolution of the unemployment rate for six randomly selected local labor markets between 1992 and 2004. Reflecting the deep recession that occurred in Sweden in the early 1990s, unemployment is relatively high at the beginning of the time period with values of more than 20 percent. Unemployment then sinks to a low around 2001/02 and subsequently rises again. To capture business cycles, we use a detrended version of the unemployment rate stripped of permanent differences across local labor markets and month-specific national shocks as well as seasonal variations. The detrended time series is illustrated in the lower panel of Figure 1. Note that the residual variation in unemployment after detrending is fairly large. For some local labor markets there appear to be secular trends in unemployment towards the end of the time period. It is unclear whether these trends are driven by third factors that might also affect newborn health outcomes or whether they constitute independent variation in unemployment. We check the sensitivity of our results to controlling for local-labor-market-specific time trends in the results section.

Since we are interested in how economic conditions during pregnancy shape birth outcomes, our main measure of unemployment will be the average unemployment rate in the nine-month period following conception, where the measurement of conception is explained in the next subsection. In additional analyses, we estimate effects by trimester and study the impact of periods before and after pregnancy.

2.2 Individual register data

We merge the unemployment data with an individual-level administrative dataset that integrates a number of different registers. The linkage of registers is possible thanks to a unique personal identifier that each individual gets assigned at birth. Because we are interested in the effect of labor market conditions during pregnancy, we use the Vital Statistics register and the Medical Birth register to identify all infants whose month of conception was after January 1992, the earliest month for which we

Figure 1: Unemployment rate (18–64 years) for a few local labor markets

Notes: Monthly unemployment rates (18–64 years) for six randomly selected local labor markets. Deviations in unemployment are after detrending the unemployment rate by taking out permanent differences across local labor markets as well as month-specific national shocks, which account for countrywide fluctuations in unemployment such as seasonal variation.

have unemployment data.¹⁰

¹⁰ We define the month of conception to be the month of the first day of the last menstrual cycle. Since this variable is sometimes missing or inaccurate, we also construct the month of conception

The Medical Birth register also contains data on birth weight, Apgar scores¹¹ and neonatal mortality, i.e. whether a newborn infant died within 28 days after birth. For infant mortality, i.e. deaths within a year of birth, we add information from the Cause of Death register, which includes deaths up until 2005, so that infant mortality is observable up until 2004. Finally, the Medical Birth register also indicates the mother's municipality of residence, which — together with the month of conception — allows us to determine local labor market conditions around the time of birth.

Where municipality of residence is not available in the Medical Birth register, we take it from the mother's socio-economic and demographic data records — the so-called LISA register. This register also provides maternal income, earnings, unemployment benefits, marital status and education. The same variables are available for the father too. However, since the Medical Birth register only indicates the mother but not the father, for fathers we have to rely on the Intergenerational Link register, which does not provide father links for children born in 2005 and later. This restriction implies that the inclusion of parents fixed effects in the empirical analysis limits the sample to the time period 1992 to early 2004.¹² To determine the birth order of a newborn infant, we count the number of children that the mother has given birth to in the past. Finally, we match records from the National Inpatient register to obtain information about hospitalizations of both the mother during pregnancy and the child after birth.

2.3 Sample

The starting point for our sample is the universe of newborn infants that were conceived in 1992 or later and born in Sweden in 2004 or earlier, as dictated by the availability of unemployment data and paternal information (see the previous subsection). We apply a number of restrictions to obtain the final sample: First, we disregard all parents from those municipalities that did not remain the same over the time period we study. More specifically, there were four municipalities that were

using the more accurate variables birth month and gestation length. If the month of conception as given in the data differs from the constructed month by more than 1 month or is entirely missing, we replace it with the constructed month. If gestation length is missing we only retain the month of conception if its implied gestation length — given birth month — ranges between 5 and 11 and set it to missing otherwise. We ignore birth records for which both month of conception and gestation length are missing.

11. The Apgar score is a summary measure for the health of newborn infants. It ranges between 0 and 10, with higher values indicating better health. It is taken 1, 5 and 10 minutes after birth.

12. Babies conceived later in 2004 are born in 2005, so that we do not have father information.

each split into two.¹³ Besides measurement error in unemployment rates due to employment offices not following the splits carefully, there might be idiosyncratic shocks to affected municipalities. Therefore, for each split, we ignore both the municipality that retained the original name and the one that was newly created. Second, we focus on singleton births. Multiples such as twins and triplets have typically quite low birth weight, which adds noise to the analysis. Moreover, since labor market conditions during pregnancy are identical for multiples, within-multiples comparisons are not informative for the relationship between economic conditions and newborn health outcomes. Finally, we limit attention to mothers who were aged between 18 and 49 at the time of conception because the drivers of pregnancy are likely different for mothers outside this age interval.

After excluding infants whose father is still unknown (to us), which applies to about 6% of births, we are left with 874,581 babies conceived between 1992 and early 2004. They are born to 590,541 distinct pairs of parents. A woman might be part of several parent pairs if she has children with different partners. Of women who have at least two children in the time period we study, 14.9% have them with two or more different partners. The corresponding number for men is a little smaller (12.3%), but recall that we exclude babies for whom the father is unknown.

In an econometric model with parents fixed effects, identification rests on parent pairs with at least two births. There are 245,036 parent pairs in the sample that fulfill this criterion (529,076 births). In the empirical analysis, we will cluster standard errors at the level of the local labor market that parents reside in at the time of birth. We therefore focus on parent pairs that have several births in exactly one local labor market (235,581 parent pairs). There are parent pairs that have several babies in multiple local labor markets, but rather than selecting a random local labor market, we choose to disregard these parent pairs. The parent pairs that we keep might have additional isolated births in a different local labor market, but then we exclude these observations from the analysis. Our final regression sample consists of 506,565 birth records.

Table 1 provides descriptive statistics for both the whole sample and the sample we ultimately use in the analysis. The main health outcomes of interest in this paper are neonatal mortality (death within 28 days of birth) and very low birth weight (birth weight less than 1,500 grams, VLBW). The incidence of these variables is relatively low. In the regression sample, only about 0.2% (2 out of 1,000 infants)

13. The splits were as follows: Bollebygd broken out of Borås (1995), Nykvarn broken out of Södertälje (1999), Knivsta broken out of Uppsala and Lekeberg broken out of Örebro (both 2003).

Table 1: Summary statistics by sample

	Whole sample			Regression sample		
	Mean	Std. Dev.	N	Mean	Std. Dev.	N
Neonatal mortality	0.0017	0.0409	874,581	0.0022	0.0472	506,565

Notes: Summary statistics for selected variables by sample. The regression sample focuses on parents that have several births in exactly one local labor market, see Section 2.3. Month unemployment is the unemployment rate in the month of conception. Pregnancy unemployment is the average unemployment rate in the nine months following conception. Developed countries include EU-15 (excl. Sweden), Norway, North America and Oceania. Developing countries include the rest of Europe, Africa, South America, Asia and Soviet Union. "No wage" takes on the value 1 if a gross wage of zero is reported in the statement of income submitted to the tax agency. "No reimbursements" takes on the value 1 if no work-related reimbursements are received.

suffer from neonatal mortality and about 0.4% (4 out of 1,000 infants) have a birth weight less than 1,500 grams. So to ease interpretation of the estimated effects, we scale up these variables to express them as per 1,000 infants in the regressions below.

3 Econometric specification

The first equation that we examine captures how the birth rate and demographic composition of the parents vary over the cycle. Specifically, in line with the literature,

$$(1) \quad Y_{lt} = \alpha + \beta \text{Unemployment rate}_{lt} + \delta_t + \lambda_l + \theta_l t + \varepsilon_{lt}$$

where Y_{lt} is an outcome relating to all births conceived in month t by parents living in local labor market l . Specifically, Y_{lt} is the birth rate — the number of births per 1,000 women aged 18–49 years — or the share of parents belonging to some demographic subgroup, such as low-educated individuals. The parameter β captures the effect of economic downturns, as measure by the unemployment rate, on the outcome. δ_t are month-fixed effects that capture nationwide fluctuations in unemployment in the month of conception. These are included to control for third factors that affect economic conditions (such as labor market policies or long-run increases in educational attainment) and also correlate with newborns' health outcomes. As a result, the identifying variation in unemployment stems from regional variation in transitory economic conditions. The λ_l are local-labor-market fixed effects that account for persistent differences in unemployment across local labor markets, as illustrated in Figure 1. In some specifications, we also allow for local-labor-market-specific linear time trends ($\theta_l t$). These may help reduce omitted variable bias further but come at the cost of increasing estimation uncertainty.

Given that local labor markets vary considerably in population size and a few small regions do not encounter a single birth in some months, we use the number of births as weights in the regression. This also makes our results more comparable with the individual-level analysis later on. To account for serial correlation in the error term, we cluster standard errors at the level of the local labor market.

For health effects we adopt the following equation which is similar in spirit to equation (1), except that it is specified at the individual (newborn) level. Accordingly, we include parental fixed effects. This results in the key model equation of the paper,

$$(2) \quad Y_{it} = \alpha + \beta \text{Unemployment rate}_{l(i)t} + \delta_t + \rho_i + \theta_{l(i)t} + X_i' \gamma + \varepsilon_{it}$$

Here, i refers to a pair of parents consisting of mother and father. Y_{it} is a health outcome such as whether the infant has a very low birth weight ($< 1,500$ grams) or suffers from neonatal mortality (death within 28 days of birth).¹⁴ By including parental fixed effects ρ_i , we essentially identify β by comparing babies born to the same parents but at different stages of the business cycle. This accounts for selective fertility over the cycle. Note that ρ_i also absorbs local-labor-market fixed effects since — by construction of the sample — all births belonging to the same parents were conceived in the same local labor market (see subsection 2.3). In sensitivity analyses, we include parental characteristics that may vary across siblings, such as marital status and birth order (X_i). We once again cluster standard errors at the level of the local labor market.

4 Results

4.1 Setting the stage: preparatory analyses on the relevance of selection

Before studying how economic conditions impact newborn health outcomes, we first investigate how the composition of parents of newborns changes over the business cycle. This exercise yields insights into which variables potentially confound health outcomes. It also sheds light on the determinants of fertility decisions, which are of independent interest.¹⁵

14. In specifying linear probability models rather than binary choice models such as logit or probit we follow the literature.

15. Rather than arising from deliberate fertility decisions, differential fertility by demographic group might also arise due to a differential propensity for fetal loss (Bhalotra 2010) or differential mobility to low-unemployment regions (Lindo 2015). The former may be more prevalent in developing countries. We return to this issue below.

Notes: Each coefficient comes from a separate OLS regression of the birth rate on the unemployment rate in the age group 18-64 years in the month of conception. Birth rates are defined as the number of births with the same month of conception in the given subgroup per 1,000 women aged 18–49 years in the overall population. Percentage changes divide the unemployment effect by the mean level of the outcome in the observations used in the regression. Both coefficients and percentage changes are for a 1-percentage-point increase in the unemployment rate, but coefficients are scaled up by 12 to obtain annualized figures. Sample includes months January 1992 to March 2004. Controls are month fixed effects, local-labor-market fixed effects and local-labor-market-specific linear time trends where indicated. Regressions are weighted by the number of births. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

We start with estimating the effect of downturns on the birth rate — defined as the number of births per 1,000 women aged 18–49 years in the overall population. Here we use the overall unemployment rate among individuals aged between 18 and 64 years in the month of conception. Recall from subsection 2.3 that the sample in the health regressions below only includes babies conceived in 1992 or later and born in Sweden in 2004 or earlier. Consistent with this restriction, we thus focus in this exercise on months of conception between January 1992 and March 2004.

Table 2 shows that recessions have no effect on the overall birth rate. When we stratify the analysis by parental characteristics, we find a negative impact on the rate of parents that are young, low-educated and Swedish. Moreover, there is a positive effect on the birth rate among high-educated and married parents and parents from developing countries. Specifically, a 1-percentage-point increase in the unemployment rate implies a rise in the birth rate among mothers from developing countries of about 7-9%. Table A.1 shows that results are similar when using the average unemployment during pregnancy, rather than unemployment in the month of conception.

We investigate the effect of the cycle on the composition of births more directly by regressing shares of demographic groups on unemployment (see Table 3). By comparing Tables 2 and 3 we see that changes in birth rates do not always result in notable changes in the composition. There is a significantly negative effect on the share of low-educated mothers and high-educated fathers, and a positive effect on the share of mothers that are divorced and parents that come from developing countries. When using the average unemployment rate during pregnancy (see Table A.2 in the appendix), we additionally find that the share of single parents increases at the expense of the share of married parents. The negative effect on high-educated fathers disappears.¹⁶

16. Our findings are consistent with some findings in existing studies on the compositional impact of the cycle in recent years (see the references in Section 1). In particular, similar to the Norwegian

study by Salvanes (2013), we observe that the share of married mothers tends to decrease with higher unemployment. In agreement with Salvanes (2013) and Aparicio and González (2014), we fail to detect a clear pattern in parental age. However, Dehejia and Lleras-Muney (2004) find fewer young- and more medium-aged mothers in recessions in the United States, and Lindo (2015), also using U.S. data, reports an increase in teen births in recessions. Finally, we find low-educated mothers to be underrepresented in recessions, which is in line with the work by Bhalotra (2010) for India, but in contrast to several studies of developed countries Dehejia and Lleras-Muney (2004), Salvanes (2013), and Aparicio and González (2014).

Notes: Each coefficient comes from a separate OLS regression of the share of infants with the same month of conception in a given subgroup on the unemployment rate in the age group 18-64 years in the month of conception. Percentage changes divide the unemployment effect by the mean level of the outcome in the observations used in the regression. Both coefficients and percentage changes are for a 1-percentage-point increase in the unemployment rate, but coefficients are scaled up by 100 to express them in percentage points. Sample includes months January 1992 to March 2004. Controls are month fixed effects, local-labor-market fixed effects and local-labor-market-specific linear time trends where indicated. Regressions are weighted by the number of births. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

If parental characteristics are correlated with newborns' health, then compositional changes in birth cohorts caused by the business cycle entail changes in average health outcomes among newborns. We explore the implications of such selective fertility for average health outcome levels using Table A.2. Recalling from Table 1 that the average number of VLBW infants is 0.0052 and that of infants dying with 28 days within birth (neonatal mortality) is 0.0017, Table A.3 provides summary statistics of VLBW and neonatal mortality for demographic subgroups of the population. As for mother's education, more highly educated mothers are less likely to have VLBW children. No such clear-cut pattern is visible for neonatal mortality, but on average a smaller fraction of low-educated mothers in recessions — *ceteris paribus* — tends to improve health among newborn infants. Similarly, babies born to married mothers suffer from neonatal mortality significantly more often. However, the pattern is opposite for VLBW, so that the effect on average health remains unclear. Regarding country of origin, mothers from developing countries have a higher propensity to give birth to babies that suffer from VLBW or neonatal mortality. An increase in the proportion of these mothers in recessions would imply reductions in average newborn health. Overall, while the evidence from Table A.3 clearly demonstrates that newborn health varies by demographic group, it remains inconclusive about the direction of the effect that compositional changes induced by recessions have on average health outcome levels.

The selection on observables means that the correlation between economic conditions and newborns' health provides a biased estimate of a causal effect. However, note that compositional changes related to the characteristics included in Table A.3 generate only negligible health effects. As an example, consider the shift from low-educated mothers to medium-educated and high-educated mothers by about 0.0034

for a 1 percentage point increase in the unemployment rate.¹⁷ From Table A.3, the average incidence of VLBW among high- and medium-educated mothers is about 0.0021 lower relative to low-educated mothers. Given an average VLBW of 0.0052, this implies that a change in the unemployment rate of 1 percentage point will decrease VLBW by only about 0.1%.

While selective fertility based on observable characteristics appears negligible, there may be unobserved variables that govern fertility over the cycle, potentially leading to fluctuations in aggregate newborns' health. This is of course why, in the key analyses in the subsequent subsections, we include parental fixed effects. In doing so, we control for time-invariant parental characteristics, both observed and unobserved.¹⁸

When using parental fixed effects, identification comes from parent pairs with at least two births. Moreover, at least two births of a parent pair have to differ in, first, the economic conditions under which they were conceived and, second, the newborns' health outcome of interest. As our indicator of economic conditions is a continuous variable, the first condition is mechanically fulfilled. The second condition is fulfilled if parents experience a specific health outcome such as VLBW in some but not all of their children. As shown above, the prevalence of VLBW and neonatal mortality, while being low overall, varies by demographic group. As a consequence, among the parents who contribute to identifying the effect of interest, the fraction of those belonging to a demographic group in which a certain health outcome (such as VLBW) is relatively frequent should be disproportionately high. This is confirmed by Table A.4, in which we compare the characteristics of those parents in the regression sample that never had a child with VLBW or neonatal mortality ("no child") and those parents that experienced VLBW or neonatal mortality in at least one but not all of their children ("at least one"). Consistent with the findings from above, it can be seen that mothers and fathers who exhibit variation in either health outcome are significantly more likely to be old, non-single,

17. In the specification with trends, add up the reductions in the shares of low-educated mothers, -0.17, and the combined increase in the share of medium-/high-educated mothers, 0.17. Divide the result by 100, since reported coefficients are scaled up by this factor.

18. Selection into pregnancy might also occur independently of the cycle. If a disproportionate number of women from a certain demographic group become pregnant and give up their jobs in response to pregnancy, then this generates a mechanical shift in the unemployment rate that will be correlated with the level of newborn health specific to this group. Note that also this type of selective fertility will be captured by parental fixed effects. Moreover, note that maternal leave laws exist in Sweden, meaning that women on maternal leave are not counted as unemployed and even encouraged to work during most of the pregnancy so as to maximize the replacement rate while on leave.

low-educated and non-Swedish and have babies with higher birth orders. At the same time, there remains sufficient demographic variation to explore heterogeneity in effects, which we will turn to when discussing mechanisms (see subsection 4.5).

In this context it is interesting to examine medical abortions as a means to control fertility. If the result of an abortion is that the family ends up with exactly one newborn child in our observation window then the abortion effectively causes the family to be omitted from the sample used in the fixed effects analyses. By analogy to the paragraph above, this should not affect the results if the model specification is correct. However, if, for example, effects of recessions are heterogeneous across families, and if this is not taken into account, then selectivity of abortions across the cycle may affect the results. Dehejia and Lleras-Muney (2004) discuss earlier studies and conclude that the evidence for an association between economic conditions and the abortion rate is inconclusive. Medical abortions are ambulatory and thus not observed in the inpatient registers. Hence they are not included in our data. Instead, they are recorded in a different register called the Outpatient Register. For a small number of years we have access to the latter for one region in Sweden (Skåne; see Tertilt and van den Berg (2015)). In this region we observe a positive association between recessions and the medical abortion rate. However, given that the association is not large, and given that abortions constitute only a small fraction of the birth rate, and given that the potential health outcomes in the absence of an abortion should not be dramatically worse than those among actual newborns, we are confident that abortions do not affect the estimation results below. It is also useful to point out that the results below when stratified by parental characteristics appear to be similar for different subgroups (see the subsequent subsections), so that effect heterogeneity does not seem to be a key issue.

4.2 Baseline effects on newborns' health

We next turn to the micro-level analysis of how unemployment affects newborn health. We estimate versions of equation 2, which controls for parents fixed effects to address selective fertility. The baseline results are presented in column 1 of Table 4.

We present estimates for our preferred indicator of economic conditions, which is the unemployment rate at the local labor market level among men aged 18-64 years, averaged across the nine months following conception. Alternative indicators will be discussed in subsection 4.3.

There is a negative and significant effect of recessions on both very low birth

Table 4: Baseline effect of unemployment on health

	LLM-specific time trends			
	Baseline	Linear trends	Quadratic trends	Maternal controls
<i>Weight < 1,500 grams (VLBW)</i>	(1)	(2)	(3)	(4)
Unemployment	-0.480** (0.207)	-0.597** (0.245)	-0.531* (0.317)	-0.476** (0.203)
% change	-11.25%	-13.98%	-12.45%	-11.17%
- Upper bound	-1.76%	-2.71%	2.13%	-1.84%
- Lower bound	-20.74%	-25.26%	-27.03%	-20.49%
Mean × 1,000	4.268	4.268	4.268	4.267
N	503,339	503,339	503,339	503,145
<i>Neonatal mortality</i>	(1)	(2)	(3)	(4)
Unemployment	-0.244** (0.110)	-0.277** (0.135)	-0.165 (0.204)	-0.228** (0.112)
% change	-10.89%	-12.38%	-7.38%	-10.21%
- Upper bound	-1.23%	-0.57%	10.46%	-0.35%
- Lower bound	-20.55%	-24.18%	-25.22%	-20.07%
Mean × 1,000	2.237	2.237	2.237	2.236
N	506,565	506,565	506,565	506,371

Notes: Each reported coefficient comes from a separate regression. Unemployment refers to the average unemployment rate among 18-64-year-old men in the nine months following conception. Percentage changes divide the unemployment effect by the mean level of the outcome in the observations used in the regression. Both coefficients and percentage changes are for a 1-percentage-point increase in the unemployment rate. Coefficients and means are scaled up to express them as per 1,000 infants. Controls are month fixed effects and parents fixed effects. Column 4 additionally controls for birth order, a third-order polynomial in mother's age, and mother's marital status. Upper/lower bound refer to the upper and lower bound of the 95% confidence interval. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

weight and neonatal mortality.¹⁹ The size of the effect is quite large. A one-percentage point (= 0.01) increase in the unemployment rate is associated with an 11 percent decrease in both very low birth weight and neonatal mortality. This is an order of magnitude larger than the health effects implied by compositional changes with respect to some observable variables such as marital status computed in subsection 4.1. Hence, our results cannot be driven by fluctuations in these variables.

The estimates are also an order of magnitude larger than comparable estimates from earlier literature, which ranged between 0.5 and 0.7% for very low birth weight and between 0.2 and 0.6% for neonatal mortality (Dehejia and Lleras-Muney 2004; Lindo 2013; Aparicio and González 2014). However, this comparison of point

19. Coefficients are for a one-percentage point (= 0.01) increase in the unemployment rate and scaled up by 1,000 to improve readability.

estimates is misleading for two reasons: First, the standard errors of our estimates are quite large, and 95% confidence intervals suggest that the effects could in fact be as small 1-2%, much closer to earlier findings. Second, our estimates, unlike the others, are based on regressions that controls for parents fixed effects, which may give rise to stronger effect sizes. Table A.7 in the appendix illustrates the importance of controlling for parents or mother fixed effects. It shows that omitting them and instead only including local-labor-market fixed effects renders the estimates smaller and insignificant (columns 2 and 7).²⁰ This suggests that those parents and mothers who select into pregnancy when unemployment is high tend to have sicker children, thus counteracting the positive impact on health.²¹

We test the robustness of this estimate by allowing for labor-market-specific time trends in columns 2 and 3. As it turns out, adding time trends affects the estimate only slightly. However, the residual variation in unemployment shrinks considerably, as reflected in enlarged standard errors, especially with quadratic trends. For this reason and because regional time trends are more likely to emerge for a longer time span — ours being relatively short compared with e.g. Dehejia and Lleras-Muney (2004) — our preferred specification will not include time trends in the following.

In column 4, we additionally control for birth order, a third-order polynomial in mother's age, and mother's marital status. These variables might help reduce bias in the estimation, but are only imprecisely identified if simultaneously controlling for parents and year fixed effects eliminates most of their variation. Once again, coefficients change negligibly with the inclusion of these variables. We therefore do not include them in our preferred specification.

Finally, Table A.8 in the appendix explores the sensitivity of our results to a logit specification. For both the model with and without fixed effects, we obtain estimates very similar to the ones from our baseline linear probability specification.²²

20. Our results differ from those of Dehejia and Lleras-Muney (2004), who do not find significant effects once they control for mother fixed effects. However, they can only conduct this exercise for a Californian subsample, which yields effect sizes different from the national sample even when not controlling for mother fixed effects, suggesting there is a more general problem with this dataset.

21. Furthermore, the effect on neonatal mortality becomes insignificant when only controlling for mother rather than parents fixed effects (column 3 of Table A.7). This is primarily driven by adding mothers whose child's father is unknown. These mothers appear to have sicker children in recessions, thereby cancelling the otherwise positive effect of recessions on newborn health.

22. In order to cluster standard errors at the local-labor-market level, we focus on parents that have several babies in exactly one local labor market. This approach excludes parents who have several babies and each of the babies while residing in a different local labor market. In additional sensitivity analysis, we include in the sample *all* parents who have at least two babies, regardless of whether or not the parents moved between births. Table A.5 presents regression results for the extended sample with standard errors clustered at the parents level. Table A.6 repeats this analysis, but assigns the

4.3 Sensitivity Analysis

4.3.1 Timing of effects

Do the beneficial effects of recessions vary over the course of a pregnancy? In Table 5, we split the analysis by trimester. Effects appear strongest in the second trimester of pregnancy (column 5), but estimates are also significant and not substantially different in the first and third trimester. Therefore, we cannot conclude that the cyclical sensitivity of newborn health varies within pregnancy.²³

For our estimates to capture the health effect of the business cycle, we expect to find significant correlations with unemployment during, but not so much before or after pregnancy. To examine this, Table 5 also presents trimester-level regressions for the 9-months periods before and after pregnancy. It is reassuring to see that the estimates become generally insignificant and smaller in absolute size as we move away from pregnancy. The only, and presumably random, exception is the significant coefficient on neonatal mortality 7-9 months before pregnancy. Overall, Table 5 justifies our choice of using the average unemployment rate during pregnancy as our baseline indicator of the cycle.

4.3.2 Male and female unemployment

Table 6 investigates whether male and female unemployment affect health outcomes differently. It shows that the effect of downturns is entirely driven by male unemployment, for which coefficients are larger and more precisely estimated. Male unemployment is typically a better proxy for the business cycle than female unemployment. One reason is that men are over-represented in the private sector, where employment is sensitive to the cycle, rather than the public sector, where employment is more stable. Using annual county-level GDP data for the period 2000–2011, we also find that in Sweden male unemployment is more strongly related to GDP than female unemployment. Moreover, note from Table 1 that the standard deviation of female unemployment is lower than that of male unemployment. Because male unemployment appears to be a better indicator of the business cycle, we will focus on it in the following. We return to this point in subsection 4.6.1, when discussing

local labor market of the first-born child to all later-born children. This allows for clustering at the local-labor-market level. Both tables demonstrate that our baseline estimates are not much influenced by excluding certain parents that move between births.

23. This is also confirmed by Table A.9 in the appendix, where we simultaneously include all three trimesters in the same regression. Given that unemployment exhibits high serial correlation, it does not come as a surprise that none of the individual coefficients is any longer significant.

Table 5: Effects by trimester in the 9 months before, during or after pregnancy

Trimester VLBW	Before pregnancy			During pregnancy			After pregnancy		
	1st (1)	2nd (2)	3rd (3)	1st (4)	2nd (5)	3rd (6)	1st (7)	2nd (8)	3rd (9)
Unemployment	-0.141 (0.193)	-0.139 (0.205)	-0.279 (0.190)	-0.377** (0.177)	-0.416** (0.185)	-0.359* (0.189)	-0.225 (0.187)	-0.228 (0.180)	-0.200 (0.163)
<i>Neonatal mortality</i>	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)
Unemployment	-0.356*** (0.135)	-0.188 (0.120)	-0.128 (0.103)	-0.194* (0.108)	-0.234** (0.105)	-0.156* (0.093)	-0.082 (0.121)	-0.099 (0.120)	-0.184 (0.125)

Notes: Each reported coefficient comes from a separate regression. Unemployment refers to the unemployment rate among 18-64-year-old men. Coefficients are for a 1-percentage-point increase in the unemployment rate and scaled up to express them as per 1,000 infants. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

Table 6: Effect by gender

<i>Weight < 1,500 grams (VLBW)</i>	Unemployment		
	Male (1)	Female (2)	Overall (3)
Unemployment	-0.480** (0.207)	-0.211 (0.175)	-0.431** (0.214)
% change	-11.25%	-4.94%	-10.11%
<i>Neonatal mortality</i>	(1)	(2)	(3)
Unemployment	-0.244** (0.110)	-0.092 (0.101)	-0.211** (0.105)
% change	-10.89%	-4.12%	-9.43%

Notes: Each reported coefficient comes from a separate regression. Unemployment refers to the unemployment rate among 18-64-year-old individuals of the indicated gender in the nine months following conception. Percentage changes divide the unemployment effect by the mean level of the outcome in the observations used in the regression. Both coefficients and percentage changes are for a 1-percentage-point increase in the unemployment rate, but coefficients are scaled up to express them as per 1,000 infants. Controls are month fixed effects and parents fixed effects. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

mechanisms.

4.3.3 Age groups and regions

In Tables A.10 and A.11 in the appendix, we explore how the effect varies depending on the age group and region we use to compute the unemployment rate.²⁴ If the

24. See Table A.12 and A.13 for corresponding regressions for female unemployment.

business cycle primarily affects newborn health via parental unemployment, focusing on unemployment among younger individuals – including most parents – might yield more precise estimates. However, including older individuals will increase the number of observations. This reduces measurement error in the unemployment rate, especially if newborn health is not so much influenced by parental unemployment, but rather general economic conditions.

In Table A.10, note that the size of the estimate rises as we include older men. This partly reflects a mechanical inflation of coefficients as a result of adding individuals for whom unemployment varies less with the cycle, so that changes in health are attributed to smaller fluctuations in the unemployment rate. However, larger – and more often significant – coefficients are also an indicator of reduced measurement error. The unemployment rate among men aged 18–64 years produces the largest and most significant effects, so we will choose this as our baseline.

As discussed earlier, there is a trade-off when choosing the optimal degree of geographic aggregation of the unemployment rate. We have chosen to compute unemployment rates at the level of the local labor market, but alternative regional units are conceivable. In Table A.11, we report results for the unemployment rate aggregated to the municipality and county level.²⁵

Table A.11 shows that estimates at the municipality level are generally smaller than those at the local-labor-market level. This is in line with spill-over effects from surrounding areas that are ignored at the municipality level. Probably for the same reason, estimates are also larger at the county level, but only for neonatal mortality. They are smaller and insignificant for very low birth weight, possibly because countervailing variation in unemployment cancels out at more aggregated levels. Overall, the local labor market level appears to balance the up- and downsides of aggregation adequately.

4.4 Effects on other health outcomes

Above we found that recessions change the incidence of neonatal mortality, i.e. deaths within 28 days of birth, by -0.244 (using the effect of male unemployment in Table 6). In Table 7, we report estimates of the effect on infant mortality — deaths within 1 year of birth — and postneonatal mortality — deaths after 28 days and

25. Each of the 283 municipalities belongs to only one local labor market. In contrast, one local labor market might extend to several counties, although in total the number of local labor markets (72) is larger than the number of counties (21). More precisely, 9 local labor market extend to 2 counties and one local labor market to 3 counties.

Table 7: Effect of male unemployment on other health outcomes

	Infant mortality	Postneonatal mortality	Weight (in grams)	Apgar score (5 min) < 5	Small for gestational age
Unemployment	-0.141 (0.158)	0.103 (0.103)	-1.606 (1.441)	0.059 (0.244)	-0.353 (0.534)
% change	-3.93%	7.64%	-0.04%	1.08%	-1.96%
Mean × 1,000	3.583	1.346	3,605.4	5.410	18.044
N	506,565	506,565	503,339	499,612	502,119
	Gestational age < 32 Weeks	Gestational age < 37 Weeks	Hospitalizations pregnancy	Hospitalizations 1 year	Hospitalizations 3 years
Unemployment	-0.479** (0.199)	0.260 (0.550)	0.001 (0.002)	0.001 (0.003)	0.006 (0.005)
% change	-8.81%	0.57%	0.61%	0.35%	1.52%
Mean × 1,000	5.432	45.177	0.134	0.168	0.370
N	506,454	506,454	506,565	503,855	454,326

Notes: Each reported coefficient comes from a separate regression. Unemployment refers to the unemployment rate among 18-64-year-old men in the nine months following conception. Percentage changes divide the unemployment effect by the mean level of the outcome in the observations used in the regression. Both coefficients and percentage changes are for a 1-percentage-point increase in the unemployment rate. Except for weight, coefficients and means are scaled up to express them as per 1,000 infants. Controls are month fixed effects and parents fixed effects. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

within 1 year of birth. Note that the coefficient of infant mortality (-0.141) are about the same size as or smaller than the coefficient on neonatal mortality, and less significant. This has two implications: First, since the effect is not significantly larger, recessions have no effect on deaths later than 28 days after birth, also shown by the insignificant estimate for postneonatal mortality. Second, since the effect is somewhat smaller, some of the deaths not happening within 28 days of birth might just be deferred to a later point in time within the first year. However, the estimated effect is still negative and not significantly different from that on neonatal mortality. This indicates that some lives are actually saved in the long run.

Table 7 also explores the effects of recessions on absolute birth weight, log birth weight, the 5-minute Apgar score and small for gestational age (SGA). For any given gestational age, the SGA definition gives upper bounds of birth weight below which an infant is deemed “light” or “small” for gestational age. We also look at indicators for being born before 32 completed weeks of gestation (“very preterm” according to the WHO classification) and before 37 completed weeks of gestation (“preterm”).

Finally, we investigate the effect on the number of hospitalizations, both during pregnancy and within 1 and 3 years of birth. There are no significant effects on these outcomes, except for the likelihood of being born with less than completed 32 weeks of gestation. We return to this finding below when discussing mechanisms.

4.5 Heterogeneity

4.5.1 Economic crisis in early 1990s

Sweden encountered a severe economic crisis at the beginning of the 1990s with GDP per capita shrinking in every year from 1991 to 1993. As a consequence, the unemployment rate escalated to 30% and more. A marginal increase in the unemployment rate from 29 to 30% in times of crisis might have different effects on newborn health than a marginal increase from 5 to 6% in normal times. The positive effects of downturns are mitigated if the income shocks associated with crises become so large that they cannot be buffered anymore, even in a developed country with social welfare and functioning capital markets. However, Ruhm (2016) using U.S. data finds that national-level crises tend to amplify the positive effects of downturns.²⁶

In Table A.14 in the appendix, we present results from regressions in which we interact the unemployment rate with an indicator for the early-1990s crisis, using alternative year ranges to define the crisis. When we define the crisis to include the recession years 1992/1993, there is no indication that unemployment would have a differential effect on health in these years. However, the picture changes when adding the year 1994, when unemployment was still high even though the economy already started to grow again. We find that unemployment is associated with even larger reductions in VLBW in times of crisis. This also holds true if we extend the year range further to 1996, until which high levels of unemployment prevailed. As a whole, the estimates suggest that downturns are beneficial to newborn health both in times of crisis and non-crisis, with effects appearing to be even larger on very low birth weight in times of crisis.

26. Bremberg (2003), who also studies the Swedish economic crisis in the early 1990s, finds no health effects on children of the crisis *per se*. This is slightly different from the question asked here, but nevertheless surprising in light of our finding that recessions are beneficial. However, his approach does not properly control for trends in health over time.

4.5.2 Socioeconomic Status

Detailed micro data allows us to study whether effects sizes vary by socio-economic status of the parents, by marital status or by the gender of the child. In the general population, Haaland and Telle (2015) find no evidence that the effect of the cycle would depend on socio-economic status.

The first column of Table 8 allows for differential effects of recessions for fathers with different levels of educational attainment.²⁷ The coefficient in the first row gives the effect on fathers who only have primary or secondary education, which is the reference category in this regression. The estimate of -0.656 is much larger than our baseline estimate of -0.480 from Table 4. The other coefficient in the same column (just below) refers to the interaction of graduate and postgraduate education with unemployment. It is significantly positive and so large that it cancels out the effect on low-educated fathers. The results are very similar for mother's education. In sum, the negative effect of unemployment on very low birth weight seems entirely driven by low-educated parents, while high-educated parents exhibit, if anything, positive effects.

In column 3, we also study effects by family income, which is another indicator for socio-economic status. This indicator ranks given parents in the distribution of family income of all parents with a baby conceived in the same year.²⁸ Our reference group are the parents in the bottom quarter of the income distribution and we contrast them with those in the top quarter. With very low birth weight as a health outcome, there are no differential effects of unemployment between top- and bottom-income parents. If we compare single with married mothers and boys with girls, the effects of unemployment do not differ either. Overall, these results provide suggestive evidence that the positive effects of recessions on very low birth weight are stronger for low-SES parents.

In the bottom part of Table 8, we repeat the above analysis for neonatal mortality. Here, recessions do not become less beneficial with increasing parental education. If

27. We define educational attainment as the education level obtained in 2006, the last year in which we observe this variable. In order to ensure that education is completed in this year, we restrict attention to individuals who are at least 26 years old at the end of 2006. This restriction excludes only about 1% of all observations. For individuals who have no education level information in 2006, we instead use the highest value ever obtained, regardless of age.

28. Ideally, we would like to base this indicator on the income distribution of potential rather than actual parents to prevent bias due to selective fertility. However, we observe family income only for couples who are married or already have common children. We would therefore ignore many potential first-time parents. To reduce bias, we also experiment with ranking today's parents according to today's income distribution of the previous year's parents. The results are very similar.

Table 8: Heterogeneity of unemployment effect by subgroup

Notes: This table explores heterogeneous unemployment effects for different subgroups. The first line in each panel reports the unemployment effect in the respective reference subgroup. Reference subgroups are: (1) Primary and secondary, (2) Primary and secondary, (3) Bottom 25%, (4) Single, (5) Boy. Unemployment refers to the unemployment rate among 18-64-year-old men in the nine months following conception. Percentage changes divide the unemployment effect by the mean level of the outcome in the observations used in the regression. Both coefficients and percentage changes are for a 1-percentage-point increase in the unemployment rate. Coefficients and means are scaled up to express them as per 1,000 infants. Controls are parents fixed effects as well as subgroup-specific month fixed effects. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

anything, the effect seems to be larger for high-educated fathers compared to low-educated fathers, but this difference is not significant. However, there is a positive, albeit insignificant, interaction effect for top-income-quarter parents.

4.6 Mechanisms

Our analysis so far has established a positive relationship between economic downturns and newborns' health. In analyzing potential mechanisms, we distinguish two main categories. The first category refers to channels that are related to parental job loss and includes more time for health-enhancing activities and lower consumption of tobacco and alcohol. The second category includes all channels unrelated to parental job loss, including reductions in air pollution and stress as well as higher availability of prenatal and neonatal care. For each of the two categories, we now evaluate whether it can rationalize the above findings.

4.6.1 Parental job loss

Recall from subsection 4.3.2 that the effect of the cycle on newborn health was entirely driven by the male unemployment rate, with the female unemployment rate being virtually uncorrelated with newborn health. At the same time, while uncorrelated with newborn health, female unemployment is a strong indicator of the mother's employment status. Table A.15 in the appendix presents regressions of two binary unemployment indicators on male and female unemployment separately.²⁹

29. The first indicator ("no wage") takes on the value one if a gross wage of zero is reported in the annual statement of income submitted to the tax agency in the year of conception. The second indicator ("no reimbursements") is defined analogously, except for being more comprehensive in the sense that — in addition to gross wage — it also accounts for work-related reimbursements such as sickness or pregnancy benefits and income from self-employment. However, it is not available

Table 9: Effect of parental unemployment (“no wage”)

Notes: In each column, all coefficients come from the same regression. Unemployment refers to the unemployment rate among 18-64-year-old men in the nine months following conception. “No wage” takes on the value 1 if a gross wage of zero is reported in the statement of income submitted to the tax agency. Coefficients involving the unemployment rate are for a 1-percentage-point increase in the unemployment rate and scaled up to express them as per 1,000 infants. Controls are month fixed effects and parents fixed effects. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

Irrespective of the indicator used, female unemployment is a much better predictor of mother’s unemployment than male unemployment (columns 2 and 6 versus columns 1 and 5). The last two columns of Table A.15 also show that female unemployment decreases log family earnings more than male unemployment. These observations stand in stark contrast with our finding that the effects on newborn health are entirely driven by men rather than female unemployment. With female unemployment strongly affecting mother’s unemployment but not newborn health, we conclude that mother’s unemployment and, consequently, more time available for prenatal care is only a negligible channel in linking downturns to improved newborn health. It also follows that income reductions — and associated decreases in the consumption of detrimental goods — do not qualify as a likely channel either.

to us in the year 2003. Both indicators have the limitation that they designate those individuals as unemployed who voluntarily receive zero work-related income, thus introducing measurement error. In our context, this particularly affects students. But note that for some students the continuation of education might only be an involuntary response to bad labor market conditions. Moreover, studying and being unemployed are not too different in terms of available income though not time.

These findings demonstrate that parental unemployment plays no major role in explaining the positive health effects of recessions.

In Table 9, we present a more direct test of the role of parental unemployment. Column 1 reproduces our baseline regression with the unemployment rate during pregnancy as the only regressor apart from controls. In column 2, we add an indicator (“no wage”) for mother’s unemployment as an additional covariate. Note that mother’s unemployment, even in the case of holding the mother fixed, might be endogenous to third factors also affecting newborn health, such as age. Its coefficient must therefore be treated with caution. However, including this variable controls for the indirect effect of the unemployment rate that operates via mother’s unemployment and isolates the direct effect.

For both very low birth weight and neonatal mortality, the coefficient of the unemployment rate does not change at all, confirming that the effect on newborn health does not operate through mother’s unemployment. In column 3, we add an interaction term of mother’s unemployment with the unemployment rate. The coefficient of the interaction is insignificant, suggesting that the unemployment rate affects employed and unemployed mothers in a similar way. Columns 4 and 5 repeat the analysis for father’s and parents’ joint unemployment, respectively, and yield comparable results. Table A.16 in the appendix reports the same set of regressions for the “No Reimbursements” indicator of parental unemployment, with results being essentially unaltered.

Finally, in Table A.17 in the appendix, we regress newborn health on first differences — rather than absolute levels — in the unemployment rate. First differences capture changes in the unemployment rate, such as a large-scale job loss due to layoffs. They exhibit no variation when unemployment remains constant at a high or low level. If a job loss has strong immediate effects that fade out over time, then first differences should give different results than levels of unemployment. Table A.17 shows the corresponding estimates for first differences in overall, male and female unemployment. There is no robust evidence that job loss captured by first differences in unemployment affects newborn health.

Overall, we find that parental employment status cannot account for the beneficial health effects of recessions. This is in line with prior work showing that job loss due to displacement actually affects individual health negatively rather than positively (e.g. Sullivan and von Wachter 2009; Eliason and Storrie 2009). Lindo (2011) provides evidence that negative effects of job loss carry over to newborn children in the form of reduced birth weight. Recall from Section 4.3.2 that male unemployment affects

newborn health much more than female unemployment and also correlates more strongly with the business cycle. Taken together, these findings suggest that the cycle operates through channels more general than individual unemployment.

4.6.2 Channels unrelated to job loss: air pollution, stress and availability of medical care

Among the most likely alternative mechanisms linking downturns to newborn health are reduced stress, less traffic and air pollution as well as higher availability of prenatal and neonatal care. Availability of care might decrease under favorable economic conditions if it becomes difficult to recruit medical staff in a tighter labor market. Stevens et al. (2015) suggest that this mechanism explains cyclically sensitive mortality among individuals in elderly care in the U.S. However, cyclical variation in staffing plays hardly any role in Sweden due to its public health care system (see also subsection 2.1). moreover, while neonatal care may affect the likelihood that a newborn infant dies, it is hardly relevant for weight at birth, for which we find positive effects just like we do for infant survival. Finally, financial barriers to prenatal care are virtually absent, so that there is no reason to expect differential effects by socioeconomic status of the parents as seen in Table 8.

Air pollution has been shown to rise in recessions to due less traffic (Chay and Greenstone 2003). We verify this relationship for Sweden by establishing a generally negative, and sometimes significant, correlation between the level of various pollutants and the municipality-level unemployment rate of men, but not women (Table A.18 in the appendix).³⁰ An enormous literature has demonstrated the impact of pollution on newborn health (Chay and Greenstone (2003), Knittel et al. (2016), see Currie et al. (2014) for a review), particularly in the first and third semester (Currie et al. 2009; Lavaine and Neidell 2017). Moreover, children of low-SES parents tend to suffer disproportionately from pollution. Reasons include sorting of low-SES families into neighborhoods with more pollution and elevated

30. We obtained pollution data from the IVL Swedish Environmental Research Institute. Unfortunately, the data are only available at the seasonal level (summer/winter) and missing for many municipalities and years, especially summer seasons. Data for nitrogen dioxide (NO₂), for instance, is only available for 108 out of 283 municipalities and only for 1051 out of 11,037 season-municipality observations between 1992 and 2011. Data availability is even worse for other pollutants. To avoid losing additional precision, we abstain from aggregating to local labor markets. We regress pollution on the unemployment rate using a version of specification (1) without trends, replacing local-labor-market with municipality fixed effects and month fixed effects with season-month fixed effects. We also experimented with merging the pollution data with our micro-level dataset, but unfortunately the sample size decreases so dramatically that we can no longer precisely estimate our baseline effect on newborn health.

vulnerability due to lower baseline health. In the Swedish context, Jans et al. (2018) show that pollution induced by episodes of inversion causes considerably more harm to low-SES children. In light of this evidence, our finding that economic conditions affect especially low-SES babies indicates that air pollution is an important mediating factor.

Additional support for the role of air pollution comes from exploiting knowledge about the production function of birth weight. Following Kramer (1987), birth weight is determined by length of gestation and by intrauterine growth. While intrauterine growth is affected by cigarette smoking and nutrition, the length of gestation is — among others — sensitive to air pollution (Currie and Walker 2011). Recall from subsection 4.4 that recessions the incidence of being born with less than 32 completed weeks of gestation (“very preterm”). This decrease has about the same size as the baseline decrease in very low birth weight from column 1 of Table 4, suggesting that a short gestation accounts for almost all of the reductions in very low birth weight. In contrast, the effect on the incidence of small for gestational age (SGA), which is an indicator of intrauterine growth (Kramer 1987), is not significantly different from zero.

Finally, recessions potentially reduce stress. Mothers, even if not experiencing job loss, enjoy fewer hours of work, which leaves more time for health-improving activities during pregnancy. In addition, for both the mother and father, lower workloads decrease job-related stress and positive spillovers among parents are likely. A large body of evidence documents the impact of stress on birth outcomes, in particular during the first trimester of pregnancy (Camacho 2008; Torche 2011; Mansour and Rees 2012; Bozzoli and Quintana-Domeque 2014; Foureaux Koppensteiner and Manacorda 2016). Moreover, gestation length responds to stress (Torche 2011; Foureaux Koppensteiner and Manacorda 2016; Persson and Rossin-Slater 2018) and stress reductions might particularly affect low-educated individuals who are disproportionately employed in sectors sensitive to the business cycle, such as manufacturing or simple services.

However, some skepticism about stress is warranted: First, there is extensive evidence that unemployment and underemployment are associated with *more* rather than *less* stress (e.g. Rosenthal et al. 2012). Catalano and Serxner (1992) even demonstrate a link between threats to employment and low birth weight. Second, stress reduction due to fewer working hours would be difficult to reconcile with our finding that the effects on unemployed mothers appear to be similarly large. Lastly, when splitting the analysis by trimester, estimates are too imprecise to identify a

specific phase of pregnancy that might drive the results (Table 5). This exercise favors neither stress nor, for that matter, pollution as a potential channel. Overall, however, our results are most consistent with air pollution playing a major role in linking recessions with improvements in newborns' health.

5 Conclusion

Downturns improve newborns' health outcomes. A one-percentage-point increase in the unemployment rate is associated with an approximately 10% reduction in the incidence of having a birth weight below 1,500 grams and of dying within 28 days after birth. The increase in infant survival is at least in part permanent and not offset by delayed death later in the first year of life.

Using detailed micro-level information about the parents, we shed light on the underlying mechanisms. Parental job loss does not act as a mediating factor. We find that downturns disproportionately affect low-SES parents and that the reduction in mortality can fully be accounted for by an equally large reduction in premature birth, i.e. less than 32 weeks of gestation. Prior work has documented that low-SES children are more vulnerable to air pollution. Moreover, premature birth has been attributed to air pollution in earlier literature. Given that air pollution decreases during downturns due to lower traffic volume, we conclude that air pollution is the most plausible channel to explain our findings. We view it as a topic for further research to extend our analysis with local pollution data.

Notes: Each coefficient comes from a separate OLS regression of the birth rate on the average unemployment rate in the age group 18-64 years in the nine months during pregnancy. Birth rates are defined as the number of births with the same month of conception in the given subgroup per 1,000 women aged 18-49 years in the overall population. Percentage changes divide the unemployment effect by the mean level of the outcome in the observations used in the regression. Both coefficients and percentage changes are for a 1-percentage-point increase in the unemployment rate, but coefficients are scaled up by 12 to obtain annualized figures. Sample includes months January 1992 to March 2004. Controls are month fixed effects, local-labor-market fixed effects and local-labor-market-specific linear time trends where indicated. Regressions are weighted by the number of births. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

Table A.2: Effect of unemployment during pregnancy on composition of birth cohorts

	Mother		Father

Notes: Summary statistics for selected variables, separately for those parents in the regression sample that never had a child with VLBW or neonatal mortality ("No child") and those parents that experienced VLBW or neonatal mortality in at least one but not all of their children ("At least one"). The latter parents allow for identifying the effect of economic conditions on health outcomes in the fixed-effects regression. t-values are from tests of equal means of parents in the "No child" group compared with parents in the "At least one" group. Developed countries include EU-15 (excl. Sweden), Norway, North America and Oceania. Developing countries include the rest of Europe, Africa, South America, Asia and Soviet Union. Developing countries include other Europe, Africa, South America, Asia and Soviet Union.

Table A.5: Robustness of baseline effect in sample with all movers

	Weight < 1,500 grams (VLBW)	Neonatal mortality
Unemployment	-0.498*** (0.189)	-0.294** (0.125)
<i>% change</i>	-11.56%	-13.52%
Mean \times 1,000	4.308	2.177
N	525,726	529,076

Notes: Each reported coefficient comes from a separate regression. Sample includes all parents that have at least two children, independently of whether or not they move between births. Unemployment refers to the unemployment rate among 18-64-year-old men in the nine months following conception. Percentage changes divide the unemployment effect by the mean level of the outcome in the observations used in the regression. Both coefficients and percentage changes are for a 1-percentage-point increase in the unemployment rate. Coefficients and means are scaled up to express them as per 1,000 infants. Controls are month fixed effects and parents fixed effects. Standard errors clustered at the parents level are given in parentheses. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

Table A.6: Robustness of baseline effect in sample with all movers and assigning local labor market of first-born child to later-born children

	Weight < 1,500 grams (VLBW)	Neonatal mortality
Unemployment	-0.552*** (0.209)	-0.250** (0.108)
<i>% change</i>	-12.81%	-11.50%
Mean \times 1,000	4.308	2.177
N	525,726	529,076

Notes: Each reported coefficient comes from a separate regression. Sample includes all parents that have at least two children, independently of whether or not they move between births. If parents move, children are assigned the local labor market of the first-born child. Unemployment refers to the unemployment rate among 18-64-year-old men in the nine months following conception. Percentage changes divide the unemployment effect by the mean level of the outcome in the observations used in the regression. Both coefficients and percentage changes are for a 1-percentage-point increase in the unemployment rate. Coefficients and means are scaled up to express them as per 1,000 infants. Controls are month fixed effects and parents fixed effects. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

% change	-10.89%	2.02%	-3.31%	-2.31%	-6.93%	-10.57%	-3.18%
Mean × 1,000	2.237	2.237	5.737	6.236	2.603	2.147	5.737
N	506,565	506,565	737,703	572,038	569,015	536,195	737,703

Notes: Each reported coefficient comes from a separate regression. Unemployment refers to the unemployment rate among 18-64-year-old men in the nine months following conception. Percentage changes divide the unemployment effect by the mean level of the outcome in the observations used in the regression. Both coefficients and percentage changes are for a 1-percentage-point increase in the unemployment rate. Coefficients and means are scaled up to express them as per 1,000 infants. Controls are month fixed effects and parents or mothers fixed effects, as indicated in the column header. The parents sample consists of all children born to parents that have several babies in exactly one local labor market (see Subsection 2.3). Analogously, the mother sample is consists of all children born to mothers that have several babies in exactly one local labor market. The mother sample is larger than the parents sample because father information is unavailable for a number of babies, in particular those born after 2004, and stillbirths. Columns 4-6 investigate how these data limitations affect the difference between parents and mother fixed effects estimates shown in columns 1 and 3. They progressively restrict the sample to babies born between January 1992 and March 2004, live births and all other babies with known father. In column 2 and 7, we report the baseline regressions without parents and mother fixed effects, respectively, and instead include local-labor-market fixed effects. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

Table A.8: Sensitivity to functional form

	With parents FE (baseline)	Without parents FE	With parents FE logit	Without parents FE logit
<i>Weight < 1,500 grams (VLBW)</i>	(1)	(2)	(3)	(4)
Unemployment	-0.480** (0.207)	-0.178 (0.174)	-15.136*** (5.873)	-4.002 (4.101)
% change	-11.25%	-4.16%	-	-3.97%
N	503,339	503,339	4,499	501,513
<i>Neonatal mortality</i>	(1)	(2)	(3)	(4)
Unemployment	-0.244** (0.110)	0.045 (0.095)	-15.692** (7.433)	2.202 (3.749)
% change	-10.89%	2.02%	-	2.19%
N	506,565	506,565	2,930	499,272

Notes: Each reported coefficient comes from a separate regression. Unemployment refers to the unemployment rate among 18-64-year-old men in the nine months following conception. Percentage changes divide the unemployment effect by the mean level of the outcome in the observations used in the regression. Columns 1 and 2 repeat the baseline regression (with parents fixed effects) and the OLS regression without parents fixed effects. Both coefficients and percentage changes are for a 1-percentage-point increase in the unemployment rate. Coefficients are scaled up to express them as per 1,000 infants. Columns 3 and 4 show coefficients from fixed effects logit and ordinary logit models, respectively. For the ordinary logit model, we also report percentages changes based marginal effects. This is not possible for the fixed effects logit model because there is no way to consistently estimates the fixed effects in short panels. Columns 2 and 4 omit parents fixed effects and instead control for local-labor-market fixed effects. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

Table A.9: Effects of all 3 trimesters at once

	Weight < 1,500 grams (VLBW)	Neonatal mortality
1st trimester	-0.152 (0.274)	-0.032 (0.213)
2nd trimester	-0.218 (0.344)	-0.252 (0.255)
3rd trimester	-0.105 (0.254)	0.056 (0.149)
N	503,339	506,565

Notes: All coefficients in one column come from a joint regression. Unemployment refers to the unemployment rate among 18-64-year-old men. Coefficients are for a 1-percentage-point increase in the unemployment rate and scaled up to express them as per 1,000 infants. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

Table A.10: Effect of male unemployment by age group

<i>Weight < 1,500 grams (VLBW)</i>	18–24 years	18–30 years	18–40 years	18–64 years
Unemployment	-0.178* (0.093)	-0.304*** (0.107)	-0.398*** (0.133)	-0.480** (0.207)
N	503,339	503,339	503,339	503,339
<i>Neonatal mortality</i>	18–24 years	18–30 years	18–40 years	18–64 years
Unemployment	-0.070 (0.052)	-0.072 (0.068)	-0.096 (0.085)	-0.244** (0.110)
N	506,565	506,565	506,565	506,565

Notes: Each reported coefficient comes from a separate regression. Unemployment refers to the average unemployment rate among men in the indicated age group in the nine months following conception. Coefficients are for a 1-percentage-point increase in the unemployment rate and scaled up to express them as per 1,000 infants. Controls are month fixed effects and parents fixed effects. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

Table A.11: Effect of male unemployment by region

<i>Weight < 1,500 grams (VLBW)</i>	County	Local labor market	Municipality
Unemployment	-0.006 (0.243)	-0.480** (0.207)	-0.282** (0.141)
N	505,040	503,339	462,543
<i>Neonatal mortality</i>	County	Local labor market	Municipality
Unemployment	-0.379*** (0.146)	-0.244** (0.110)	-0.102 (0.088)
N	508,296	506,565	465,504

Notes: Each reported coefficient comes from a separate regression. Unemployment refers to the unemployment rate among 18-64-year-old men in the nine months following conception. Coefficients are for a 1-percentage-point increase in the unemployment rate and scaled up to express them as per 1,000 infants. Controls are month fixed effects and parents fixed effects. Standard errors clustered at the level of the indicated region are given in parentheses. There are 21 counties, 72 local labor markets and 283 municipalities in the sample. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

Table A.12: Effect of female unemployment by age group

<i>Weight < 1,500 grams (VLBW)</i>	18–24 years	18–30 years	18–40 years	18–64 years
Unemployment	-0.120 (0.085)	-0.179* (0.104)	-0.188 (0.132)	-0.211 (0.175)
N	503,339	503,339	503,339	503,339
<i>Neonatal mortality</i>	18–24 years	18–30 years	18–40 years	18–64 years
Unemployment	-0.008 (0.044)	-0.007 (0.057)	-0.022 (0.071)	-0.092 (0.101)
N	506,565	506,565	506,565	506,565

Notes: Each reported coefficient comes from a separate regression. Unemployment refers to the average unemployment rate among women in the indicated age group in the nine months following conception. Coefficients are for a 1-percentage-point increase in the unemployment rate and scaled up to express them as per 1,000 infants. Controls are month fixed effects and parents fixed effects. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

Table A.13: Effect of female unemployment by region

<i>Weight < 1,500 grams (VLBW)</i>	County	Local labor market	Municipality
Unemployment	-0.176 (0.170)	-0.211 (0.175)	-0.067 (0.150)
N	505,040	503,339	462,543
<i>Neonatal mortality</i>	County	Local labor market	Municipality
Unemployment	-0.219** (0.100)	-0.092 (0.101)	-0.069 (0.100)
N	508,296	506,565	465,504

Notes: Each reported coefficient comes from a separate regression. Unemployment refers to the unemployment rate among 18-64-year-old women in the nine months following conception. Coefficients are for a 1-percentage-point increase in the unemployment rate and scaled up to express them as per 1,000 infants. Controls are month fixed effects and parents fixed effects. Standard errors clustered at the level of the indicated region are given in parentheses. There are 21 counties, 72 local labor markets and 283 municipalities in the sample. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

Table A.14: Heterogeneous effects during the economic crisis in the early 1990s

Crisis years	1992-1993	1992-1994	1993-1994	1992-1996
<i>Weight < 1,500 grams (VLBW)</i>	(1)	(2)	(3)	(4)
Unemployment	-0.483** (0.210)	-0.507** (0.200)	-0.343 (0.240)	-0.393** (0.192)
Unemployment × Crisis	-0.021 (0.134)	-0.192* (0.115)	-0.198* (0.119)	-0.238*** (0.074)
Mean - non-crisis	4.051	4.085	4.085	4.122
Mean - crisis	5.510	4.860	4.519	4.468
% - non-crisis	-11.93%	-12.41%	-8.39%	-9.54%
% - crisis	-9.16%	-14.39%	-11.95%	-14.12%
N	503,339	503,339	465,589	503,339
<i>Neonatal mortality</i>	(1)	(2)	(3)	(4)
Unemployment	-0.231** (0.114)	-0.238** (0.114)	-0.241* (0.130)	-0.276*** (0.106)
Unemployment × Crisis	0.086 (0.094)	0.040 (0.070)	0.046 (0.089)	0.088 (0.055)
Mean - non-crisis	1.933	1.874	1.874	1.836
Mean - crisis	3.983	3.418	3.127	2.790
% - non-crisis	-11.94%	-12.7%	-12.89%	-15.02%
% - crisis	-3.65%	-5.78%	-6.25%	-6.73%
N	506,565	506,565	468,694	506,565

Notes: In each column, all coefficients come from the same regression. Unemployment refers to the unemployment rate among 18-64-year-old men in the nine months following conception. Percentage changes divide the unemployment effect by the mean level of the outcome in the observations used in the regression. Both coefficients and percentage changes are for a 1-percentage-point increase in the unemployment rate. Coefficients and means are scaled up to express them as per 1,000 infants. Controls are parents fixed effects, month fixed effects as well as crisis-specific month fixed effects. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

Table A.15: Effect on labor market outcomes

	No wage				No reimbursements					
	Mother		Father		Mother		Father		Log family income	
	Male (1)	Female (2)	Male (3)	Female (4)	Male (5)	Female (6)	Male (7)	Female (8)	Male (9)	Female (10)
<i>Unemployment 18–64 years</i>										
Unemployment	2.318*** (0.808)	3.849*** (0.938)	1.089 (0.732)	-0.452 (0.580)	1.795** (0.758)	3.534*** (0.893)	1.832** (0.772)	-0.251 (0.682)	-4.747 (3.582)	-6.619*** (2.245)
N	506,561	506,561	505,592	505,592	450,847	450,847	449,999	449,999	411,554	411,554

Notes: Each reported coefficient comes from a separate regression. Unemployment refers to the unemployment rate among 18-64-year-old individuals of the indicated gender in the nine months following conception. “No wage” and “No reimbursements” are indicators for parental unemployment (mother or father). “No wage” takes on the value 1 if a gross wage of zero is reported in the statement of income submitted to the tax agency. “No reimbursements” takes on the value 1 if no work-related reimbursements are received. Coefficients are for a 1-percentage-point increase in the unemployment rate and scaled up to express them as per 1,000 infants. Controls are month fixed effects and parents fixed effects. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

Table A.16: Effect of parental unemployment (“no reimbursements”)

	Baseline	Mother		Father		Both parents	
<i>Weight < 1,500 grams (VLBW)</i>	(1)	(2)	(3)	(4)	(5)	(6)	(7)
Unemployment	-0.480** (0.207)	-0.586*** (0.204)	-0.579*** (0.197)	-0.578*** (0.203)	-0.570*** (0.202)	-0.578*** (0.203)	-0.578*** (0.204)

No reimbursements		0.003 (0.005)	-0.008 (0.012)	-0.009* (0.005)	-0.041 (0.027)	-0.010 (0.012)	-0.071 (0.064)
No reimbursements × Unemployment			0.008 (0.009)		0.024 (0.020)		0.046 (0.049)
N	506,565	475,651	475,651	475,082	475,082	475,082	475,082

Notes: In each column, all coefficients come from the same regression. Unemployment refers to the unemployment rate among 18-64-year-old men in the nine months following conception. “No reimbursements” takes on the value 1 if no work-related reimbursements and no income from self-employment are received. Coefficients involving the unemployment rate are for a 1-percentage-point increase in the unemployment rate and scaled up to express them as per 1,000 infants. Controls are month fixed effects and parents fixed effects. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

Table A.17: Effect of first differences of unemployment

<i>Weight < 1,500 grams (VLBW)</i>	Overall	Male	Female
Unemployment	-0.367* (0.208)	-0.307 (0.191)	-0.278 (0.202)
N	448,208	448,208	448,208
<i>Neonatal mortality</i>	Overall	Male	Female
Unemployment	-0.117 (0.191)	-0.135 (0.181)	-0.033 (0.164)
N	451,242	451,242	451,242

Notes: Each reported coefficient comes from a separate regression. Unemployment refers to the unemployment rate among the indicated gender among 18-64-year-old men. Unemployment is the first-differenced average unemployment rate in the nine months following conception. First-differencing means subtracting the average unemployment rate from the previous nine-months-period. Coefficients are for a 1-percentage-point increase in the unemployment rate and scaled up to express them as per 1,000 infants. Controls are month fixed effects and parents fixed effects. Standard errors clustered at the local labor market level are given in parentheses. There are 72 local labor markets. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.

Table A.18: Effect on various pollutants

	Nitrogen dioxide (NO ₂)	Sulphur dioxide (SO ₂)	Particulate Matter (PM ₁₀)	Ozon (O ₃)
Men unemployment	-0.248** (0.118)	-0.052 (0.054)	-0.488* (0.255)	-0.202 (0.187)
<i>% change</i>	-2.08%	-2.90%	-2.80%	-0.33%
Women Unemployment	-0.106 (0.120)	0.057 (0.088)	-0.177 (0.263)	-0.294 (0.189)
<i>% change</i>	-0.89%	3.18%	-1.01%	-0.48%
Mean ($\mu\text{g}/\text{m}^3$)	11.94	1.79	17.45	61.09
N	1051	789	404	526
N municipalities	108	93	71	66

Notes: Each reported coefficient comes from a separate regression. Unemployment refers to the unemployment rate among 18-64-year-old individuals (men or women) in the nine months following conception. Percentage changes divide the unemployment effect by the mean level of the pollutant in the observations used in the regression. Both coefficients and percentage changes are for a 1-percentage-point increase in the unemployment rate. Controls are season \times year fixed effects and municipality fixed effects. Seasons are summer (April to September) and winter (October to March). Pollution data come from the IVL Swedish Environmental Research Institute. Standard errors clustered at the municipality level are given in parentheses. *, ** and *** denote significance at the 10, 5 and 1 percent level, respectively.
