## Abstract\*

This paper presents a forecasting exercise that assesses the predictive potential of a daily price index based on online prices. Prices are compiled using web scrapping services provided by the private company PriceStats in cooperation with a finance research corporation, State Street Global Markets. This online price index is tested as a predictor of the monthly core inflation rate in Argentina, known as “resto IPCBA” and published by the Statistics Office of the City of Buenos Aires. Mixed frequency regression models offer a convenient arrangement to accommodate variables sampled at different frequencies and hence many specifications are evaluated. Different classes of these models are found to produce a slight boost in out-of-sample predictive performance at immediate horizons when compared to benchmark naïve models and estimators. Additionally, an analysis of intra-period forecasts, reveals a slight trend towards increased forecast accuracy as the daily variable approaches one full month for certain horizons.

## 1. Introduction

Forecasting inflation has become increasingly important in Argentina, as it is essential for economic agents to adjust wages and prices—particularly in recent years—in a context of high and volatile inflation. Having timely updates on the future trajectory of the inflation rate is essential for conducting monetary policy, especially since the Central Bank is transitioning towards an inflation targeting regime. Recent developments in the use of “big data” have greatly facilitated tracking macroeconomic variables in real-time. A remarkable example is the construction of online price indexes that are sampled daily, rather than monthly, as is standard for traditional price indexes from statistical offices. The question naturally arises of whether this information can help predict the future trajectory of traditional consumer price indexes. Ghysels, Kvedaras and Zemlys (2004) introduced a regression framework that allows for the exploitation of times series sampled at different frequencies, known in the literature as Mixed Data Sampling (MIDAS) regression models. The methodology reduces to fitting a regression model to a low-frequency variable using high-frequency data as regressors. As will be shown later, this technique closely resembles distributed lag models. This paper employs this methodology to assess whether the combination of price series sampled at different frequencies is an effective tool for improving forecast accuracy compared to naïve models, using the online price index constructed by PriceStats in cooperation with State Street Global Markets.

The rest of the paper is organized as follows. In the next section, a brief introduction to MIDAS models is presented. In the third section, existing theoretical research on MIDAS regressions as well as some applications in forecasting inflation are briefly reviewed. In the fourth section, the forecasting exercise is described, and the results are discussed. Finally, the fifth section concludes.

## 2. MIDAS Regression Models

MIDAS regression models propose a data-driven method to aggregate high-frequency variables into lower-frequency predictors. They provide an alternative to the well-known “bridge” approach (Schumacher, 2016) in which high-frequency variables are aggregated with equal weights (flat aggregation).<sup>1</sup> Ghysels, Santa-Clara and Valkanov (2004) suggested combining  $y_t$ , a low-

---

<sup>1</sup> In fact, this can be considered a special case of a MIDAS regression.

frequency process, and  $x_\tau$ , a high-frequency process that is observed a discrete and fixed number of times  $m$  each time a new value of  $y_t$  is observed, in a plain regression equation,

$$y_t = \sum_{j=0}^{m-1} \theta_j x_{t-j/m} + u_t, \quad (2.1)$$

or more compactly,

$$y_t = (\boldsymbol{\theta}' \mathbf{x}_t')' + u_t, \quad (2.2)$$

where  $\mathbf{x}_t \equiv [x_t \dots x_{t-(m-1)/m}]$  is a  $1 \times m$  row vector that collects all the  $x_\tau$  corresponding to period  $t$  and  $\boldsymbol{\theta} \equiv [\theta_0 \dots \theta_{m-1}]'$  is the  $m \times 1$  vector of weight coefficients.<sup>2</sup> Each  $j$  high-frequency observation  $x_{t-j/m}$  within the low frequency period  $t$  enters the model linearly as a variable accompanied by its specific weight,  $\theta_j$ , totaling  $m$  explanatory variables and  $m$  weights, plus an error term. The high frequency subindex  $\tau$  needs to be represented in terms of the low frequency index  $t$  by noting that  $\tau = t - 1 + j/m$  for  $j = 1, \dots, m$  since  $m$  is fixed, where  $x_{t-0/m}$  would be the most recent observation. This structure actually conceals a high-frequency lag polynomial  $\theta(L^{1/m}) \equiv \sum_{j=0}^{m-1} \theta_j L^{j/m} x_t$  so that  $L^{j/m} x_t = x_{t-j/m}$  is similar in fashion to a distributed lags model.

To provide a clearer perspective, it is perhaps easier to introduce matrix notation. Defining  $\mathbf{X} \equiv [\mathbf{x}_1' \dots \mathbf{x}_T']'$  as the  $T \times m$  matrix that groups all the  $\mathbf{x}_t$  vectors together;  $\mathbf{y} \equiv [y_1 \dots y_T]'$ , the collection of the low frequency observations of size  $T \times 1$ ; and  $\mathbf{u} \equiv [u_1 \dots u_T]'$ , the residuals of the same length as  $\mathbf{y}$ , it is possible to unveil a simple multiple regression equation,

$$\begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_{T-1} \\ y_T \end{bmatrix} = \begin{bmatrix} x_1 & \dots & x_{1-(m-1)/m} \\ x_2 & \dots & x_{2-(m-1)/m} \\ \vdots & \ddots & \vdots \\ x_{T-1} & \dots & x_{T-1-(m-1)/m} \\ x_T & \dots & x_{T-(m-1)/m} \end{bmatrix} \begin{bmatrix} \theta_0 \\ \vdots \\ \theta_{m-1} \end{bmatrix} + \begin{bmatrix} u_1 \\ u_2 \\ \vdots \\ u_{T-1} \\ u_T \end{bmatrix}. \quad (2.3)$$

Indeed, this problem can be solved by ordinary least squares (OLS) and this method will produce consistent coefficient estimates. Equation (2.1) is usually referred to as the unrestricted MIDAS regression model (U-MIDAS).<sup>3</sup> However, an inconvenience arises when  $m$ , the length of

<sup>2</sup> This equation may also include constants, trends, seasonal terms or other low frequency explanatory variables.

<sup>3</sup> Foroni, Marcellino and Schumacher (2015) present a detailed assessment of this strategy.

the vector  $\theta$ , is large relative to the sample size  $T$ , as is usually the case in MIDAS regressions. When this occurs, the models suffer from parameter proliferation and OLS induces poor estimates and consequently poor forecasts. A straightforward way to overcome this deficiency is to impose restrictions on the coefficients of the high-frequency lag polynomial and restate each  $\theta_j$  as a function of some  $q$  hyperparameters and its subindex  $j$  (its position within the low frequency lag polynomial) in such a way that  $q \gg m$ . Each  $\theta_j$  is redefined as  $\theta_j \equiv w_j(\gamma; j)$  where the vector  $\gamma$  is the collection of  $q$  hyperparameters that characterize the weight function  $w_j(\cdot)$ . Equation (2.1) is transformed to

$$y_t = \lambda \sum_{j=0}^{m-1} \left( \frac{w_j(\gamma; j)}{\sum_{j=0}^{m-1} w_j(\gamma; j)} \right) x_{t-j/m} + u_t. \quad (2.4)$$

where  $\lambda$  is an impact parameter and the weights are normalized so that they sum up to unity. Ghysels, Santa-Clara and Valkanov (2004) initially recommended what is known as the exponential Almon polynomial as a candidate for weight function as it allows for many different shapes and depends on only a few parameters. This is an exponentiated version of an Almon lag polynomial, which is well known in the distributed lags literature,<sup>4</sup>

$$w_j(\gamma_1, \dots, \gamma_q; j) = e^{\sum_{s=1}^q \gamma_s j^s}. \quad (2.5)$$

Another conventional candidate is the beta probability density,

$$w_j(\gamma_1, \gamma_2; j) = z_j^{\gamma_1 - 1} (1 - z_j)^{\gamma_2 - 1}, \quad (2.6)$$

with  $z_j \equiv j/(m - 1)$ ,  $\gamma_1 > 0$  and  $\gamma_2 > 0$ .

Parameterization as in equation (2.5) has proved to be quite popular and has become the standard among researchers, particularly when  $q = 2$ .

The introduction of constrained coefficients has many far-reaching implications. The model turns nonlinear and lacks a closed form solution. It is necessary to resort to nonlinear least squares and approximate the solution by numerical optimization routines. Additionally, the constraints are highly likely to introduce a bias in each  $\theta_j$ . However, based on Monte Carlo simulations, when the sample size is small relative to the number of parameters, Ghysels, Kvedaras

---

<sup>4</sup> See, for example, Judge et al. (1985).

and Zemlys (2016) argue that both parameter estimation precision and out-of-sample forecast accuracy, gained by the increase in degrees of freedom, far offset the effects of the bias generated by misspecified constraints.

MIDAS models are generally intended as a direct forecasting tool since this could prove to be more robust against misspecification (Marcellino, Stock and Watson, 2006). This implies that estimation additionally depends on the time displacement of the variables,  $d \in \mathbb{Q}$ , and the forecast horizon,<sup>5</sup>  $h \in \mathbb{N}$ . The direct strategy requires estimation of as many models as per pair  $(d, h)$  is required. If  $T_Y$  is the time index of latest  $y_t$  available for estimation, and  $T_X$  is the time index of the latest  $x_t$  available for both estimation and forecasting, then  $d$  can be defined as  $d \equiv T_Y - T_X$ . Setting  $W(L^{1/m}; \boldsymbol{\gamma}) \equiv \sum_{j=0}^{m-1} w_j(\boldsymbol{\gamma}; j) L^{1/m}$ , a forecast can be computed with

$$\hat{y}_{T+h} = \hat{\lambda}_{d,h} W(L^{1/m}; \hat{\boldsymbol{\gamma}}_{d,h}) x_{T-d}. \quad (2.7)$$

The “nowcast” can be retrieved when  $d = -1$  and  $h = 1$ . Note also that the fact that  $d$  is a rational number implies that it is possible to generate intra-period forecasts.

To arrive at equation (2.7), it is first necessary to estimate

$$y_t = \lambda W(L^{1/m}; \boldsymbol{\gamma}) x_{t-h-d} + u_t, \quad (2.8)$$

and then compute  $\hat{y}_{T+h}$  with the estimated parameters,  $\hat{\lambda}_{d,h}$  and  $\hat{\boldsymbol{\gamma}}_{d,h}$ , and the vector  $\mathbf{x}_{T-d}$ .

It is possible to extend the MIDAS model by allowing for more than  $m$  high frequency regressors. For example, by including  $p_X$  lags of the vector  $\mathbf{x}_t$  totaling  $m \times L_X$  high frequency variates where  $L_X = p_X + 1$ , the MIDAS-DL model is formed,

$$y_t = \sum_{r=0}^{p_X} (\boldsymbol{\theta}'_r \mathbf{x}'_{t-r})' + u_t, \quad (2.9)$$

or equivalently,

$$y_t = \sum_{r=0}^{p_X} \sum_{j=0}^{m-1} \theta_{r,j} x_{t-r-j/m} + u_t. \quad (2.10)$$

In matrix notation, this can be represented by

---

<sup>5</sup> In other words, how many periods into the future it is necessary to forecast.

$$\begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_{T-1} \\ y_T \end{bmatrix} = \begin{bmatrix} x_1 & \cdots & x_{1-(m-1)/m} & \cdots & x_{1-p_X} & \cdots & x_{1-p_X-(m-1)/m} \\ x_2 & \cdots & x_{2-(m-1)/m} & \cdots & x_{2-p_X} & \cdots & x_{2-p_X-(m-1)/m} \\ \vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\ x_{T-1} & \cdots & x_{T-1-(m-1)/m} & \cdots & x_{T-1-p_X} & \cdots & x_{T-1-p_X-(m-1)/m} \\ x_T & \cdots & x_{T-(m-1)/m} & \cdots & x_{T-p_X} & \cdots & x_{T-p_X-(m-1)/m} \end{bmatrix} \begin{bmatrix} \theta_{0,0} \\ \vdots \\ \theta_{0,m-1} \\ \vdots \\ \theta_{p_X,0} \\ \vdots \\ \theta_{p_X,m-1} \end{bmatrix} + \begin{bmatrix} u_1 \\ u_2 \\ \vdots \\ u_{T-1} \\ u_T \end{bmatrix}$$

(2.11)

If different weight functions for each  $\theta_r$  in equation (2.9), then the multiplicative or aggregates-based MIDAS model is obtained (Ghysels, Kvedaras and Zemlys, 2016). On the contrary, employing a single weight function for all  $m \times L_X$  coefficients vectors  $\theta_r$  is also possible. The first method allows for greater flexibility but at the cost of more parameters to estimate, so this possibility will not be considered, as this may not be convenient for a very short sample size.

Other possible extensions include constructing high frequency factors (Marcellino and Schumacher, 2010), incorporating cointegration relations (Miller, 2013), integrating Markov switching (Guérin and Marcellino, 2013), estimating multivariate models (Ghysels, Sinko and Valkanov, 2007), using infinite polynomials (Ghysels, Sinko and Valkanov, 2007) or adding low-frequency autoregressive augmentations (Ghysels, Sinko and Valkanov, 2007; Clements and Galvão, 2008; Duarte, 2014). Foroni and Marcellino (2013) provide a comprehensive survey of possible extensions in a recent survey of mixed-frequency models.

### 3. Literature Review

Clements and Galvão (2008) were among the first to study applications of MIDAS regressions to macroeconomic variables. In their paper, they forecast U.S. real quarterly output growth in combination with three different monthly variables: i) industrial production, ii) employment growth, and iii) capacity utilization. They find a slight increase in out-of-sample forecast accuracy with both vintage and revised data compared to two benchmark models, an autoregression and an ADL model in particular, for short-term horizons. They also derive and assess a model with autoregressive dynamics introduced as a common factor shared by the low and the high-frequency lag polynomials. Based on comments by Ghysels, Sinko and Valkanov (2007), they argue that including an autoregressive term in a standard MIDAS model, as in the next equation,

$$y_t = \phi y_{t-1} + \lambda W(L^{1/m}; \gamma) x_t + u_t, \quad (3.1)$$

induces a seasonal response from  $y_t$  to  $x_t$  irrespective of whether  $x_t$  exhibits a seasonal pattern. They suggest further restricting the model by adding a common lag polynomial shared between  $y_t$  and  $x_t$ ,

$$(1 - \phi L)y_t = \lambda(1 - \phi L)W(L^{1/m}; \gamma)x_t + u_t \quad (3.2)$$

so that when writing the model in distributed lag representation, the polynomial in  $L$  cancels out, eliminating the spurious seasonal response. A multi-step generalization of (3.2) for  $h$ -step-ahead forecasts would be

$$(1 - \phi L^h)y_t = \lambda(1 - \phi L^h)W(L^{1/m}; \gamma)x_t + u_t. \quad (3.3)$$

Armesto, Engemann and Owyang (2010) analyze the performance of MIDAS models for the U.S. economy for four different variable combinations: i) quarterly GDP growth and monthly employment growth, ii) monthly CPI inflation and daily Fed funds rate, iii) monthly industrial production growth and a measure of term spread and iv) employment growth and again a measure of term spread. They contrast the results of flat aggregation, the exponential Almon polynomial and a step weight function, but are unable to find a dominant model specification. They provide detailed results for one-step-ahead intra-period forecasting performance of the models, computed by accumulating leads<sup>6</sup> as the high-frequency variable approaches a full low-frequency period. They find an erratic pattern for the root mean square forecast error (RMSFE) of the models as a function of the leads included in the regression. Thus, in a real-time setting, which intra-period forecasts could be the most accurate would not be trivial.

Monteforte and Moretti (2013) develop MIDAS models to forecast the euro area harmonized price index inflation. They put forward a two-step approach involving low and high frequency variables. In the first place, they estimate a generalized dynamic factor model (Forni et al., 2000) for the inflation rate based on a set of variables, and then they extract a common component and separate that into a long-run and a cyclical, or short-run, component. The second step consists in fitting the model of Clements and Galvão (2008) to capture short-term dynamics and use financial time series as high-frequency regressors, in addition to the long-run component

---

<sup>6</sup> In this instance “lead” refers to an observation of the high-frequency predictor that corresponds to the same temporal period of the low frequency variable.

previously estimated as well as other low-frequency variables. They design three MIDAS models, M1, M2 and M3, each with different high frequency regressors: i) M1 includes the short-term interest rate, changes in interest rate spread and oil future prices; ii) M2 uses changes in the wheat price, oil future quotes and the exchange rate; and finally, iii) M3 consists of long-term rates, changes in the interest rate spreads, and changes in the short-term rate. They contrast the out-of-sample performance in terms of RMSFE of these models against the equations for the inflation rate of two different low frequency vector autoregressions, and univariate random walks, autoregressions and autoregressive-moving average models. They compute all the intra-period forecasts for the MIDAS models and the monthly average of these daily forecasts and compare this average to all the low frequency models. All the analysis is conducted for one-month-ahead and two-month-ahead forecasts. They find on average a 20 percent reduction in forecast error dispersion. The authors also provide a final empirical exercise by using forecast combinations with the MIDAS models and the inflation rate implied by financial derivatives, but this approach does not produce any significant gains.

Duarte (2014) discusses in detail the implications of autoregressive augmentations in MIDAS regression models and diverse ways to incorporate them. She explores the out-of-sample performance of MIDAS models with autoregressive augmentations with no restrictions, with an autoregressive augmentation with a common factor restriction, and models with autoregressive augmentations with no restrictions and a multiplicative scheme to aggregation. She then compares these models to the same models but without the autoregressive component, and to two low-frequency benchmark models, a low frequency autoregression and multiple regression model. She computes forecasts for quarterly euro area GDP growth based on three different series: i) industrial production, ii) an economic sentiment indicator and iii) the Dow Jones Euro Stoxx index. She disregards the seasonal spikes impulse responses as the relevant impulse responses, as she argues that it is not possible to single out a particularly relevant impulse response for a mixed-frequency process since responses vary depending on when the shocks occur within the low-frequency process. Although there is no superior model among all tested, Duarte finds once again that there are sizable gains compared to the benchmarks at all horizons.

Breitung and Roling (2015) propose a “nonparametric” MIDAS model to forecast monthly inflation rates using a daily predictor. Instead of imposing any particular polynomial

parameterization, the nonparametric approach consists on enforcing some degree of smoothness to the lag distribution by minimizing a penalized least squares cost function

$$S(\boldsymbol{\theta}) = (\mathbf{y} - \mathbf{X}\boldsymbol{\theta})'(\mathbf{y} - \mathbf{X}\boldsymbol{\theta}) + \eta \boldsymbol{\theta}' \mathbf{D}' \mathbf{D} \boldsymbol{\theta} \quad (3.4)$$

where  $\mathbf{D}$  is a  $(m - 1) \times (m + 1)$  matrix such that

$$\mathbf{D} = \begin{bmatrix} 1 & -2 & 1 & 0 & \cdots & 0 \\ 0 & 1 & -2 & 1 & \cdots & 0 \\ \vdots & \ddots & \ddots & \ddots & \ddots & \vdots \\ 0 & \cdots & \cdots & 1 & -2 & 1 \end{bmatrix}, \quad (3.5)$$

and  $\eta$  is a pre-specified smoothing parameter. They refer to this estimator as the Smoothed Least Squares estimator, and its structure closely resembles the well-known Hodrick-Prescott filter. If  $\eta$  is not known, they suggest solving for the  $\eta$  that minimizes the Akaike Information Criterion. Their target variable is the harmonized index of consumer prices for the euro area and they use a commodity price index as a high frequency regressor. They compare their model with the unconditional mean and the parametric MIDAS model (exponential Almon weights) for two different forecast horizons. They conclude that the commodity index paired with the nonparametric MIDAS results in reasonably good one-month-ahead forecasts. Additionally, the authors conduct a Monte Carlo experiment and compare their model to four parametric MIDAS alternatives: i) the exponential Almon polynomial, ii) a hump shaped function, iii) a declining linear function, and iv) a sinusoidal function. They find that the nonparametric method performs on par with the parametric competitors.

## 4. Data, Exercise, and Results

The out-of-sample predictive performance of an online price index will be analyzed to forecast the core inflation rate in real-time. To be more specific, this will be assessed using many different MIDAS specifications discussed in the previous sections, and these estimations will be compared with benchmark single frequency naïve models and estimators. MIDAS regressions turn out to be intuitive for this purpose since the monthly inflation rate can be approximately decomposed as the aggregation of daily inflation rates of the corresponding month, when evaluated in logarithmic differences,  $\pi_t^m \approx \sum_{\tau \in t} (\log p_\tau^d - \log p_{\tau-1}^d)$ . Atkeson and Ohanian (2001), Stock and Watson (2007) and Faust and Wright (2009) have shown that simple benchmarks are not easily beaten by

more sophisticated models (at least in the case of the U.S. economy), so these could serve as a good starting point to gauge the predictive power of the daily series.

#### **4.1. Data**

The online price index is compiled by the company PriceStats in cooperation with State Street Global Markets, a leading financial research corporation. PriceStats is a spin-off company that emerged from the Billion Prices Project at MIT, founded by professors Alberto Cavallo and Roberto Rigobón. It is the first company, institution, or organization to apply a big data approach to produce real-time (daily) price indexes to track general price inflation and other related metrics. Essentially, they collect daily data of prices from online retailers by “web scraping” (i.e., recording price information contained inside specific HyperText Markup Language tags in the retailers' websites) and aggregate the data by replicating the methodology of a traditional consumer price index, as is done by National Statistics Offices with offline prices. Cavallo (2013) goes through the methodology and provides comparisons between online and offline price indexes for Argentina, Brazil, Chile, Colombia, and Venezuela. He concludes that online price indexes can track the dynamic behavior of inflation rates over time fairly well, with the exception of Argentina. In fact, the construction of online price indexes was initially motivated by the desire to provide the public with an alternate measure of the inflation rate in Argentina because, that from the years 2007 to 2015, there were large discrepancies between the official price indexes compiled by the National Institute of Statistics and Census (INDEC) and price indexes compiled by provincial statistics offices or those compiled by private consultants. Throughout the rest of the paper, this price index will be referred to as the State Street PriceStats Index (SSPS). Data for Argentina are available from November 1, 2007 with a three-day publication lag.

A provincial price index that raised itself to prominence in recent years is the consumer price index compiled by the General Department of Statistics and Censuses of the Government of the Autonomous City of Buenos Aires, known as IPCBA. Although this index only takes into account the territory of the City of Buenos Aires (with a population close to 3 million), it should be reasonable to expect that price dynamics in the Buenos Aires Metropolitan Area (which encompasses a much larger population, close to 14 million or 1/3 of the total population of Argentina) share most of its features with the pricing structure of the City Buenos Aires, resulting from arbitrage by reason of geographical proximity, as this should prevent large distortions, at

least in nonregulated markets. A more restricted version of the index is also published, called “resto IPCBA” (rIPCBA), which serves as a measure of core inflation. Compared to the headline version, it excludes products with strong seasonal patterns and regulated prices (e.g., public utility services) and represents 78.15% of the headline index. rIPCBA is available from July 2012 onward and is released monthly, with approximately a two-week publication lag.

These two indexes, as well as other provincial, private and public price indexes are closely monitored by monetary authorities as well as the general public; this is particularly true of INDEC’s recently introduced National Consumer Price Index. As the name implies, this is the only index with full national coverage. However, this index so far consists of less than two years of data points and this limits the possibility of drawing any relevant inferences.

Inflation in Argentina in recent years has been high, unstable and volatile, particularly from 2012 to most of 2016 when Argentina experienced high monetization of fiscal deficits, strict capital controls and two major devaluations of the currency.<sup>7</sup> The average monthly inflation rate has been fluctuating around 2.2 percent for rIPCBA and 2.1 percent for the monthly aggregated SSPS series, with coefficients of variation at 35 percent and 49 percent, respectively. This should pose a significant challenge for economists’ ability to formulate accurate forecasts. Figure 1 illustrates the comparison between these two indexes and provides a quick glimpse at the potential predictive power of the high-frequency index. Overall and for the scope of this work, rIPCBA is available from July 2012 to December 2017 (66 data points), while SSPS ranges from November 1, 2007 to December 31, 2017 (3,714 data points).

---

<sup>7</sup> The last one coinciding with the lifting of the majority of the capital controls in December 2015 and a subsequent transition to a flexible exchange rate regime and inflation targeting.

**Figure 1. Comparison between rIPCBA Inflation and SPSS Inflation  
Aggregated at Monthly Frequency**

#### **4.2. Forecasting Exercise**

The MIDAS specifications tested were the MIDAS-DL, the unrestricted autoregressive MIDAS-DL (MIDAS-ADL), and the autoregressive MIDAS-DL with the common factor restriction (MIDAS-ADL-CF). All MIDAS specifications were evaluated with several high-frequency regressors equal to  $m \times L_X$ ,<sup>8</sup> with  $L_X \in \{1, 2, 3\}$ , and forecasts were computed for horizons  $h \in \{1, 2, 3\}$  over a 36-observation evaluation sample, spanning from January 2015 to December 2017, and an 18-observation subsample from July 2016 to December 2017 (a period with a more stable inflation rate), using recursive (expanding) windows. MIDAS-ADL-CF models included quadratic and cubic variations of the standard Almon polynomial and the exponential version, as well as the Beta probability density function. MIDAS-ADL models further added flat aggregation (equal

<sup>8</sup> First order MIDAS-ADL-CF models include  $m \times [L_X + \min(L_X, h)]$  high-frequency regressors since the common factor restriction increases the number of variates depending on the forecast horizon and the number of high-frequency lags.

weights); and finally, MIDAS-DL models added the nonparametric (NP) model described in Section 3. Forecast combinations of the various MIDAS models with equal weights were also considered. In addition, all these models were compared to two benchmarks: i) the low-frequency unconditional mean and ii) a low-frequency first order autoregression.<sup>9</sup>

In a first stage, the models were estimated with a balanced dataset. In other words, there is exact frequency matching:  $m$  daily observations from the same month or  $L_X$  groups of  $m$  daily observations from the same months correspond to a specific low-frequency monthly observation of the dependent variable. In total, two sets of RMSFE were computed, one corresponding to the large sample and the other to a reduced subsample. For all forecast horizons,  $d$  was set to  $d = -1$ .

A second stage involved estimating intra-period forecasts for the best selected  $L_X$  for each forecast horizon based on the results from the large sample of the first stage and briefly analyzing the stability of the forecasts as more recent information is incorporated in the models. When intra-period forecasts were computed,  $d$  is a fraction in the interval  $[-1, 0)$ . More specifically,  $d = -1 + i/m$  for  $i$  in  $1, \dots, m$ , where  $m$  is the frequency. Forecasts from the autoregression and the unconditional mean remained the same throughout the month.

To account for the fact that SSPS is an irregularly spaced series, the frequency was assumed fixed at  $m = 28$ , and so days 29, 30 and 31 of each month are discarded. Daily inflation rates were first computed with the full dataset and then the observations beyond day 28 of each month were discarded.

Estimation was conducted in **R** with the **midasr** package developed by Ghysels, Kvedaras and Zemlys (2016), while optimization was performed with three routines included in **optimx**<sup>10</sup> for nonlinear models or with the **lm** function from the **stats** package for linear ones. Models that require **optimx** were solved simultaneously with three optimization routines (**ucminf**, **nlminb** and **Nelder-Mead**) for each model, forecast horizon  $h$ , number of high-frequency regressors  $L_X$ , and out-of-sample period. Only the best solution was kept. The algorithm was initialized taking the hypothesis of equal weights and a null impact parameter as starting conditions. This strategy delivered reasonable results empirically and serves as a check on whether the high-frequency regressors are actually relevant.

---

<sup>9</sup> A detailed list of the models can be found in Appendix A.

<sup>10</sup> A comprehensive description about this package can be found in Nash and Varadhan (2011).

### 4.3. Empirical Results

Tables 1 and 2 summarize the main results of the first stage. In general, for  $h = 1$  (nowcasts), larger values of  $L_X$  produce better results, while this tends to reverse when forecasting further into the future, i.e.,  $h = 3$ . For  $h = 2$ , the results are ambiguous and indicate that  $L_X = 2$  or  $L_X = 3$  perform best. All three classes of MIDAS models exhibit similar performance irrespective of the inclusion of the autoregressive term or how it is incorporated. For all  $h$ , most MIDAS models for at least some  $L_X$  are able to produce a small gain at around 10 percent when compared to the autoregression and a larger 25 percent compared to the unconditional mean.<sup>11</sup> The smaller sample greatly amplifies these results. Note that for each  $h$  there is a flat aggregation model that performed very well—and even better at times than standard MIDAS models—but overall there is not a single MIDAS model that systematically outperforms the rest. The forecast combination tested does not seem to improve on any particular MIDAS model.

Figures 2-4 condense the main findings of the second stage. Forecasts for  $h = 1$  display a clear trend towards better accuracy as the high frequency variable reaches a full low frequency period. In day 1 to day 28 point-to-point comparison, the RMSFE is reduced by approximately 20 percent and particularly, in the second half of the month, the models start to surpass the accuracy of the autoregression by up to 15 for some days. The improved performance, when evaluated in the subsample, suggests that it is possible to obtain even better results as the inflation rate stabilizes. Similar behavior, although less evident, is observed for forecasts for period  $h = 3$  in the case of MIDAS-DL models. Forecasts for horizon  $h = 2$  display a rather erratic pattern, excepting the flat aggregation MIDAS-DL and MIDAS-ADL models.

Figure 5 zooms in on the evolution of all intra-period forecasts for selected models, either  $h = 1$ ,  $h = 2$  or  $h = 3$ . Despite the intra-period forecasts evidencing some volatility within the month, this does not seem to be a major concern as inflation stabilizes at the end of the sample. Additionally, note that forecasting further into the future yields a dynamic closer to the unconditional mean of the whole process. In the future, these results could be used as a training sample from which to compute inverse mean square error weights and perform forecast combinations, which could prove to be effective in mitigating intra-period forecast volatility.

---

<sup>11</sup> Tables with RMSFE ratios are presented in Appendix B.

Although the results look promising, they should be interpreted with caution. The predictive ability of the models was tested with the methodology by Giacomini and White (2006),<sup>12</sup> and both the unconditional and conditional versions of the test were examined. The MIDAS models were evaluated against the two naïve benchmarks, modeling the difference in forecast accuracy as a constant (unconditional) and also as a first order autoregression (conditional). The results do not indicate that the difference in forecast accuracy is significant (at 0.05) for most MIDAS models. However, since the “large” out-of-sample evaluation set actually constitutes a small sample by literature standards, the result of the tests cannot be taken as final. As more observations become available, the tests could be updated with a larger sample to arrive at a more robust conclusion.

---

<sup>12</sup> This is similar to the standard test by Diebold and Mariano (1995). The key difference lies in that the estimation sample size is kept fixed instead of ever expanding, as this allows to better incorporate estimation uncertainty and to compare nested models.

## 5. Conclusion

For some particular MIDAS specifications, there is a slight improvement compared to the low-frequency benchmark autoregression and the unconditional mean. In principle, this would imply that high-frequency online price indices have good potential to forecast future behavior of consumer inflation for immediate horizons in Argentina, but these results are still not robust. This could serve as a useful complementary tool to assess the out-of-sample performance of perhaps more sophisticated models. Future research could focus on building an alternative variable such as a daily financial factor as suggested by Monteforte and Moretti (2013) or comparing with measures of market expectations in order to further validate the findings of this paper.

## Appendix A. MIDAS Specifications

The full set of specifications of the models is detailed below. All models were estimated with  $L_X \in \{1,2,3\}$ ,  $h \in \{1,2,3\}$  and  $d$  as explained in Subsection 4.2. The subscript  $(d, h)$  on parameter estimates denoting dependence on  $d$  and  $h$  has been suppressed for simplicity.

### MIDAS-DL:

$$\hat{\pi}_{T+h}^{rIPCBA} = \hat{\alpha} + \hat{\lambda} \sum_{j=0}^{m \times L_X - 1} \left( \sum_{s=1}^2 \hat{\gamma}_s j^s \right) \pi_{T-d-j/m}^{SSPS} \quad (A.1)$$

$$\hat{\pi}_{T+h}^{rIPCBA} = \hat{\alpha} + \hat{\lambda} \sum_{j=0}^{m \times L_X - 1} \left( \sum_{s=1}^3 \hat{\gamma}_s j^s \right) \pi_{T-d-j/m}^{SSPS} \quad (A.2)$$

$$\hat{\pi}_{T+h}^{rIPCBA} = \hat{\alpha} + \hat{\lambda} \sum_{j=0}^{m \times L_X - 1} \left( \frac{e^{\sum_{s=1}^2 \hat{\gamma}_s j^s}}{\sum_{j=0}^{m \times L_X - 1} e^{\sum_{s=1}^2 \hat{\gamma}_s j^s}} \right) \pi_{T-d-j/m}^{SSPS} \quad (A.3)$$

$$\hat{\pi}_{T+h}^{rIPCBA} = \hat{\alpha} + \hat{\lambda} \sum_{j=0}^{m \times L_X - 1} \left( \frac{e^{\sum_{s=1}^3 \hat{\gamma}_s j^s}}{\sum_{j=0}^{m \times L_X - 1} e^{\sum_{s=1}^3 \hat{\gamma}_s j^s}} \right) \pi_{T-d-j/m}^{SSPS} \quad (A.4)$$

*Notes:* The evaluation sample comprises 18 data points, from July 2016 to December 2017. Characters in **bold** indicate the best number of variables, *L<sub>X</sub>*, for each model and forecast horizon, *h*. Characters in *italics* indicate the best model for each number of variables, *L<sub>X</sub>*, and forecast horizon, *h*.
