February 27, 2019

## Abstract

We analyze the impact of overconfidence on gender differences in wage expectations using elicited beliefs of German university applicants. Interestingly, female students have lower wage expectations and are less overconfident than their male counterparts. Oaxaca-Blinder decompositions show that a substantial part (7.6%) of the gender gap in wage expectations can be explained by stronger overconfidence of males. Applying recentered influence function decompositions, we find that the impact of overconfidence on the gender gap is particularly strong at the bottom and top of the wage expectation distribution, suggesting that females with the lowest expectations feature a very low level of confidence while males with the highest expectations feature a very high level of confidence.

# 1 Introduction

Pay differences between men and women are one of the most intensively investigated phenomena in Economics. Although the gender pay gap has been declining over the last decades in developed countries, females still earn considerable less than males (Blau and Kahn, 2017). Gender differences not only exist in realized wages, but already emerge in expectations of young people about their future salaries (Reuben et al., 2017). One reason why females do not earn as much as males might be lower wage expectations. Career and financial interests are an important determinant of college major choice and therefore affect occupational choice (Arcidiacono et al., 2017). Moreover, expected starting salaries of people can become self-fulfilling. Whereas people with high income expectations are more likely to negotiate for a higher salary, people with low income expectations are more likely to accept a less-paying job as it matches their beliefs (Reuben et al., 2017). In turn, the gender difference in wage expectations might be in part down to differences in confidence between males and females: males tend to be more confident in their abilities (e.g. Bengtsson et al., 2005).

In this paper, we analyze the impact of overconfidence on gender differences in wage expectations. In so doing, we combine three research areas: gender differences in pay, wage expectations, and (over)confidence. We use elicited expectations from a survey conducted at Saarland University, Germany: during the application process in 2011 and 2012, among other things, prospective students were asked to report expectations of their own future salary as well as their fellow students' future salary. Thus, we can create an overconfidence index for students by comparing their own salary expectations with their expectations for the average salary of students from the same field of study. In a first step, we estimate linear regressions to investigate the effect of overconfidence on expected salaries of students. In a second step, we then quantify the contribution of overconfidence to gender differences in wage expectations by applying Oaxaca-Blinder decompositions. Moreover, we also explicitly examine the gender gap and the contribution of overconfidence at different parts of the wage expectation distribution. For this purpose, we use the

method proposed by Firpo et al. (2018), which is based on recentered influence functions (RIFs) and allows to decompose the gender gap at any quantile of the distribution. In addition, we elaborate on heterogeneity, i.e., whether the gender gap and the effect of overconfidence differs between certain subgroups of students.

We find that female applicants have 17 percent lower wage expectations than their male counterparts. Our measurement of overconfidence suggests that males are more likely to be overconfident with regard to their future salary. Moreover, overconfidence of students does positively affect their wage expectations. These results already indicate that overconfidence partly explains different earnings expectations of males and females. Indeed, results of the Oaxaca-Blinder decomposition show that 7.6 percent of the gender gap in wage expectations is caused by the fact that male students are more overconfident. Furthermore, we find that the gender gap is present along the whole wage expectation distribution. However, the contribution of overconfidence to the gender gap is particularly strong at the top and at the bottom of the distribution. This indicates that females who expect the lowest salaries are particularly low in confidence. Males with the highest expectations, in contrast, seem to be exceptionally overconfident. Our results further show that gender differences in i) college major choice and ii) how important students value their future income affect the gender gap in wage expectations. Comparing medical students to all other students, we detect that overconfidence has a particularly pronounced effect on the gender gap in wage expectations of prospective physicians. We also find that the gender difference in wage expectations is especially large for applicants in so-called STEM fields (Science, Technology, Engineering, and Mathematics).

The fact that men on average earn more than women has been found in numerous studies over the last decades, as the meta-analysis of Weichselbaumer and Winter-Ebmer (2005) shows. The gender pay gap is often particularly pronounced in the lower (sticky floor effect) and upper tail (glass ceiling effect) of wage distributions (Christofides et al., 2013). In most studies, a substantial part of the gender gap can be explained by observed characteristics of males and females. The largest part of the gender pay gap is most

often attributed to the fact that men and women sort differently into occupations and industries. For high-skilled individuals, the choice of occupation and industry is closely linked to their college major choice. Similarly to gender differences in occupational choice, men and women also sort differently into college majors (Zafar, 2013). Males, for instance, are more likely to study in STEM fields than females are (Osikominu and Pfeifer, 2018). This suggests that part of the gender pay gap for high skilled individuals is already caused by college major choice, since there exist large earning differences across college majors (Arcidiacono, 2004). Human capital theory suggests that individuals choose level and type of education based on expected market returns to education (Betts, 1996). Indeed, several studies back this claim and find that earning expectations are an important determinant of college major choice (e.g. Arcidiacono et al., 2017; Wiswall and Zafar, 2015).

Moreover, expected future earnings of students are also good predictors for realized earnings some years later. Webbink and Hartog (2004) find no systematic difference between expected starting salaries and realizations four years later for Dutch students. However, their key finding is that differences in the expected starting salary by type of study and by various other individual characteristics are quite similar to the respective differences in realizations. There might be several reasons for this. First of all, most students probably have at least a vague idea of average starting salaries in occupations related to their field of study. Hence, it is not surprising that the field of study similarly affects expected starting salaries of students and later realizations. Furthermore, students with high abilities might not only expect higher starting salaries but also earn more at labor market entry. Contrarily, students with strong preferences for non-pecuniary aspects of jobs, such as flexible working hours, might have lower expectations and choose a job that is less well paid than students with weak preferences for non-pecuniary aspects. Additionally, students with lower wage expectations are probably less inclined to negotiate for a higher salary with employers (Reuben et al., 2017). There are also indications that expectations of students affect their academic performance, which in turn affects their realized earnings (e.g. Jacob and Wilder, 2011).

Analyzing gender differences in wage expectations can therefore be very helpful to understand why men earn on average more than women. In contrast to the gender gap in realized earnings, however, there are relatively few studies on gender differences in earning expectations. This might be in part related to the rather historical reluctance of economists to work with subjective expectations data, stemming from the doubt whether elicited subjective expectations of survey participants reflect their true expectations. Botelho and Pinto (2004) show that these concerns are unwarranted. They find that giving financial incentives to students for accurate reporting does not change their wage expectations significantly. Thus, they conclude that students tend to respond meaningfully to questions regarding their earnings expectations. This result might be one reason why the use of subjective expectations data in Economics has increased over the last years (see, e.g., Arcidiacono et al., 2017; Baker et al., 2018; Reuben et al., 2017; Zafar, 2013).

One factor determining expected salaries of students is how confident they are in their own abilities. The previous literature on confidence shows that people are often overconfident in their own abilities (Croson and Gneezy, 2009). Moreover, many studies find differences between males and females with regard to overconfidence (Barber and Odean, 2001; Bengtsson et al., 2005; Soll and Klayman, 2004; Niederle and Vesterlund, 2007; Dahlbom et al., 2011). Barber and Odean (2001) find that male investors are considerably more overconfident than female ones. Some other studies indicate that, while females are not as confident as males, they tend to be overconfident as well (Soll and Klayman, 2004; Niederle and Vesterlund, 2007). Dahlbom et al. (2011), contrarily, find that girls are even underconfident regarding their mathematics performance. Gender differences in overconfidence, however, are not present in all settings. Nekby et al. (2008) analyze overconfidence of men and women in a running competition in Sweden, which is a competitive male-dominated setting. Their results suggest that female runners are even slightly more overconfident than male ones. Similarly, Hardies et al. (2013) study overconfidence in a highly selected and highly socialized group of professionals, namely

external auditors, and compare it to overconfidence of Belgian students. They find that male students are more overconfident than female ones, however, they find no gender difference regarding overconfidence in the group of auditors. The previous literature suggests that men are more overconfident than women on average in most settings. However, as soon as women self-select into competitive, male-dominated environments, this difference seems to disappear.

Closest to our study is the work of Reuben et al. (2017), who analyze the impact of overconfidence and preferences for competitiveness and risk on students' earnings expectations and college major choice. They use an experiment to measure such three factors and combine corresponding figures with data from a survey eliciting students' beliefs about their future income. Their estimations show that overconfidence and competitiveness do have a positive impact on expected future salaries. They also study gender differences in expected earnings and how this difference is influenced by their experimental measures. They find that male students have considerably higher earnings expectations. Their results further suggest that overconfidence and competitiveness together are responsible for a substantial part of the gender gap. However, they do not find that these factors are related to college major choice.

Our paper contributes to the literature in several regards. To begin with, we show how much of students' gender gap in wage expectations is caused by gender differences in overconfidence. In contrast to Reuben et al. (2017), we go beyond simple linear regressions and analyze the impact of overconfidence in more detail by applying Oaxaca-Blinder decompositions. Hence, we estimate the contribution of overconfidence in a way that is path independent (Firpo et al., 2011). Moreover, our measure of overconfidence differs considerably from the measure used by Reuben et al. (2017). Whereas they measure overconfidence w.r.t. an mathematical task<sup>1</sup>, we introduce overconfidence w.r.t. comparative wage expectations. Since gender differences in overconfidence can depend on the particular setting at hand (Nekby et al., 2008; Hardies et al., 2013), it might be more informative

---

<sup>1</sup>Reuben et al. (2017) measure overconfidence by comparing students' subjective probability of being ranked first in a mathematical task with with their true probability of ranking first.

to evaluate students' confidence in direct relation to expected future salaries. Moreover, we restrict our analysis to students' wage expectations within their chosen college major. Reuben et al. (2017) include students' expected salaries across all majors, not only their chosen ones. Given that students supposedly are better informed about salaries concerning their chosen major, it might be more precise to exclusively focus on this respective field of study. Furthermore, we condition on the degree with which students intend to earn their first salary. Consequently, we isolate the overconfidence effect from the effect of the expected level of education. Compared to most of the relevant literature, we also use a larger sample and draw on representative survey data. To the best of our knowledge, we are also first to examine the gender gap and the contribution of overconfidence along the entire wage expectation distribution. Thus, we are able to evaluate whether the gap and the contribution of overconfidence is larger at certain points of the distribution in order to draw more specific conclusions.

The remainder of the paper is organized as follows. Section 2 describes the data, shows descriptive statistics, and explains our overconfidence measure. In Section 3, we describe the methods applied to decompose the gender gap in wage expectations. Results of the estimations are shown in Section 4. We first report simple linear regression estimates, followed by results of the Oaxaca-Blinder decomposition with a particular interest in the overconfidence measure. Next, we decompose the gender gap along the wage expectations distribution and outline decomposition results for several subgroups of students. Section 5 reports results of robustness checks, and Section 6 concludes.

## **2 Data and Descriptives**

### **2.1 Data Set**

The data we use is based on a student survey at Saarland University, Germany. Students applying for enrollment in academic years 2011 and 2012 were widely surveyed about their beliefs regarding starting salaries conditional on field of study. The data were first used

by Klößner and Pfeifer (2018), who evaluate characteristics causing German students to make larger or smaller estimation errors in the prediction of future salaries after adjusting wage expectations for misconceptions of the German income tax.<sup>2</sup> Whereas in 2011 only 500 students completed the survey, the number increased to 1,561 students in 2012 since two further fields of study were added (Education and Medicine). So, overall the sample consists of 2,061 students, which is a relatively large data set compared to other studies examining students wage expectations (e.g. Reuben et al., 2017; Webbink and Hartog, 2004).<sup>3</sup>

Moreover, as Klößner and Pfeifer (2018) show, Saarland University and its students constitute a good representation of the average university and the average student body in Germany. Figures like student/teacher ratio, male/female ratio, student age distribution, distribution of graduates across fields, distribution of gender across fields, number of exams passed, grades, duration of studies, etc., are all close to the German average. Saarland University does also appear in the middle of international rankings across items such as Teaching/Learning, Research, Knowledge Transfer, International Orientation, or Regional Engagement.

The prospective students first had to state in which field of study and for which degree (Bachelor, Master, or State Examination) they had currently applied for. They were also asked whether they are planning to do a further degree afterwards (Master, Second State Examination, or Doctoral Degree) and with which degree they would aim to earn their first salary. In the second part of the survey, the prospective students were asked to answer several questions regarding monthly gross salaries.<sup>4</sup> First, they had to state their expectations of their own salary at labor market entry and after five years on the job, referring to the degree with which they intend to earn their first salary. Second, they were asked to estimate the respective salaries for average others within the same field of study and with the same degree.

---

<sup>2</sup>Throughout this study, we focus on wage expectations that are adjusted for students' misconceptions of the progressive income tax.

<sup>3</sup>We drop 13 prospective students since they have missing values in their wage expectations.

<sup>4</sup>Students were provided with detailed explanations about the difference between gross and net salaries.

Furthermore, the students were asked about several characteristics of their personal and family background. They should provide the following information: their gender; their age; their working experience; their final grade in secondary school; whether their mother and father graduated from college and, if so, in which major discipline; whether they intended to live at their parents' house while studying; whether they expect to receive "BAfoeG"<sup>5</sup> and, if so, how much; their school system in secondary school; and the federal state in which they obtained their higher education entrance qualification.

Finally, students should also answer two questions regarding the importance of their future income: they were asked how influential the income expectation has been on their college major choice and how important it is to receive an above-average salary.

## 2.2 Descriptive Statistics

Table 1 depicts the means and standard deviations of wage expectations and several other relevant variables for male and female students, respectively. The last column of Table 1 also shows t-values regarding a test of equality of means between males and females.

Male students have on average significantly higher expectations w.r.t. their starting salary as well as w.r.t. the salary they earn after five years on the job than female students. Males expect on average a starting gross salary of 3,579 € and a gross salary after five years of 5,540 €. Females, in comparison, expect to earn on average just 3,015 € at labor market entry and 4,652 € after five years. Both male and female students plausibly expect their earnings to rise with increasing working experience. Moreover, male students do not only have significantly higher expectations with regard to their own future earnings but also with regard to the earnings of average others within the same field of study. Hence, males do expect higher wages for themselves and a higher overall wage level in their field of study than females do. There is also a gender difference in the relation between expected own salaries and expected salaries of average others. Whereas the means of own expected salaries are higher than those of expected average salaries for male

---

<sup>5</sup>The Bundesausbildungsförderungsgesetz (BAfoeG) is a Federal Training Assistance Act that regulates federate student grants and loans in Germany. It supports students from a weaker financial background.

Table 1: Descriptive Statistics

	Male	Female	<i>t</i> -value
Wage Expectations			
Own Starting Salary	3,579.12 (1,908.16)	3,014.89 (1,558.45)	7.14
Average Starting Salary	3,571.00 (1,839.61)	3,178.37 (1,620.37)	5.02
Own Salary After Five Years	5,539.82 (3,262.18)	4,652.17 (2,654.29)	6.58
Average Salary After Five Years	5,339.48 (3,276.44)	4,767.36 (2,688.77)	4.21

Very Unimportant	4.94 (21.69)	5.52 (22.84)	-0.58
Unimportant	8.51 (27.91)	11.88 (32.37)	-2.53
Neutral	35.29 (47.81)	42.44 (49.45)	-3.00
Important	42.30 (49.43)	35.14 (47.76)	3.28
Very Important	8.97 (28.59)	5.01 (21.82)	3.41
Observations	870	1,178	

*Note:* First two columns show means and standard deviations (in parenthesis). Last column shows *t*-values of a test of equality of means between males and females. Wage expectations are expected gross salaries.

students, the opposite is the case for female students. Table 10 in the appendix shows wage expectations differentiated by field of study. Mathematics and Computer Science students expect the highest starting salaries for themselves and for average others. Law Students, however, expect the highest earnings after five years on the job. Education and Humanities students, contrarily, feature the lowest income expectations.

Male students in the sample are on average 21.22 years of age, which is slightly older than female students, who are on average 20.78 years of age. There is no significant gender difference with respect to working experience. However, male students did perform

worse in secondary school on average than their female counterparts. The final grade in secondary school of males is on average 2.31, whereas that of females is only 2.16.<sup>6</sup>

Moreover, males and females differ substantially with regard to the choice of the field of study, as is also found by the previous literature (e.g. Zafar, 2013). Males in the sample are significantly more likely to apply for a program in Business Studies as well as in Mathematics and Computer Science than females are. 16 percent of males, for instance, are applying for a program in Mathematics and Computer Science compared to only 4 percent of females. Contrarily, a significantly larger share of females is applying for a program in Education, Humanities, and Medicine. For example, whereas 29 percent of females do apply for a program in Medicine, only 19 percent of males do.

There are also differences between male and female students in terms of the view on the importance of income. An above-average salary seems to be more important for male students. 9 percent of males, for instance, state that an above-average salary is very important compared to only 5 percent of females. 42 percent of males compared to 35 percent of females regard an above-average income as important. This indicates that males are more strongly driven by pecuniary incentives than females are and that females have stronger preferences for non-pecuniary aspects of jobs, which is also found, amongst others, by Wiswall and Zafar (2018). Males and females differ less, though, with regard to the question how influential the potential income was on their college major choice.

### **2.3 Overconfidence Measure**

Our data allows to compare the expectations of students for their own starting salary, conditional on field of study, with their expectations for the average starting salary of a student in the same field of study. This can be used to construct a measurement of the individual overconfidence of a respective student. For our analysis the following

---

<sup>6</sup>In Germany, grades are scaled from 1 to 6, with 1 being the best grade, and 6 being the worst.

Table 2: Mean of the Overconfidence Index by Gender

	$OC_{start}$	$OC_{five}$	$t$ -value
Male	1.061 (0.624)	1.101 (0.671)	-1.294
Female	0.983 (0.325)	1.016 (0.773)	-1.348
Overall	1.016 (0.477)	1.052 (0.732)	-1.865
$t$ -value	3.353	2.658	

*Note:* Means and standard deviations (in parenthesis) of the respective overconfidence index. The last column shows  $t$ -values of a test of equality of means between the overconfidence index with regard to the starting salary and with regard to the salary after five years. The last row shows  $t$ -values of a test of equality of means between males and females.

overconfidence index is used:

$$OC_{it} = \frac{y_{own,it}}{y_{other,it}} \quad \text{with } t = \text{start, after five years.} \quad (1)$$

Which is simply the ratio of the expected own salary of individual  $i$ ,  $y_{own,it}$ , to the average salary of all other fellow students, expected by individual  $i$ ,  $y_{other,it}$ . Thus, the index takes on a value larger than one if the student expects to earn more than average, which we consider as overconfidence. Similarly, it takes on a value smaller than one if the student expects to earn less than others, which could be interpreted as underconfidence. Consequently, the index is equal to one if a student expects to earn as much as her fellow students.

Means of the overconfidence index for males and females are shown in Table 2. Males are on average more overconfident than females, both w.r.t. the starting salary as well as the salary after five years. The differences between males and females are statistically significant as the test of equality of means shows in the last row. This is in line with most of the previous literature on overconfidence (e.g. Barber and Odean, 2001; Bengtsson et al., 2005; Niederle and Vesterlund, 2007; Dahlbom et al., 2011). The mean of males is larger than one for both salaries, i.e., male students on average expect to earn more than the expected average salary at the start of their working career (6 percent) as well as five years after (10 percent). Contrarily, females expect to earn on average 2 percent

Table 3: Overconfidence Shares

	<i>OC<sub>start</sub></i>			<i>OC<sub>five</sub></i>		
	> 1	= 1	< 1	> 1	= 1	< 1
Male	23.45	46.67	29.89	32.30	40.69	27.01
Female	16.21	45.50	38.29	20.12	44.06	35.82
Overall	19.29	46.00	34.72	25.29	42.63	32.08

*Note:* Table shows the respective shares in percent.

less than the expected average starting salary. However, they are more confident w.r.t. the salary they earn after five years. Here, they expect to earn on average 2 percent more than average others. The difference in overconfidence with regard to the starting salary and the salary after five years is insignificant for males and females separately, but it is weakly significant in the full sample as the test statistics in the last column show. A reason for this difference could be that overconfident students expect their presumed superior ability or higher working effort to be more influential on their own salary after they have proven their skills to their employer for a few years.

Even though the mean of the overconfidence index is larger than one for males (both salaries) and females (salary after five years), it is not the case that the majority of students are overconfident. In fact, a larger share of both male and female students expects to earn even less than the expected average starting salary, which can be seen in Table 3. Nevertheless, 23 percent of males and 16 percent of females are overconfident w.r.t. the starting salary. The largest share of males (47 percent) and females (46 percent) expects the same starting salary as the starting salary of their fellow students. Regarding the salary after five years, the shares of males and females that are overconfident are larger compared to the starting salary. There are more males that are overconfident than males who are underconfident. However, the share of overconfident females is still smaller than the share being underconfident. Once again, the largest share of male and female students expects to earn the average salary, i.e., showing an overconfidence ratio of one. However, the shares are somewhat smaller for the salary after five years compared to the starting salary.

Table 4 reports differences in the mean overconfidence indices w.r.t. the field of study a

Table 4: Mean of the Overconfidence Index by Gender and Field of Study

Field of Study	<i>OC<sub>start</sub></i>		<i>OC<sub>five</sub></i>	
	Male	Female	Male	Female

Natural Sciences	1.023 (0.253)	0.967 (0.187)	1.052 (0.216)	1.272 (2.636)
Overall	1.061 (0.624)	0.983 (0.325)	1.101 (0.671)	1.016 (0.773)

*Note:* Table shows means and the standard deviations (in parenthesis) of the respective overconfidence index.

student applied for. In most fields, males are on average more overconfident than females. However, a few exceptions exist. Male Education students, for instance, are less confident than their female counterparts. They expect to earn on average slightly less than the average salary, while female Education students expect to earn slightly more than the average salary. Females who study Natural Sciences are also more overconfident than males w.r.t. the salary after five years. Comparing all fields of study shows that male Medicine students are by far the most overconfident subgroup w.r.t. both salaries. On average, they expect to earn 27 percent more than the average salary at the start of their working career, and 34 percent more than average five years later. Female students of Natural Sciences are very confident w.r.t. the salary after five years. They expect their own salary after five years to be 27 percent higher than the average salary. Male Business and Law students are also fairly confident. Students who study Humanities, contrarily, are relatively pessimistic about their own future earnings.

An obvious concern with this measurement of overconfidence is that it may not solely reflect the individual overconfidence per se. A prospective student who expects to earn

more than average others in the same field of study might do so on merit. For example, if a student had a much better final grade in secondary school than the average final grade of students in the same field of study, it is probably not unrealistic to expect that this student will earn an above-average salary in the future. Students who expect to earn more than average might simply have above average abilities. The prospective students might evaluate their own abilities in comparison to others in the same field of study when forming their wage expectations. If all students would be able to realistically assess their own abilities and would base their wage expectations on it, the overconfidence index would just measure relative abilities of students. However, our descriptive evidence as presented above suggest otherwise. Even though female students performed on average better in secondary school, they do have a lower overconfidence on average. Nonetheless, the true abilities of students could have an effect on the overconfidence ratio. There could be further other plausible reasons why a student expects to earn more than average others. Some students might already have good prospects for a well-paying job at the workplace of their parents or other family members after their studies. So, have close relationships to high ranked employees or owners of companies could also play a role when students expect to earn above average salaries. A further possibility why students might expect their future income to differ from the average income might be that they have very strong preferences for non-pecuniary aspects of jobs. A student who values flexible working hours, the atmosphere at the workplace, and the enjoyment of a job as more important than the salary might realistically expect to earn less than average others. Therefore, one should be cautious when interpreting the means of our overconfidence index. This index is unlikely to be a perfect measurement of the true overconfidence of students. The main purpose of this study, however, is not to perfectly measure overconfidence of students, but to evaluate the impact of overconfidence on gender differences in wage expectations. Throughout our estimation procedure, which will be outlined in the next section, we control for the final grade in secondary school of the student, which can be viewed as a proxy for her ability. Moreover, we include dummy variables indicating whether the

parents of a student graduated from college, whether they did so in the same field of study for which the student is applying, and whether the student expects to receive financial support ("BAfoeG") while studying. We also include dummy variables indicating answers of the students to questions regarding income importance. Such views are probably closely linked to students' preferences for non-pecuniary aspects of jobs. Thus, above mentioned, potential concerns w.r.t. our specific overconfidence measure should not pose a major problem for the purpose of this study.

## 3 Methodology

### 3.1 Linear Regression

The simplest way to get an estimator of the gender gap in wage expectations that cannot be explained by differences between male and female students in the observed characteristics and to evaluate the impact of overconfidence on wage expectations is to run an OLS regression of the linear model

$$\ln y_i = \delta \cdot d_{Fi} + \mathbf{x}_i \boldsymbol{\beta} + v_i. \quad (2)$$

Where the outcome variable,  $\ln y_i$ , is the logarithm of the own expected starting salary (or salary after five years on the job) of individual  $i$ ,  $d_{Fi}$  is a dummy variable which is equal to one if the student is female and  $\delta$  is its coefficient.  $\mathbf{x}_i$  is a vector that contains all observed characteristics of the students and a constant.  $\boldsymbol{\beta}$  is the corresponding coefficient vector of  $\mathbf{x}_i$  and  $v_i$  denotes the error term. By controlling for all observed variables the overall gender gap in wage expectations is purged of the part that is caused by the different characteristics of males and females. Thus, the estimator of  $\delta$  reflects the gender gap in wage expectation that would exist if male and female students would not differ in observed characteristics.

The coefficient of the overconfidence index can be interpreted as the effect of an in-

crease in overconfidence on the expectation of the own future salary of a student if the overconfidence index is exogenous in Equation (2). Unobserved factors are unproblematic w.r.t. the exogeneity of the overconfidence index as long as they equally affect the expected own salary and the expected average salary, so both parts of the ratio. Only unobserved factors that affect the relative difference between the expected own salary and the expected average salary cause a bias in the estimated coefficient of the overconfidence index. Unobserved factors that might have an effect on the overconfidence index are the ability of students, the advantage of having already good prospects for a well paying job after graduation, and preferences of students regarding non-pecuniary aspects of jobs, as was discussed in the previous section. We control for the final grade in secondary school, the family background, and the view on the importance of income. Thus, these factors should not cause a bias in the estimated impact of the overconfidence index on wage expectations.

Even though a simple linear regression can already show how much of the gender gap in wage expectations can be explained by observed variables it is not possible to determine how much of the explained part can be attributed to a certain variable. Therefore, we use so-called decomposition methods, described below, for an extensive analysis of the gender difference in wage expectations and to determine the contribution of overconfidence to this difference.

### **3.2 Oaxaca-Blinder Decomposition**

Mean differences between two groups in an outcome variable can be analyzed by applying the well known decomposition method proposed by Oaxaca (1973) and Blinder (1973). The method allows to divide the difference in the mean of an outcome variable between two groups into a part that can be explained by different group characteristics and into an unexplained part.

For the standard Oaxaca-Blinder decomposition, it is assumed that the outcome variable can be expressed by a linear model that is separable into observed and unobserved

characteristics (Firpo et al., 2011). So, we assume that the logarithm of the own expected salary,  $\ln y_{gi}$ , is given by the following model for males ( $M$ ) and females ( $F$ ), respectively:

$$\ln y_{gi} = \mathbf{x}_i \boldsymbol{\beta}_g + v_{gi} \quad \text{for } g = M, F. \quad (3)$$

Where  $\mathbf{x}_i$  is again the vector containing observed explanatory variables and a constant,  $\boldsymbol{\beta}_g$  is the corresponding coefficient vector and  $v_{gi}$  represents the error term that is unobserved. Furthermore, it is assumed that  $\mathbb{E}[v_{gi} | \mathbf{x}_i, d_F = d] = 0$  holds, for  $d = 0, 1$ . Under these assumptions the overall mean difference between females and males,  $\Delta_O^\mu$ , can be decomposed as follows (Firpo et al., 2011):<sup>7</sup>

$$\begin{aligned} \Delta_O^\mu &= \mathbb{E}[\ln y | d_F = 1] - \mathbb{E}[\ln y | d_F = 0] \\ &= \underbrace{\mathbb{E}[\mathbf{x} | d_F = 1] \cdot (\boldsymbol{\beta}_F - \boldsymbol{\beta}_M)}_{\Delta_U^\mu} + \underbrace{(\mathbb{E}[\mathbf{x} | d_F = 1] - \mathbb{E}[\mathbf{x} | d_F = 0]) \cdot \boldsymbol{\beta}_M}_{\Delta_E^\mu}. \end{aligned}$$

So, the overall mean difference between females and males in their wage expectation,  $\Delta_O^\mu$ , can be decomposed into the two components  $\Delta_U^\mu$  and  $\Delta_E^\mu$ . The first component,  $\Delta_U^\mu$ , is the unexplained part of the mean difference and captures the difference between the male and female coefficient vector  $\boldsymbol{\beta}$ . Hence, it is the part that is caused by the difference in the way females and males form their wage expectations given their personal characteristics  $\mathbf{x}$ . The second component,  $\Delta_E^\mu$ , in contrast, is the explained part, which captures the part of the mean difference that can be explained by the difference between female and male students in their personal characteristics.

The estimation of the two components  $\Delta_U^\mu$  and  $\Delta_E^\mu$  is straightforward. One can simply replace  $\mathbb{E}[\mathbf{x} | d_F]$  by the respective sample mean  $\bar{\mathbf{x}}_g$  and plug in the estimator of the respective coefficient vector  $\hat{\boldsymbol{\beta}}_g$ , which can be obtained by running an OLS regression of Equation (3) for females and males, respectively (Firpo et al., 2011). The estimated

---

<sup>7</sup>In this case the male coefficient vector is chosen to form the counterfactual distribution. Alternatively, the female or pooled coefficient vector can be used (Firpo et al., 2011).

overall mean difference,  $\hat{\Delta}_O^\mu$ , can thus be decomposed as follows:

$$\hat{\Delta}_O^\mu = \overline{\ln y_F} - \overline{\ln y_M} = \underbrace{\bar{\mathbf{x}}_F(\hat{\beta}_F - \hat{\beta}_M)}_{\hat{\Delta}_U^\mu} + \underbrace{(\bar{\mathbf{x}}_F - \bar{\mathbf{x}}_M)\hat{\beta}_M}_{\hat{\Delta}_E^\mu}. \quad (4)$$

Due to the additive linearity assumption it is also very easy to compute a detailed decomposition of the overall mean difference, which further divides the two components  $\hat{\Delta}_U^\mu$  and  $\hat{\Delta}_E^\mu$  into the contributions of different explanatory variables (Firpo et al., 2011).

One problem with the Oaxaca-Blinder decomposition is that the estimation of the explained and the unexplained part is inconsistent when the linearity assumption is not satisfied (Barsky et al., 2002). In Equation (3) it was assumed that the relationship between the logarithm of the expected salary and the explanatory variables is linear. However, this might not necessarily be true. If the relationship is nonlinear the average counterfactual wage expectations that females would have if they would form their expectations the same way as males do is not equal to  $\mathbb{E}[\mathbf{x}|d_F = 1] \cdot \beta_M$  (Firpo et al., 2011). This problem can be solved by using a reweighted regression approach. The idea of this approach is to use a reweighting function that makes the characteristics of male students similar to those of female students.<sup>8</sup> The reweighted regression approach allows to measure the specification error, which occurs when the regression model is misspecified. A specification error close to zero indicates that the linear model is accurate. In addition, we need to calculate the reweighting error. If the reweighting function is consistently estimated the reweighting error should be close to zero.

### 3.3 RIF Decomposition

To get a better understanding of the gender gap in wage expectations, it can be interesting to not only consider the difference at the mean but also the gender differences at other parts of the wage expectation distribution. The glass ceiling effect, which is often found

---

<sup>8</sup>It is also possible to choose females as the reference group and use a reweighting function that makes the characteristics of females similar to those of males.

in the distribution of realized wages, might already be present in the distribution of wage expectations. Furthermore, it can be interesting to see whether the contribution of the gender difference in overconfidence varies along the wage expectation distribution.

To be able to do this, the gender gaps at different quantiles of the wage expectations distribution have to be decomposed. Unfortunately, this is a more difficult task than in case of the mean. It is not possible to decompose quantiles by simply using quantile regressions instead of standard OLS regressions and applying the Oaxaca-Blinder decomposition. The reason for this is that the Oaxaca-Blinder decomposition relies on the law of iterated expectations which does apply in case of the mean but not in case of quantiles.

The RIF-regression approach proposed by Firpo et al. (2018), however, allows to perform a detailed decomposition at different quantiles of the wage expectation distribution. The idea of this method is to replace the outcome variable,  $\ln y$ , by a recentered influence function of the respective quantile,  $Q_\tau$ , which can be expressed as

$$\text{RIF}(\ln y; Q_\tau) = Q_\tau + \text{IF}(\ln y; Q_\tau) = Q_\tau + \frac{\tau - \mathbb{1}\{\ln y \leq Q_\tau\}}{f_{\ln y}(Q_\tau)}. \quad (5)$$

Where  $\text{IF}(\ln y; Q_\tau)$  is the influence function of the quantile,  $Q_\tau$ ,  $f_{\ln y}(\cdot)$  is the density of the marginal distribution of  $\ln y$ , and  $\mathbb{1}\{\cdot\}$  is an indicator function taking on the value one if the condition in  $\{\cdot\}$  is true (Firpo et al., 2009). Influence functions are an often used tool in the robust statistics literature and represent the contribution of an individual observation to a given distributional statistic. A useful property of influence functions is that by definition  $\mathbb{E}[\text{IF}(\ln y; Q_\tau)] = \int \text{IF}(\ln y; Q_\tau) \cdot dF(\ln y) = 0$ . Thus, the expected value of the recentered influence function,  $\text{RIF}(\ln y; Q_\tau)$ , of the quantile  $Q_\tau$  is equal to  $Q_\tau$  itself (Firpo et al., 2018). Using the law of iterated expectations the unconditional quantile,  $Q_\tau$ , can therefore be written as

$$Q_\tau = \mathbb{E}[\mathbb{E}(\text{RIF}(\ln y; Q_\tau)|\mathbf{x})] = \int \mathbb{E}[\text{RIF}(\ln y; Q_\tau)|\mathbf{x}] \cdot d\mathbf{F}_\mathbf{x}(\mathbf{x}).$$

For the simplest form of the RIF regression approach it is assumed that the conditional

expectation of the recentered influence function can be modelled as a linear function of the explanatory variables  $\mathbf{x}$  (Firpo et al., 2011):

$$\mathbb{E}[\text{RIF}(\ln y_i; Q_\tau) | \mathbf{x}_i] = \mathbf{x}_i \boldsymbol{\gamma}_\tau + v_{\tau i}. \quad (6)$$

Moreover, it is again assumed that the error term,  $v_{\tau i}$ , satisfies the condition  $\mathbb{E}[v_{\tau i} | \mathbf{x}] = 0$ . Under these assumptions the unconditional expectation of  $\text{RIF}(\ln y; Q_\tau)$ , which is equal to the quantile  $Q_\tau$ , can be expressed as

$$Q_\tau = \mathbb{E}[\text{RIF}(\ln y; Q_\tau)] = \mathbb{E}[\mathbb{E}(\text{RIF}(\ln y; Q_\tau) | \mathbf{x})] = E[\mathbf{x}] \cdot \boldsymbol{\gamma}_\tau \quad (7)$$

Consequently, the coefficient  $\gamma_{\tau j}$ , which can easily be estimated by running an OLS regression, can now be interpreted as the effect of an increase in mean value of  $x_j$  on the  $\tau^{\text{th}}$  unconditional quantile of  $\ln y$ . This means that the gender gap at a certain quantile of the wage expectation distribution can be decomposed as in the standard Oaxaca-Blinder decomposition when  $\ln y$  is replaced by the respective  $\text{RIF}(\ln y; Q_\tau)$ .

Before this can be done though the estimates of  $\text{RIF}(\ln y; Q_\tau)$  have to be computed. One can do this by inserting the respective sample quantile,  $\hat{Q}_\tau$ , and the estimator of the density at that point,  $\hat{f}_{\ln y}(\hat{Q}_\tau)$ , which can be obtained by kernel density estimation (Firpo et al., 2009). This has to be done separately for male and female students. When the estimates,  $\widehat{\text{RIF}}(\ln y; Q_\tau)$ , are computed for both groups it can be proceeded as in the standard Oaxaca-Blinder decomposition.

The explained and the unexplained part are again only consistently estimated when the linearity assumption is true. Since RIF models are unlikely to be linear for distributional statistics besides the mean, it is even more important in case of RIF decompositions to use a reweighting approach and check the specification error (Firpo et al., 2011, 2018).

Table 5: Linear Regressions

Observations	2,048	2,048	870	1,178

*Note:* Outcome variable is the logarithm of the respective gross salary expectation. In Columns 2 to 4, we control for the degree, the field of study, the degree with which the student intends to earn first salary, the view on the importance of income, human capital variables, the personal as well as the family background, and the survey year. Overconfidence is measured by the respective overconfidence index. Standard errors are shown in parenthesis. \*, \*\* and \*\*\* indicate statistical significance at the 10%, 5%, and 1%-level, respectively.

## 4 Results

### 4.1 Linear Regressions

The estimated overall gender gaps in wage expectations are shown in Column 1 of Table 5 for the starting salary, Panel (a), and the salary after five years, Panel (b), respectively. They are obtained by running an OLS regression of the logarithm of the respective expected salary on a constant and a dummy variable that is equal to one if the student is female. Female students are less optimistic with regard to both salaries. The expected starting salaries of female students are on average 17.2 percent lower than those of male students. Their expectations of their salary after five years on the job are on average 16.6 percent lower. There are substantial gender gaps in the wage expectations that are highly significant and are similar in size for both salaries. In comparison to the results of Reuben et al. (2017), however, we find smaller gender gaps.<sup>9</sup>

<sup>9</sup>Reuben et al. (2017) find a gender gap of 31 percent in the expected salary at age 30 and a gender gap of 39 percent in the expected salary at age 45.

Column 2 shows the coefficient estimates of Equation (2), where the respective wage expectation is additionally regressed on the overconfidence index and the other observed characteristics of students. The estimated coefficient of the female dummy variable can now be interpreted as the relative difference in the wage expectations between male and female students that would exist in the absence of any gender differences in the observed characteristics. Controlling for the observed characteristics of students reduces the gender gap in wage expectations considerably. In the case of the starting salary the gap reduces by roughly 7 percentage points to 9.9 percent. The gender gap in expectations of the salary after five years is now 10.2 percent, which is roughly 6 percentage points lower than the overall gender gap. Thus, already simple linear regressions show that more than a third of the gender gaps in wage expectations can be explained by differences in observed characteristics between male and female students. Nevertheless, there remain sizable unexplained gender gaps in wage expectations that are still highly significant.

Overconfidence of a student w.r.t. the respective salary has a positive impact on wage expectations. This finding is in line with the results of Reuben et al. (2017). The estimated coefficients of the respective overconfidence index are positive and significantly different from zero in both regressions. However, the effect is much larger in case of the starting salary. A ten percentage points increase in overconfidence increases on average the expectation of the starting salary by 2 percent holding all other factors constant. An equivalent change in overconfidence w.r.t. the salary after five years only leads to an increase of the expected salary after five years by 0.5 percent on average. The size of the overconfidence effect on wage expectations also differs between male and female students, which can be seen when the model is estimated for males and females separately. A ten percentage points increase in the overconfidence increases the estimated starting salary by 2.9 percent for females compared to only 1.7 percent for males. Contrarily, in case of the salary after five years the overconfidence effect is somewhat stronger for males than for females.

## 4.2 Decomposition of the Gender Gap

The results of the standard Oaxaca-Blinder decomposition in case of the expected starting salary are shown in Table 6.<sup>10</sup> We use the male coefficient vector to form the counterfactual distribution.<sup>11</sup> As was already shown by linear regressions the overall relative gender difference in wage expectations is 17.2 percent in case of the starting salary. 8.5 percentage points of this gender gap can be attributed to differences in observed characteristics between males and females. 8.7 percentage points of the gap, however, remain unexplained and are down to differences in the male and female coefficient vector. This means that almost 50 percent of the gender gap in the expectation of the own starting salary can be explained by the differences in observed characteristics.

The results of the detailed decomposition show that the difference in overconfidence between male and female students does significantly contribute to the gender gap in the expected own starting salary. 1.3 percentage points of the gender gap can be attributed to the difference in overconfidence. This means that about 8 percent of the gender gap in the expected starting salary is due to the higher overconfidence of male students. This is in line with Reuben et al. (2017) who also find that gender differences in overconfidence are partly responsible for larger expected salaries of male students.<sup>12</sup> The contribution of overconfidence to the gender gap is almost a quarter of the contribution of the field of study. Thus, we find that overconfidence plays an important role for the gender gap in wage expectations. Gender differences in the choice of the field of study together contribute 5.6 percentage points to the gender gap, which corresponds to roughly 32 percent. So, around a third of the gap is down to the fact that males and females sort differently into fields of study. As was shown in Section 2, females are more likely to apply in a program in Education and Humanities, which are the fields with the lowest expected

---

<sup>10</sup>From now on we concentrate on the starting salary. The results for the salary after five years are very similar and are available on request.

<sup>11</sup>The decomposition results are very similar when the pooled or female coefficient vector is used as the reference vector instead.

<sup>12</sup>Reuben et al. (2017) find that gender differences in overconfidence and competitiveness together explain 18% of the gender gap in earnings expectations.

*Note:* Outcome variable is the logarithm of the expected gross starting salary. The male coefficient vector is used as the reference vector. Overconfidence is measured by the overconfidence index with regard to the starting salary. The standard errors are calculated as described by Jann (2008) and are shown in parenthesis. \*, \*\* and \*\*\* indicate statistical significance at the 10%-, 5%-, and 1%-level, respectively. Column 2 shows relative impact on the gender gap in percent.

starting salaries. Males, in contrast, are more likely to apply in a program in Business Studies as well as in a program in Mathematics and Computer Science, which are the fields with the highest expected starting salaries. The third characteristic of students that significantly contributes to the explained part of the gender gap in expected starting salaries is the view on the importance of income. 1.4 percentage points of the gap can be attributed to gender differences in the set of dummy variables indicating answers of students to two questions regarding the importance of income. This corresponds to a contribution of around 8 percent in relative terms. A possible explanation for this is that females might be more inclined than males to not just look at the salary but also consider non-pecuniary aspects when searching for a job, because they view their income as less important than males do. This might cause them to already have lower expectations of their own starting salary than males.

The decomposition of the unexplained part into the contributions of explanatory variables allows to see how much of the gender gap is due to the difference in the expected return to a certain characteristic. Only the difference in the coefficient of the overconfidence index has an effect on the gender gap that is statistically different from zero. However, the effect is in the opposite direction. It even reduces the gender difference in the expected starting salary. The main contribution to the unexplained part of the gender gap in the expected starting salary comes from the difference in the male and female intercepts, which capture unobserved factors. Hence, it seems not to be the case that males have higher expectations regarding their starting salaries because they expect higher returns to certain characteristics than females do.

### **4.3 Heterogenous Effects**

#### **Heterogeneity along the Wage Expectation Distribution**

The gender gap in wage expectations and the causes of it might differ between different points in the wage expectation distribution. To see whether this is the case we apply the

Figure 1: Aggregate Decomposition: Expected Starting Salary

*Note:* Outcome variable is the logarithm of the expected gross starting salary. Males are chosen as the reference group. Overconfidence is measured by the overconfidence index with regard to the starting salary. Standard errors are bootstrapped (400 replications).

RIF-regression approach, described in Section 3.3. The results are depicted in Figures 1 and 2. The gender gap is evaluated at every decile of the wage expectation distribution. The left panel of Figure 1 depicts the gender gap in the expected starting salary along the distribution of expected starting salaries. The gender gap is present at all deciles of the distribution. The gap varies from 13.5 percent at the 10%-quantile to 19.5 percent at the median. As shown above, the mean of expected starting salaries of males is 17.2 percent higher than the mean of females. So, whereas the gender gap at the bottom of the expected starting salary distribution is considerably smaller than at the mean it is larger in the middle of the distribution. Although the size of the gender gap does vary along the wage expectation distribution, we do not find a glass ceiling or sticky floor effect. However, the reason for this could be that our sample only includes prospective college students who are a group of relatively high skilled individuals.

The right panel of Figure 1 depicts how much of the gender gap in wage expectations at the different quantiles can be explained by gender differences in observed characteristics. In contrast to the overall gender gap, the explained part of the gender gap varies considerably less along the distributions of the expected starting salary. Hence, the variation of the overall gender gap is mainly down to the variation of the unexplained part. The explained part of the gap lies between 11.2 and 6.8 percentage points. In compar-

Figure 2: Contribution of Overconfidence

*Note:* Outcome variable is the logarithm of the expected gross starting salary. Males are chosen as the reference group. Overconfidence is measured by the overconfidence index with regard to the starting salary. Standard errors are bootstrapped (400 replications).

ison, the explained part of the gender gap at the mean is 8.5 percentage points. It is somewhat larger at the edges of the distribution but does not vary a lot in between. At the 10%-quantile the explained part is largest even though the overall gender gap in the expected starting salary is smallest at that quantile. Contrarily, the explained part is smallest at the median of the distribution where the overall gender gap is largest. This means that despite low variation of the explained part the share of the explained part at the respective gender gap does vary a lot. Whereas 83 percent of the gender gap in the expected starting salary at the 10%-quantile can be explained by differences in observed characteristics less than 35 percent of the gap can be explained at the median.

Figure 2 shows the contribution of overconfidence to the explained part of the gender gap in wage expectations along the distribution. Differences between male and female students w.r.t. overconfidence do have a significant positive effect on the gender gap in the expected starting salary at every evaluated quantile. The part attributed to gender differences in overconfidence varies, however, between 1.7 and 0.6 percentage points. In line with the total explained part the contribution of overconfidence is higher at the edges of the distribution than in the middle. The contrast between the edges and the middle of the distribution is even larger in relative terms. Whereas gender differences in overconfidence are responsible for 13 percent of the gap at the 10%-quantile and for

8 percent of the gap at the 90%-quantile, they are only responsible for 3 percent of the gap at the median. The U-shape of the contribution of overconfidence indicates that female students with the lowest expectations are particularly underconfident and that male students with the highest expectations are particularly overconfident.

## **Heterogeneity between Subgroups of Students**

We also analyze whether there are heterogenous effects for some subgroups of students. The results of the standard Oaxaca-Blinder decomposition for these different subgroups are shown in Tables 7 and 8.

First, in Table 7 we differentiate between prospective Medicine students, who make up roughly a quarter of all students in the sample, and all other prospective students. As was highlighted in Section 2, male students applying in a program in Medicine are by far the most overconfident subgroup. This raises the question whether the result that gender differences in overconfidence partly explain the gender gap in wage expectations is solely driven by Medicine students. The results show that the overall gender gap in the expected starting salary as well as the size of the explained part is substantially smaller for Medicine students than for other students. However, the part attributed to gender differences in overconfidence is much larger for Medicine students. 4.5 percentage points of the gender gap in the expected starting salary, which corresponds to approximately 39 percent in relative terms, can be explained by the difference in overconfidence for Medicine students. For other students, in contrast, only 0.8 percentage points corresponding to around 4 percent of the gap are caused by the difference in overconfidence. But the contribution is still weakly significant. This shows that the part of the gender gap in the expected starting salary that can be explained by the larger overconfidence of male students is mainly but not solely driven by Medicine students.

Second, in Table 8 the sample is divided into the group of students applying in a STEM field and the group of students applying in non-STEM fields. In the sample Mathematics and Computer Science as well as Natural Sciences can be classified as STEM fields

*Note:* Outcome variable is the logarithm of the expected gross starting salary. In all columns the male coefficient vector is used as the reference vector. Overconfidence is measured by the overconfidence index with regard to the starting salary. The standard errors are calculated as described by Jann (2008) and are shown in parenthesis. \*, \*\* and \*\*\* indicate statistical significance at the 10%-, 5%-, and 1%-level, respectively.

and all other fields as non-STEM fields. Thus, the STEM group comprises 334 students and the non-STEM group 1714 students. Not only are wages in occupations related to STEM fields on average higher than in occupations related to non-STEM fields, but it is also expected that STEM employment opportunities will grow in the future. Nonetheless, females remain underrepresented in STEM fields and STEM related occupations (Osikominu and Pfeifer, 2018). Therefore, it might be interesting to see whether there is a difference with regard to the gender gap in wage expectations between students applying in a STEM-field and students applying in a non-STEM field. The gender gap in the expected starting salary is substantially larger in STEM fields than in non-STEM fields. Female students in STEM fields on average expect to earn 29.4 percent less at labor market entry than their male counterparts. The equivalent gender gap in non-STEM fields is only 13.5 percent. Moreover, while a considerable part of the gender gap in non-STEM fields can be explained by differences in the observed characteristics almost the whole gender gap in STEM-fields remains unexplained. So, the very large gender gap in STEM fields is not caused by differences in observed characteristics between male and female students in STEM fields but by unobserved factors. The contribution of overconfidence to the explained part of the gender gap in STEM fields is smaller compared to the full sample and is insignificant. In non-STEM fields the contribution of the differences in overconfidence is a bit larger than in the full sample.

## 5 Robustness Checks

As discussed in Section 3, the decomposition results are only valid if the linearity assumption is satisfied. Therefore, we also apply the reweighted-regression approach, described above. In case of the standard Oaxaca-Blinder decomposition we find a specification error of 0.002 which is statistically not different from zero.<sup>13</sup> Moreover, the reweighting error is also very close to zero and statistically insignificant, which indicates that the reweighting factors are consistently estimated. In case of RIF decompositions we also find no sta-

---

<sup>13</sup>All other results of the decompositions using the reweighting approach are available on request.

tistically significant specification error at any point of the distribution of the expected starting salary. This suggests that the decomposition results without reweighting are not invalid because of a misspecification of the regression models. Hence, we conclude that the linear specification is quite accurate and continue with it.

In Section 2 it was outlined that the mean of the overconfidence index regarding the expected starting salary is larger than one, even though more students are underconfident than overconfident. This indicates that there are a few students who are extremely overconfident. Hence, it could be the case that our results are mainly driven by such outliers. Furthermore, there are also some concerns that the overconfidence index might be endogenous. To check the robustness of our results we use other overconfidence measures that are likely to be less affected by these concerns. Table 9 shows the results of the Oaxaca-Blinder decompositions using these different overconfidence measures.

First, we use a dummy variable that is equal to one if the student expects to earn more than average others instead of the overconfidence index. The results are shown in Column 1. The decomposition results using the dummy indicator of overconfidence are less prone to outliers, since the dummy indicator is not affected by the level of overconfidence. The dummy indicator does not show differences between students who expect to earn slightly more than average others and students who expect to earn much more than average others. For the same reason, it is probably also less likely that the estimated coefficient of the dummy indicator of overconfidence is biased. The decomposition result using the dummy indicator is very similar to our previous result using the overconfidence index. The contribution of overconfidence to the explained part is even a bit larger.

In Column 2, we use again a dummy indicator of overconfidence, but this time w.r.t. the salary after five years. That way the overconfidence measure is even less prone to an endogeneity problem since the outcome variable is no longer part of the overconfidence measure. The contribution of overconfidence to the explained part of the gender gap in the expected starting salary is then again larger compared to the result when the overconfidence index is used.

Other	-0.0811 (0.2202)	-0.1015 (0.2216)	-0.0920 (0.2217)
Constant	0.1327 (0.2233)	0.1600 (0.2245)	0.1415 (0.2248)
Observations	2,048	2,048	2,048

*Note:* Outcome variable is the logarithm of the expected gross starting salary. In all columns the male coefficient vector is used as the reference vector. Overconfidence is measured by the respective dummy variable. The standard errors are calculated as described by Jann (2008) and are shown in parenthesis. \*, \*\* and \*\*\* indicate statistical significance at the 10%-, 5%-, and 1%-level, respectively.

Lastly, in Column 3 a dummy variable that indicates whether the student is overconfident w.r.t. any of the two salaries is used. The dummy variable is equal to one if the student expects to earn more than average others at labor market entry, or after five years on the job, or at both points. The decomposition result does not differ much from the result when the overconfidence index is used. As in the two previous cases, the contribution of overconfidence to the explained part is a bit larger than when the overconfidence index is used.

Overall, one can conclude that the decomposition results are robust to the use of a different overconfidence measure. The estimated contribution of overconfidence to the explained part of the gender gap in the expected starting salary is always similar in size no matter which of the different overconfidence measures are used. Moreover, neither the size of the explained part nor the contributions of the other observed characteristics changes dramatically when a different overconfidence measure is used. This indicates that the previous results are not only driven by a few outliers. Furthermore, the concern that the estimated coefficient of the overconfidence index is biased upwards seems to be not warranted. If that would be the case the contribution of overconfidence to the explained part should be smaller when these other overconfidence measures are used and not larger.

## 6 Conclusion

We use large and rich survey data on students' beliefs about their future salaries, which is representative for the German student population, and show that female students expect to earn around 17 percent less at labor market entry as well as after five years on the job than male students. This finding is relevant for an explanation of the gender wage gap, since previous studies indicate that wage expectations do affect realized wages (Webbink and Hartog, 2004). We further evaluate effect heterogeneity w.r.t. two dimensions—across different levels of wage expectations as well as across different subgroups. Our analysis of the gender gap along the wage expectation distribution suggests that there is neither

a sticky floor nor a glass ceiling effect in the earnings expectations of students. However, the gender gap in wage expectations does differ between some subgroups of students. In STEM fields, for instance, the gender gap is even larger than in the full sample.

Furthermore, we measure overconfidence of students by comparing expectations of their own salaries with their expectations of their fellow students' average salaries. As is suggested by previous studies, we find that male students are significantly more overconfident than female students (Barber and Odean, 2001; Bengtsson et al., 2005). Linear regressions of wage expectations on our overconfidence measure show that overconfidence of students indeed affects their wage expectations. Students who are more overconfident tend to expect higher future salaries. Our decomposition results suggest that a substantial part of the gender difference in wage expectation is down to larger overconfidence of male students. This raises the question whether overconfidence is an intrinsic characteristic of students that is given by birth or whether it is possible to influence the confidence of individuals. If confidence of individuals can indeed be influenced, policy measures aimed at raising the confidence of females before they leave secondary school might reduce the gender difference in pay. Gender differences in overconfidence seem to be particularly influential at the bottom and at the top of the wage expectation distribution, as results of our RIF decompositions indicate.

Moreover, we also find that gender differences in college major choice and in the view on the importance of income significantly contribute to the gender gap in wage expectations. Females seem to choose fields with lower income expectations and seem to have stronger preferences for non-pecuniary aspects of jobs than males. A large part of the gender gap in wage expectations, however, cannot be explained by the observed characteristics of students. Even in the hypothetical case that female students would not differ from male students in observed characteristics, more than half of the gender gap would still remain. Hence, there must exist more factors that cause females to have lower wage expectations than males. Nevertheless, by estimating the impact of overconfidence on the gender gap in wage expectations, we can make a step forward by contributing to the existing literature

on wage expectations and gender differences.

Observations	2,048	2,048	2,048	2,048

*Note:* Outcome variable is the respective estimated RIF of the logarithm of the expected gross starting salary. Males are chosen as the reference group. Overconfidence is measured by the overconfidence index with regard to the starting salary. The standard errors are bootstrapped (400 replications) and are shown in parenthesis. \*, \*\* and \*\*\* indicate statistical significance at the 10%-, 5%-, and 1%-level, respectively.
