Abstract

We examine the effect of finance on long-term economic growth using Bayesian model averaging to address model uncertainty in cross-country growth regressions. The literature largely focuses on financial indicators that assess the financial depth of banks and stock markets. We examine these indicators jointly with newly developed indicators that assess the stability and efficiency of financial markets. Once we subject the finance-growth regressions to model uncertainty, our results suggest that commonly used indicators of financial development are not robustly related to long-term growth. However, the findings from our global sample indicate that one newly developed indicator – the efficiency of financial intermediaries – is robustly related to long-term growth.

1 Introduction

Numerous studies investigate the effect of financial development on economic growth and predominantly conclude that there is a positive causal relationship between the two (King and Levine, 1993; Levine and Zervos, 1998; Atje and Jovanovic, 1993). Nevertheless, some opposing views hold that the financial sector removes scarce resources from the rest of the economy (Tobin, 1984; Bolton et al., 2011) and encourages to greater exposure and vulnerability to crises, thus severely burdening the real sector during periods of instability (Kindelberger, 1978; Minsky, 1991; Stiglitz, 2000). The effect of financial development on growth has recently drawn greater attention again because of the financial crisis that began in 2007-2008. Moreover, conclusions referring to diminishing and eventually negative returns from financial development have become increasingly common in the literature (Arcand et al., 2012; Cecchetti and Kharroubi, 2012; Law and Singh, 2014). This highlights the importance of the financial sector for the functioning of the economy and has provoked extensive debate among policymakers.

This paper evaluates the finance-growth nexus but differs from previous research in two main respects. First, it employs Bayesian model averaging (BMA) to overcome certain drawbacks of previous research approaches. BMA is well grounded in statistical theory (Raftery et al., 1997) and addresses the inherent regression model uncertainty, which is quite high in cross-country growth regressions (Fernandez et al., 2001; Sala-I-Martin et al., 2004; Durlauf et al., 2008). The control variables in finance-growth regressions are often selected in a somewhat *ad hoc* manner with reference to certain relevant theories while ignoring other relevant theories.

BMA essentially allows us to control for dozens of potentially relevant determinants of growth within a unifying framework. The variety of theories of economic growth has given rise to a large number of determinants and resulted in substantial uncertainty concerning the true growth model. In essence, the BMA procedure estimates different combinations of explanatory variables and subsequently weights the coefficients using various measures of model fit. As a consequence, BMA also conveniently limits concerns regarding omitted variable bias and its adverse consequences of inconsistently estimated coefficients, an issue that is typically abstracted from in the empirical work on finance and growth. BMA is capable of evaluating numerous possible regressors and estimating their posterior inclusion probability (PIP), i.e., the probability that they are relevant in explaining the dependent variable, in addition to the weighted mean and variance of their corresponding coefficients. While model averaging has become standard in the empirical growth literature (Sala-I-Martin et al., 2004; Durlauf et al., 2008), it has not been applied to study the finance-growth nexus.

Second, we differ from previous research by examining additional financial indicators to appreciate the multidimensionality of financial systems. Importantly, previous research, including recent studies implying that excessive financial development harms growth (Arcand et al., 2012; Cecchetti and Kharroubi, 2012; Law and Singh, 2014), largely focuses on measures of the depth of financial development such as the credit to GDP ratio. We differ from previous research in jointly examining whether the depth, stability or efficiency of financial markets (or all of them) is crucial for long-term growth. In so doing, we can unify and re-examine previous studies on

the finance-growth nexus that show that a) financial development is conducive to growth, b) excessive financial development is not, and c) financial instability has negative consequences for growth.

The theoretical concepts regarding the functions of the financial industry are difficult to operationalize in empirical research, and there is no universal consensus regarding the measurement of financial development (King and Levine, 1993). Although measuring financial development is complex, researchers typically consider only those variables capturing financial depth, such as the credit to GDP ratio or stock market capitalization, to assess the degree of financial development. Financial indicators assessing the degree of financial access, financial stability or the efficiency of the financial industry have largely been ignored in cross-country studies due to data limitations. The newly developed Global Financial Development Database (GFDD) represents a significant improvement in this respect and provides a comprehensive set of financial indicators that reflect various functions and characteristics of the financial sector. In addition to financial depth, the GFDD provides measures of the efficiency and stability of and access to financial markets. Although data availability remains somewhat limited, we extend the existing literature by including these additional dimensions of the financial sector in our regression analysis to more completely evaluate the effect of finance on growth. Specifically, the indicators we use represent the depth, stability, and efficiency of the banking sector and stock markets as defined by Cihak et al. (2013). In addition to the GFDD, we employ the widely used dataset on the determinants of long-term growth developed by Fernandez et al. (2001), which encompasses over 40 explanatory variables capturing various economic, political, geographical, and institutional indicators.

While it is commonly assumed that causality goes from financial development to economic growth, some scholars argue that a growing financial sector merely follows the increasing needs of the real economy or may be determined simultaneously with growth due to other factors. The quantitative survey of the finance and growth literature by Valickova et al. (2015), for example, indicates that those studies ignoring endogeneity are more likely to report a stronger positive effect of financial development on growth. Therefore, we examine the robustness of our results through specifications that account for endogeneity. Specifically, we use the two stage least squares (2SLS) estimation combined with BMA introduced by Durlauf et al. (2008). To the best of our knowledge, this is the first study to combine various characteristics of the financial sector, a rich dataset on growth, and an approach that addresses model uncertainty and endogeneity.

Using data on real economic growth in 68 countries between 1960 and 2011, we find that bank efficiency is robustly related to long-term growth and exhibits very high PIP. The relevance of traditional variables, such as credit provided to the private sector or stock market capitalization, is weaker. This result is robust to a series of checks such as employing a different sample period or addressing endogeneity. Therefore, our results highlight that the approach to measuring financial development is crucial for the estimated effect of finance on growth. Our policy implication is that those managing the current worldwide wave of regulatory changes

in the financial industry should not underestimate the importance of the efficiency of financial intermediaries for long-term growth.

This paper is structured as follows. Section 2 provides a literature review on finance and growth. Section 3 presents the data. We describe Bayesian model averaging in section 4. We provide the regression results in section 5. The conclusions are presented in section 6. An appendix with additional results follows.

2 Empirical Literature on Finance and Growth

We briefly survey the empirical literature on the effect of financial development on growth. In addition, we discuss certain issues regarding the measurement of financial development. We refer readers to Levine (2005), Ang (2008) and Valickova et al. (2015) for more comprehensive surveys of this literature.

2.1 Empirical Evidence

Focusing on the period between 1960 and 1989, King and Levine (1993) show how the initial levels of various financial indicators, such as the liabilities to the financial sector, bank ratios, credit to nonfinancial private sector/total domestic credit, and credit to the private sector to GDP, explain the real growth of GDP per capita, capital accumulation, and efficiency of capital utilization in the following period. Atje and Jovanovic (1993) examine the stock market's effects on economic growth and find that more active stock markets induce growth. The conclusion regarding stock market activity is subsequently confirmed by Levine and Zervos (1998). In addition to providing evidence on stock market effects, Levine and Zervos (1998) simultaneously control for banking sector development by including credit to the private sector. Interestingly, both the banking sector and stock markets are significant in fostering growth. This leads the authors to conclude that each of the sectors has a different function in the economy and a different financial function. Furthermore, they add that the mere size of the stock market as measured by total capitalization is irrelevant to growth and that the relevant factor is the activity of the stock market. Nevertheless, this link may be an outcome of an unobserved third factor that stimulates both trading activity and economic growth. For instance, information regarding new technology may spur trading activity due to conflicting opinions on the future benefits of the innovation. The subsequent economic growth is a result of technological advancement rather than greater trading volumes (Levine, 2005).

Rajan and Zingales (1998) initiate the research on the finance-growth nexus using industry-level data. They show that more developed financial markets decrease firms' cost of external capital. They also find evidence that industries that are relatively more dependent on external finance grow faster in countries with better developed financial intermediaries. Building on this methodology, Claessens and Laeven (2005) arrive at a similar conclusion using measures of bank competitiveness. They find that more competitive banking systems benefit financially dependent industries. Next, Beck et al. (2005) show that industries typically composed of small

firms enjoy relatively superior growth rates in countries with developed financial sectors. This is consistent with theory positing that financial development is a crucial factor in alleviating financial constraints. Also, Hasan et al. (2009) examine the effect of financial development on regional growth in Europe and find that the efficiency of financial intermediaries (measured by bank efficiency) is substantially more important for growth than financial depth (measured by outstanding credit). Berger et al. (2004) also provide international evidence on the importance of bank efficiency for growth. Similarly, using German data, Koetter and Wedow (2010) find that bank efficiency is positively related to growth. Jayaratne and Strahan (1996) report that the relaxation of bank branch restrictions in the United States improves growth. Interestingly, they find that the relaxation of restrictions does not increase the volume of bank lending but improves loan quality. In addition, Cetorelli and Strahan (2006) extensively examine the mechanism how financial development affect growth and find that more competition among local U.S. banks improves firms' performance.

Panel and time-series analyses predominantly argue that the relationship goes from financial development to growth rather than in the reverse direction, essentially moderating endogeneity concerns. Christopoulos and Tsionas (2004), Fink et al. (2003) and Peia and Roszbach (2015) observe positive long-run growth effects of financial development using cointegration techniques. Christopoulos and Tsionas (2004) argues in favor of long-run causality from financial development to growth and dismisses the backward channel. Fink et al. (2003) is one of the few papers investigating the relationship by considering private bond markets. Peia and Roszbach (2015) investigate the causality of the finance-growth relationship and demonstrate that the causality depends on the measurement employed and the level of financial development. Recently, Thumrongvit et al. (2013) revisit the question and compare the impact of bond markets while also accounting for the role of the banking sector. They report that the importance of bank credit in determining growth declines as alternative debt financing options become increasingly available. Although studies positing "finance-lead" growth prevail, there are opposing views that stress finance's irrelevance in this respect. Garretsen et al. (2004), for example, document that the causal link reported by Rajan and Zingales (1998) disappears after accounting for societal and legal factors. It may be that the development of financial markets simply follows growth, reflecting the needs of a more developed economy. Ultimately, accounting for time- and country-specific effects does not entirely eliminate the caveats applicable to such analyses. Time coverage is often short, and utilizing more frequent observations, such as quarterly data, does not properly address hypotheses concerning the long-term nature of the relationship (Ang, 2008).

Researchers have devoted greater attention to the finance and growth literature of late following the economic crisis of 2007-2008. They raise questions regarding possible non-linearities in the relationship between finance and growth, specifically, whether excessive financial development is harmful to growth. Rousseau and Wachtel (2011) report that a positive correlation between the development of the financial sector and economic growth is typical for the period before 1990. The effect diminishes when subsequent years are considered. Additional studies

report evidence of an inverted U-shaped relationship suggesting financial development is conducive to growth only up to a certain threshold. Thereafter, it acts as a drag on economic growth (Cecchetti and Kharroubi, 2012; Arcand et al., 2012; Law and Singh, 2014). Some research advances explanations to justify these findings. One is the comparatively large amount of credit going to households in the later stages of financial development. These loans generally tend to be less productive than loans to enterprises (Beck et al., 2012). Cecchetti and Kharroubi (2013) emphasize that a larger financial sector leads to lower total factor productivity through relatively larger benefits for high-collateral/low-productivity projects, primarily in construction. Other lines of reasoning rely on Tobin’s early work discussing how finance lures talent from other sectors (Bolton et al., 2011; Cecchetti and Kharroubi, 2012; Kneer, 2013). Yilmazkuday (2011) shows that growth enhancing effect of finance depends on a number of factors such as price stability, economic development or trade openness. Overall, these recent empirical studies find that the growth-enhancing effects of financial development are not guaranteed and suggest that the relationship is more complex than originally thought.

2.2 Measurement of Financial Development

Levine (2005) argues that it is difficult to link empirical and theoretical research on finance and growth. Concepts such as information asymmetry, improved corporate governance, risk management, pooling savings, and easing exchange are in reality difficult to measure accurately. The most common indicators of financial development address financial depth, primarily because of their widespread availability. Conventional variables used as proxies for the depth of the financial sector are total liquid liabilities of the financial sector, credit to the private sector, and various measures of monetary aggregates. The aforementioned variables depict the development of the banking sector, in stock market studies, broadly employed proxies include the ratio of total market capitalization to GDP, the total value traded to GDP (stock market activity ratio), and the total value traded to the total value of listed shares (turnover ratio). The extent to which these traditional measurements reflect the ability of financial intermediaries to serve the functions assigned to them in theory remains unclear. For instance, Cihak et al. (2013) illustrate that private bond market capitalization represents a substantial share of the total securities market capitalization within a country. However, when addressing the question of depth, private bond markets are often ignored. In addition, total credit data do not include trade credit, where firms *de facto* act as financial intermediaries (Petersen and Rajan, 1997). In addition, Levine (2005) notes that this factor may be particularly important in countries with poor legal environments or overly regulated financial systems. Ultimately, there is no general consensus among researchers regarding the appropriate approach to measure financial development. Generally, studies consider several potential indicators to assess the robustness of their results, but these indicators are typically only proxies for the level of financial depth (Valickova et al., 2015).

3 Data

We use the dataset from a seminal paper on long-term economic growth determinants and BMA by Fernandez et al. (2001). The dataset contains 41 explanatory variables that might be important for growth in 72 countries. We update the dependent variable (average real economic growth per capita in 1960-2011). The regressors in the dataset comprise various measures of economic, political, geographic, demographic, social, and cultural factors. As many of these factors may be determined simultaneously with growth, the regressors typically come from 1960 or even before to alleviate endogeneity concerns. We describe this dataset in greater detail in the appendix.

To this dataset, we add selected financial indicators from the World Bank’s GFDD, which collects information on various aspects of financial sectors around the globe. Cihak et al. (2013) describe this dataset’s content in detail and offer a 4x2 dimensional classification of financial indicators that reflects their utility in representing the depth, breadth, efficiency, and stability (4) of both the banking sector and the stock market (2). We choose to employ several indicators for which the database provides the richest data. Specifically, we select five different indicators representing various aspects of the financial system:

- **Private sector credit to GDP:** domestic private credit to the real sector to GDP; a measure of the depth of the banking sector.
- **Stock market capitalization to GDP:** value of listed shares to GDP; a measure of the depth of stock markets.
- **Net interest margin:** accounting value of banks’ net interest revenue as a share of average interest-bearing assets; a measure of the efficiency of the banking sector.
- **Stock market turnover ratio:** stock market value traded to total market capitalization; a measure of the efficiency of stock markets.
- **Bank Z-score:** return on banks’ assets plus the ratio of banks’ equity and assets, divided by the standard deviation of the return on assets $\left(\frac{ROA + \frac{equity}{assets}}{sd(ROA)} \right)$; a measure of the stability of the banking sector.

The aforementioned dimensional distinction allows us to differentiate and compare the effects of the banking sector and the stock market on economic growth. In addition, unlike the previous literature, we examine whether the depth, efficiency and stability of a financial system are important for growth.

The time and cross-country coverage of financial variables varies. Private credit to the real sector is available for the majority of the countries in the dataset since 1960. However, the remaining variables are typically available only from the 1980s onward. We average the indicator values corresponding to a selected period (i.e., 1960-2011) and to their data availability. This is a standard procedure in estimating empirical long-term growth models, despite the risk

of introducing endogeneity into the model and information loss introduced by averaging over extended time periods. The benefit of averaging is a focus on long-term trends while abstracting from short-term fluctuations. Given the data availability and the construction of the dataset, all the financial variables could be endogenous. We address endogeneity concerns through our BMA approach. Table 1 presents descriptive statistics on the individual financial indicators.

Table 1: Descriptive statistics, financial indicators

	Min	Max	Mean	Std.dev
Net interest margin	0.59	13.31	4.52	3.25
Bank Z-score	-1.61	42.35	15.00	9.62
Private credit	5.16	146.66	46.58	35.29
Market capitalization	0.67	303.77	51.28	52.98
Market turnover	0.96	197.50	48.22	47.13

4 Bayesian Model Averaging

To illustrate the application of BMA, we begin with a traditional linear model structure:

$$y = \alpha + X\beta + \varepsilon \quad \varepsilon \sim N(0, \sigma^2 I) \quad (1)$$

where y is a dependent variable, α is a constant, X is the matrix of explanatory variables, β represents the corresponding coefficients, and ε is a vector of normally distributed IID error terms with variance σ^2 . In many applications, the list of potentially relevant regressors can be large. In the typical case in which the true regression model is unknown, its construction often begins by including all the variables in the model. However, this strategy is likely to yield imprecise estimates, as the large number of regressors inflates standard errors. Empirical research typically addresses this issue by sequentially eliminating the least significant explanatory variables on the basis of statistical tests to arrive at the single best model with all the irrelevant regressors omitted.

The process described above entails the risk of the researcher retaining an irrelevant variable or dropping an important variable. Koop (2003) emphasizes that the probability of making such mistakes increases rapidly with the number of sequences performed. The various iteration paths may also lead to different regression model specifications. In addition, even if we assume that this procedure identifies the “best” model, it is rarely acceptable to present only the results from the single “best” model and disregard the results of “second-best” models. In summary, then, this model-selection approach ignores the model uncertainty that the researcher faces when she or he defines the model. BMA allows the researcher to account for such uncertainty and presents a rigorous method for treating multiple models.

BMA considers all possible combinations of X from equation 1 and takes a weighted average of the coefficients (see also the remarks on the MCMC sampler below). The substructure of the

model can be captured as follows:

$$y = \alpha_i + X_i\beta_i + \varepsilon \quad \varepsilon \sim N(0, \sigma^2 I) \quad (2)$$

Here, X_i is a subset of X and α_i and β_i are the corresponding coefficients. Assuming that the total number of possible explanatory variables is K , the total number of models is equal to 2^K and $i \in [1, 2^K]$.

Researchers are interested in describing coefficients based on observed data. It follows from Bayes' rule that

$$p(\beta|y, X) = \frac{p(y, X|\beta)p(\beta)}{p(y, X)} \quad (3)$$

where $p(\beta|y, X)$ is the posterior density, $p(y, X|\beta)$ is the marginal likelihood (ML), also known as the data generating process, $p(\beta)$ is the prior density, and $p(y, X)$ is the probability of the data. In the BMA, we essentially compare numerous different models $M_1, \dots, M_i$. Assuming K possible regressors as discussed above, we have $M_1, \dots, M_i$, where $i \in [1, 2^K]$. Given the Bayesian logic whereby we formally define the model using a likelihood function and a prior density, M_i depends on the parameters β_i , and their posterior probability can be derived as follows:

$$p(\beta_i|M_i, y, X) = \frac{p(y|\beta_i, M_i, X)p(\beta_i|M_i)}{p(y|M_i, X)} \quad (4)$$

The following subsections describe the averaging principle of BMA and individual components of equation 3.

4.1 Posterior Model Probability

The posterior model probability (PMP) is fundamental to the BMA framework, as it provides the weights for averaging model coefficients across submodels. PMP also arises from Bayes' theorem:

$$p(M_i|y, X) = \frac{p(y|M_i, X)p(M_i)}{p(y|X)} \quad (5)$$

where $p(y|X, M_i)$ is the marginal likelihood (ML) of the model (i.e., the probability of the data given the model M_i), $p(M_i)$ is the prior model probability, and $p(y|X)$ is the integrated likelihood. The term in the denominator is typically disregarded, as it is constant across all models under consideration. The PMP is then directly proportional to ML and the prior probability. A popular practice is to set the prior probability $p(M_i \propto 1)$ to reflect the lack of knowledge regarding the true model.

$$p(M_i|y, X) \propto p(y|M_i, X)p(M_i) \quad (6)$$

We discuss the calculation of ML in detail in section 4.4. The model prior needs to be elicited by the researcher and reflects the initial beliefs before inspecting the data.

4.2 Posterior Mean

Point estimates of the model parameters are often the focus of research, and it is possible to derive them within the Bayesian framework. Zeugner (2011) and Moral-Benito (2012) assert that the weighted posterior distribution of any statistic (most notably the β coefficients) is obtained using the following:

$$p(\beta|y, X) = \sum_{i=1}^{2^K} p(\beta_i|M_i, y, X)p(M_i|y, X) \quad (7)$$

where $p(M_i|y, X)$ is the PMP of the corresponding model M_i from equation 5. The point estimates can be acquired by taking expectations across the equation:

$$E(\beta|y, X) = \sum_{i=1}^{2^K} E(\beta_i|M_i, y, X)p(M_i|y, X) \quad (8)$$

Here, $E(\beta|y, X)$ is the averaged coefficient and $E(\beta|M_i, y, X)$ is the estimate of the β_i coefficients from model M_i . The posterior distribution of the coefficients is dependent on the choice of the prior g . Zeugner (2011) expresses the expected value of the parameter in M_i as follows:

$$E(\beta_i|y, X, g, M_i) = \frac{g}{1+g}\hat{\beta}_i \quad (9)$$

with $\hat{\beta}_i$ representing the standard OLS estimate.

4.3 Posterior Variance

Moral-Benito (2012) presents a formula for variance corresponding to the expected values of coefficients derived in the previous section:

$$\begin{aligned} Var(\beta|y, X) = & \sum_{i=1}^{2^K} p(M_i|y, X)Var(\beta_i|M_i, y, X) + \\ & + \sum_{i=1}^{2^K} p(M_i|y, X)(E(\beta_i|M_i, y, X) - E(\beta|y, X))^2 \end{aligned} \quad (10)$$

The variance consists of the weighted average of variance estimates across different regression models $Var(\beta_i|M_i, y, X)$ and the weighted variance across different models captured in the second component $E(\beta_i|M_i, y, X) - E(\beta|y, X))^2$. $E(\beta|y, X)$ is the posterior mean from equation 8. As a consequence, this may result in uncertainty regarding the parameter estimates due to the substantial differences across models even if the estimates of individual models are highly precise. Zeugner (2011) shows how the value of the prior g affects the posterior variance of the parameters:

$$Cov(\beta_i|y, X, g, M_i) = \frac{(y - \bar{y})'(y - \bar{y})}{N - 3} \frac{g}{1 + g} \left(1 - \frac{g}{1 + g} R_i^2 \right) (X_i' X_i)^{-1} \quad (11)$$

where $\bar{y}$ is the mean of vector y , N is the sample size and R_i^2 is the R-squared of model i .

4.4 Marginal Likelihood

ML can be calculated using equation 4 for each M_i . We need to integrate both sides of the equation with respect to β_i , employ $\int_{\beta} p(\beta_i|M_i, y, X) d\beta_i = 1$, and rearrange to arrive at

$$p(y|M_i, X) = \int_{\beta} p(y|\beta_i, M_i, X) p(\beta_i|M_i, X) d\beta_i \quad (12)$$

The above equation illustrates the general textbook derivation, but the computation depends on the elicited priors. Zeugner (2011) employs the "Zellner's g prior" structure, which we utilize in this paper. The ML for a single model can then be expressed using the prior as in Feldkircher and Zeugner (2009):

$$p(y|M_i, X, g) = \int_0^{\infty} \int_{\beta} p(y|\beta_i, \sigma^2, M_i) p(\beta_i, \sigma^2|g) d\beta d\sigma \quad (13)$$

Furthermore, the authors assert that ML is in this case simply proportional to

$$p(y|M_i, X, g) \propto (y - \bar{y})'(y - \bar{y})^{-\frac{N-1}{2}} (1 + g)^{-\frac{k_i}{2}} \left(1 - \frac{g}{1 + g} R_i^2 \right)^{-\frac{N-1}{2}} \quad (14)$$

In this equation, R_i^2 is the R-squared of model M_i , and k_i is the number of explanatory variables in model i introduced to include a size penalty for the model. N and $\bar{y}$ are the same as in Equation 11, the number of observations and the mean of vector y , respectively.

4.5 Posterior Inclusion Probability

The standard BMA framework reports the PIP, which reflects the probability that a particular regressor is included in the "true" model. PIP is the sum of the PMPs of the models including the variable k in question:

$$PIP = p(\beta_k \neq 0|y, X) = \sum_{i=1}^{2^K} p(M_i|\beta_k \neq 0, y, X) \quad (15)$$

4.6 Conditional Posterior Positivity

An interesting feature of the parameter posterior is its sign (Koop, 2003). Conditional on the inclusion of the regressor in the model, its positivity is calculated as follows:

$$p(\beta_k \geq 0|y, X) = \sum_{i=1}^{2^K} p(\beta_{i_k}|M_i, y, X) p(M_i|y, X), \quad (16)$$

where values of conditional positivity close to 1 indicate that the parameter is positive in the vast majority of considered models. Conversely, values near 0 indicate a predominantly negative sign. This characteristic is very useful in assessing parameter stability in greater detail.

4.7 Priors

The BMA methodology requires determining two types of priors: g on the parameter space and $p(M_i)$ on the model space. The priors are crucial in determining the posterior probabilities (Feldkircher and Zeugner, 2009; Ciccone and Jarocinski, 2010; Liang et al., 2008). In the following subsections, we present the prior framework and support our choices.

4.7.1 Parameter Priors

As noted previously, we use the Zellner's g prior structure, which is a common approach in the literature. It assumes that the priors on the constant and error variance from equation 2 are evenly distributed, $p(\alpha_i) \propto 1$ and $p(\sigma) \propto \sigma^{-1}$. Zeugner (2011) notes that this is very similar to the normal-gamma-conjugate model accounting for proper model priors on α and σ described in Koop (2003), for example, with practically identical posterior statistics.

We assume that the β_i coefficients follow the normal distribution, and we have to formulate beliefs regarding their mean and variance before examining the data. Conventionally, researchers assume a conservative mean of 0 to reflect the lack of prior knowledge regarding the coefficients. Zellner's g defines their variance structure $\sigma^2(g(X_i'X_i)^{-1})$. Together, we have the coefficient distribution dependent on prior g :

$$\beta_i|g \sim N(0, \sigma^2(g(X_i'X_i)^{-1})) \quad (17)$$

The prior variance of the coefficients is proportional to the posterior variance $(X_i'X_i)^{-1}$ estimated from the sample. Parameter g denotes how much weight we attribute to the prior variance as opposed to the variance observed in the data (Feldkircher and Zeugner, 2009). Selecting a small g results in low variance in the prior coefficients and thus reduces the coefficients to zero. Conversely, a large g attributes higher importance to the data and expresses researchers' uncertainty regarding zero β_i coefficients (Zeugner, 2011). Note that with $g \rightarrow \infty$, $\beta_i \rightarrow \beta_i^{OLS}$. Popular choices include the following:

- UIP; $g = N$.
- BRIC; $g = \max\{N, K^2\}$.
- hyper-g; $\frac{g}{1+g} \sim \text{Beta}(1, \frac{a}{2} - 1)$, where $a \in (2, 4]$, which is a Beta distribution with mean $\frac{2}{a}$.

While the first two are known as "fixed- g " priors for the parameter prior set for all the models under consideration, hyper- g allows the researcher to update the prior for individual models of a Bayesian nature and therefore limits the unintended consequences of prior selection based on posterior results. Note that setting $a = 4$ corresponds to the UIP, whereas $a = 2$ concentrates the prior mass close to unity, corresponding to $g \rightarrow \infty$. For details on hyper- g , see Liang et al. (2008).

We employ the so-called hyper-g prior to estimate the baseline models, following Feldkircher and Zeugner (2009), who suggest that using model-specific priors leads to a more stable posterior structure. We then check the robustness of the results by applying the UIP parameter prior.

4.7.2 Model Priors

Moral-Benito (2012) notes that the most popular setting in the BMA literature is the binomial distribution, where each of the covariates is included in the model with a probability of success θ . The prior probability of model M_i with k regressors given θ is then

$$p(M_i) = \theta^{k_i} (1 - \theta)^{K - k_i} \quad (18)$$

A popular setting is $\theta = \frac{1}{2}$, which assigns equal probability $p(M_i) = 2^{-K}$ to all the models under consideration. This model prior is also known as the uniform model prior. Assuming different values of θ can shift the prior model distribution to either smaller or larger sizes (see Zeugner (2011)).

We focus on models using the uniform model prior following Fernandez et al. (2001), as it allows us to compare our results to those of their study. However, the uniform model prior tends to assign greater weight to intermediate model sizes. For illustration, consider our dataset of 42 regressors. The expected model size is $\frac{K}{2} = 21$, but there is clearly a larger number of possible models of size 21 than 1. Specifically, there are 42 possible models of size 1, whereas $\binom{42}{21}$ combinations (more than half a trillion) exist for a model size of 21. Therefore, Ley and Steel (2009) propose an alternative model prior that is less restrictive regarding the expected model size, drawing parameter θ from the Beta distribution. Their argument is that this alternative better reflects the lack of *a priori* knowledge concerning the model. We use this "random" beta binomial prior in the specifications designed to check the robustness of our baseline estimations.

4.8 MCMC Sampler

One of the limitations of the BMA is its computational difficulty when the number of potential explanatory variables K is very large. Historically, this was the primary factor preventing researchers from employing Bayesian methods. Zeugner (2011) notes that for small models, it is possible to enumerate all variable combinations. When $K > 25$, it becomes impossible to evaluate the entire model space within a reasonable time frame. In such cases, BMA utilizes MC³ samplers to approximate the crucial part of the posterior model distribution containing the most likely models. BMA applies the Metropolis-Hastings algorithm, which is outlined in Zeugner (2011), in following way:

At any step i , the sampler is currently at model M_i , having PMP $p(M_i|y, X)$. In the next step $i + 1$, model M_j is proposed to replace M_i . The sampler accepts the new model M_j with the following probability:

$$p_{i,j} = \min \left(1, \frac{p(M_j|y, X)}{p(M_i|y, X)} \right) \quad (19)$$

If model M_j is rejected, the next model M_k is suggested and compared with M_i . With the growing number of iterations, the number of times each model is retained converges to the distribution of posterior model probabilities. Typically, one of the following MC³ samplers is used to draw the models:

- Birth-death sampler - randomly chooses one of the explanatory variables, which is included if it is not already part of the current model M_i or dropped if it is already in M_i .
- Reversible-jump sampler - with 50% probability, the Birth-death sampler is used to determine the next candidate model. With 50% probability, the sampler randomly swaps one of the covariates in M_i for a covariate previously excluded from M_i .

Because the sampler can begin with a "poor" model with low PMP, the predefined number of initial draws, the so-called burn-ins, are usually dropped. The quality of the approximation can be evaluated on the basis of the correlation between the PMP derived from an analytical approach and those obtained from the MC³ sampler. It depends on the number of iterations (draws) and the likelihood of the initially selected model. Zeugner (2011) notes that a PMP correlation of approximately 0.9 indicates a "good degree of convergence". In the event that the correlation is lower, the number of sampler iterations should be increased.

4.9 Endogeneity Issues

Our dataset is constructed such that most regressors are exogenous except for certain financial indicators. To address the potential endogeneity of these indicators, we apply the methodology developed by Durlauf et al. (2008). The endogenous financial variables are regressed on a set of instruments in the first stage, and their fitted values are used in the second stage, which is a standard BMA procedure. We acknowledge that the first stage is not fully Bayesian, but it is important to note that the number of endogenous variables and instruments is rather low. In addition, Durlauf et al. (2008) performs Monte Carlo simulations and shows that this two-stage least squares BMA approach (2SLS-BMA) approximates the data generating process accurately.

We use the financial reform index and information on financial reform reversal compiled by Abiad et al. (2010) and the data from Reinhart and Rogoff (2008) on the history of financial crises as the instruments.

The financial reform index incorporates information on credit conditions, financial market supervision, and competition characteristics. It represents the reform inputs (which are typically initiated by international organizations such as the International Monetary Fund) and not reform outcomes; therefore, it is likely to be independent of growth. Moreover, previous research shows that financial reforms spur financial development (Jayaratne and Strahan, 1996; Tresselt and Detragiache, 2008). In addition, the key characteristic of financial development is its continuity, and financial reform reversals may have particularly devastating effects on financial development (Rajan and Zingales, 2003). Therefore, using the data in Abiad et al. (2010), we include the average size of the reversal of financial reform (the reversal is defined as the decrease in the index value, and the average value of reversals is used as the instrument) and the total

number of large reversals over the observed period (we consider a large reversal to be a decrease in the non-standardized index value larger than 3).

Next, we use the historical data on financial crises as our instrument. Reinhart and Rogoff (2008) recognize several types of financial distress: currency, inflation, debt, bank crises and stock market crashes. Furthermore, they distinguish between domestic and external debt crises. For each year, they assign a value of 1 if a particular type of crisis occurs. The total crisis tally in a year can therefore take values from 0 to 6. We believe that the legacy of troubled financial systems may be deeply rooted in the economy and have a long-term impact on financial development. For example, Guiso et al. (2008) show how a lack of trust leads to lower stock market participation. Specifically, we consider the average crisis tally (average number of crises per year) in the countries over the period of their independence. In addition to this, we consider the severity of these crises by assuming the maximum crisis tally value in the first-stage regressions. The dependence between financial crises and economic growth is likely to be only temporary, with the effect eventually diminishing (Ranciere et al., 2006). Therefore, their occurrence is likely unrelated to long-term growth. To these five outside of the model instruments, which ensure the identification of the two-stage model, we add the rule of law and the years for which the country has had an open economy as additional instruments. Rajan and Zingales (2003) and Baltagi et al. (2009) identify these two variables as determinants of financial development. In addition, these two variables exhibit high correlation with most of our financial indicators. Furthermore, absolute latitude is included to control for the geographical endowment of individual countries. Latitude is exogenous to growth and is shown to affect financial development (Beck et al., 2003a,b).

Some instruments are not available for all countries. To prevent reducing our sample, in exceptional cases, we use the regional averages for missing data. The regions are defined as follows: Sub-Saharan Africa, Latin America and the rest of the world. The countries for which we are missing financial reform indices are Botswana, Cyprus, Malawi, Panama, and Zambia.

5 Results

This section presents two sets of our main results. The first set examines the effect of private credit to GDP on long-term growth. Our results suggest that this standard measure of financial development - *financial depth* - is not a robust determinant of growth once we account for model uncertainty.

The second set investigates the importance of new financial indicators that capture not only depth, but also stability and efficiency. We present a series of results, with and without addressing endogeneity and with the lagged financial indicators, to examine how current financial development is related to future growth. All these results suggest that the efficiency of financial intermediaries is robustly related to long-term growth.

5.1 Private Credit

Figure 1 illustrates the relationship between private credit and economic growth. Linear and quadratic fit, the latter with 95% confidence intervals, is also included. In a preliminary examination of the data, we observe a weak and possibly diminishing relationship between credit and growth.

Figure 1: Private credit and growth, 1960-2011

Table 2 presents our baseline results for private credit. We sort the explanatory variables according to their PIPs. We find that the initial level of GDP in 1960, the dummy variable for Sub-Sahara, the share of GDP in mining, the fraction of Confucian population, equipment investment, distortions in the exchange rate, and covariates capturing black market characteristics exhibit the highest PIPs. These findings are broadly in accord with the specification from Fernandez et al. (2001) despite the choice of an alternative parameter prior and the consideration of an extended period.

Although private credit ranks near the middle of the list of explanatory variables, its PIP is only 7%. This result indicates that credit is rarely included as the explanatory variable in the "true" growth model. The mean value of the coefficient is positive. In addition, Figure 2 depicts the marginal density of the coefficient on private credit. Note that the distribution is based on the conditional inclusion of the variable in the model; therefore, the conditional mean value in the figure is higher than that reported in Table 2, which includes models in which that do not consider the private credit variable. Overall, we find very limited support for the notion that financial depth is important for long-term economic growth.

In the baseline estimation, we follow Fernandez et al. (2001) and use a uniform model prior.

However, we depart from that study in the selection of the parameter prior. Instead of using the BRIC prior, we employ the hyper-g prior, as the literature now considers it superior. The essential disadvantage of employing the BRIC prior is documented by Feldkircher and Zeugner (2012). They describe a phenomenon of a "supermodel effect", arguing that with a high fixed prior g , the shrinkage-factor $\frac{g}{1+g}$ in equation 14 increases, thus increasing the size penalty, and

Figure 2: Marginal density, private credit (PIP 7%)

may skew the posterior model distribution to smaller models. This choice of a large g under fixed priors can result in a preference for overly simplistic models. According to Feldkircher and Zeugner (2012), the phenomenon is characteristic of BMA applications to growth regressions with numerous covariates. They further claim that using a model-specific hyper- g prior leads to more robust estimates. This is why we abstain from employing the BRIC prior and focus on alternative options for parameter priors in our robustness checks.

The Birth-death MC³ sampler described in section 4.8 is our preferred approach for approximating the PMP distribution. To ensure sufficient convergence of the sampler, we specify 15 million iterations with 3 million initial burn-ins. Table A2 presents the estimation diagnostics. The average number of regressors included in the model is 19.09, and the correlation between analytical and sampler PMP stands at 0.56. We realize that this PMP correlation is far from ideal, but estimation with higher iteration counts and subsequently higher PMP correlation yields nearly identical results¹. Note that below, we employ different parameters and model prior structures and achieve a PMP close to 1, while the PIPs remain largely unchanged.

Next, we examine whether the baseline results are robust to different parameter priors. Ciccone and Jarocinski (2010) posit that BMA results are sensitive to data revisions under certain prior structures. Eicher et al. (2011) find that the PIPs of some growth determinants depend on the chosen parameter prior. Therefore, we perform the estimation using UIP. We also check the robustness of the MC³ sampler using the "reverse-jump" algorithm and the model prior by employing a random binomial model prior (see Zeugner (2011) for details).

¹Specifically, we ran the estimation using 50 million iterations and 5 000 000 burn-ins to arrive at a PMP correlation of 0.82. Characteristics in terms of mean model size and PIPs remain virtually the same.

The model comparison for different parameter priors and MC³ algorithms is depicted in Figure 3. Model 1 includes the PIPs under our baseline specification. Model 2 employs the same priors but applies the "reverse-jump" MC³ algorithm. Models 3 and 4 yield the results when we use UIP under the birth-death and reverse-jump samplers, respectively. Though employing the reverse-jump sampler only marginally alters the PIPs, switching to the UIP prior leads to slightly lower inclusion probabilities and model size. Overall, these findings indicate that our baseline results are robust.

Figure 3: Model comparison with private credit, Model 1=hyper-g,birth-death; Model 2=hyper-g,reverse-jump; Model 3=UIP,birth-death; Model 4=UIP,reverse-jump

The beta-binomial (random) model prior offers meaningful insights. This setting allows for a less restrictive selection of model priors around the prior expected model size and limits the risk of imposing any particular one (Ley and Steel, 2009). Thus, if the true model size is lower than that expected by the prior (21), we should expect the mean model size to decline in this setting. We present the results of the estimation using this model prior in Figure A1. In the first setting with a hyper-g prior, the mean size declines to 15.05 and the PMP correlation between analytical and MC³ sampler likelihood achieves a satisfactory value of 0.96. The most important variables according to their PIPs remain nearly unchanged, although their relative positions adjust. One significant change is the decline in the PIP of the volatility of the black market premium to 14%. Finally, the inclusion probability of private credit increases marginally to 9%.

Finally, we examine the importance of various subsamples and the possibility of a nonlinear relationship between private credit and growth. Several recent studies on financial development and economic growth devote substantial attention to nonlinearities in the relationship between

financial development and economic growth (see, for example, Cecchetti and Kharroubi (2012); Law and Singh (2014)). We additionally introduce the squared value of private credit to GDP to examine the diminishing returns of finance on growth. We also limit the period under consideration to 1960-1990 and examine whether the effect of financial development is stronger for this time period, as suggested by Rousseau and Wachtel (2011). We find that none of these modifications substantially affects our primary results concerning the relationship between private credit and economic growth. The squared value of private credit takes a negative sign, suggesting a potentially diminishing effect, but with very low PIP. The PIP of private credit estimated on the subsample before 1990 does not appear to differ from that obtained for the full period up to 2011. These results are available upon request.

5.2 New Financial Development Indicators

We examine the effect of new financial indicators on long-term growth in this subsection. Specifically, we include the following variables in our estimation: bank Z-score, net interest margin, stock market turnover, and stock market capitalization. Cihak et al. (2013) identify these as proxies for different aspects of the financial sector. Specifically, they propose using bank Z-score to assess the stability of the banking sector, the net interest margin to proxy for the efficiency of the banking sector, stock market turnover as a proxy for the efficiency of the stock market, and stock market capitalization to measure the depth of stock markets. These measures, particularly the first two, are rarely used in growth regressions (Berger et al. (2004) and Hasan et al. (2009) being the exceptions), despite the fact that they might better depict the relationships outlined by theory than traditionally employed variables. As we outline in section 3, the main issue lies in their availability. However, the GFDD provides a significant improvement in this regard, and many series are available since the late 1980s. In addition, we retain domestic credit to the private sector among the covariates to account for the overall size of the banking sector. Given the data limitations, our sample is reduced to 60 countries. For eight countries from our original sample used for private credit, at least one value of the new financial indicators is missing.

Figure 4 provides an initial examination of the interaction between individual financial indicators and economic growth. First, we observe a distinct inverse relationship between the net interest margin and economic growth. Second, bank Z-score and growth display only a marginally positive relationship. Third, market capitalization and market turnover appear to be positively related to growth, which is in line with Levine and Zervos (1998). In addition, Table 3 provides the correlations among the financial indicators. The correlations are typically far from 1, thus providing additional impetus to examine further measures of financial development in the growth regressions.

We report the results of the estimation in a similar fashion as we did for private credit. We retain the baseline specification with the hyper-g prior, uniform model prior, and birth-death MC³ sampler. The number of iterations remains at 15 million, and we specify 3 million burn-ins. Table A3 presents a summary of the estimation diagnostics. As in the previous subsection,

Figure 4: Financial indicators and growth

Table 3: Correlation matrix of new financial indicators

Net interest margin	1.00				
Bank Z-score	-0.14	1.00			
Private credit	-0.71	0.03	1.00		
Market capitalization	-0.44	0.08	0.71	1.00	
Market turnover	-0.54	0.02	0.47	0.33	1.00

running more iterations does not affect the resulting PIPs and posterior means, although it leads to a higher convergence of the sampler. We primarily focus on the interpretation of the results concerning financial indicators, as the other explanatory variables' PIPs remain broadly similar to those of specification for private credit.

We present the posterior statistics of the explanatory variables in Table 4. Interestingly, the variable proxying for bank efficiency exhibits a comparatively higher PIP than that reflect-

ing its depth. Net interest margin ranks high among the explanatory variables with a 97% inclusion probability. The posterior mean of the coefficient is negative, in accordance with our expectations. The marginal density of the net interest margin is depicted in Figure 5. A lower interest margin stems from a smaller discrepancy between banks' borrowing and lending rates. Thus, if banks are able to channel resources at a lower margin, this appears to positively affect long-term economic growth (Rousseau, 1998). Additionally, the posterior mean of bank Z-score is positive, implying that stable banking systems are beneficial for economic growth, although the PIP at 25% does not offer much confidence that the Z-score is a crucial determinant of long-term growth. Stock market turnover is also accorded little importance, with a PIP of 17%. The positive sign of the mean is in line with our expectations regarding an efficient resource allocation being beneficial for growth. Moreover, it supports the conclusion of Levine and Zervos (1998) that an active stock market contributes to economic growth. However, we wish to note that this indicator might not coherently capture the efficiency of the markets. A high turnover ratio could reflect low friction in trading and the spread of information (Levine, 2005). On the other hand, other research finds that more trading does not necessarily prevent asset price misalignments and its corrections (Brunnermeier and Nagel, 2004). Strikingly, the measures capturing the depth of both the banking sector and stock markets exhibit very small PIPs. Overall, our results indicate that the approach used to measure financial development is crucial in determining the estimated effect of finance on growth.

random model prior². Figure 6 illustrates the comparison. The implications of different priors are similar to those experienced in the estimation regarding private credit. The UIP parameter prior subtly alters the PIPs of the covariates without having a major effect on the interpretation. Providing greater flexibility in selecting model size by assuming a random model prior reduces the posterior mean model size and the PIPs of several variables, but the set of top-ranked regressors remains largely unchanged. The relative importance of financial indicators changes to some extent. Net interest margin remains among the most important variables with an 86% PIP. All the remaining indicators exhibit low PIPs below 10%. This is due to the smaller size induced by the random model prior.

Figure 6: Model comparison with all financial indicators 1960-2011, priors Model 1=hyper-g, Model 2=UIP.

Table 5 reports the results using 2SLS-BMA estimation. The results from the first-stage regressions in which we regress the endogenous financial indicators on instruments are presented in the appendix in Table A4. Among the top regressors, there are no apparent qualitative differences between the baseline and 2SLS results. The posterior inclusion probability of net interest margin remains high at 98%. The PIP for bank Z-score and market capitalization decline to very low levels, and these variables now rank in the bottom half of the regressors. Concerning bank Z-score, the results might be affected by the low fit of the first-stage regression. Private credit and stock market capitalization, the traditional financial development proxies, continue to display low inclusion probabilities.

Our baseline and 2SLS-BMA estimations suggest that bank efficiency is crucial for growth.

²We also perform estimations using an alternative MC³ sampler, but the differences in posterior statistics are marginal.

We perform an additional estimation to check the robustness of this finding. Instead of 2SLS–BMA, we estimate BMA with lagged covariates. For reasons of data availability, we use real growth in GDP per capita over the period 2000–2011 and take the values of the financial indicators in the year 2000. The advantage of this approach is that we examine how past financial indicators influence current growth. Clearly, the disadvantage is that the time coverage for the dependent variable is restricted to just over a decade. We present the results in Table 6. Interestingly, the results remain largely unchanged. Net interest margin remains among the covariates with the highest PIP. The posterior mean of the coefficient is negative. The PIP of private credit is 49%, but the mean is negative. We hypothesize that the negative mean is a consequence of our sample period including the current global financial crisis, which has been characterized by deleveraging in many developed countries. The PIP of the other financial indicators is not high.

6 Conclusions

We contribute to the voluminous finance and economic growth literature in two ways. First, we use Bayesian model averaging (Raftery et al., 1997). This methodology is firmly grounded in statistical theory and allows the researcher to jointly evaluate a large number of potential covariates considered in the literature. This is important because we know that regression model uncertainty in growth regressions is high (Sala-I-Martin et al., 2004; Durlauf et al., 2008) and there are numerous potential determinants of growth that could be included. Without considering model uncertainty, researchers examining the finance-growth nexus risk omit variable bias and inconsistently estimate parameters.

Second, the previous literature examining the finance-growth nexus largely employs measures of financial depth (for both the banking sector and stock markets) but rarely examines measures of the efficiency of financial intermediaries or financial stability. For this reason, we use newly developed financial indicators from the World Bank’s GFDD. These indicators capture not only depth but also efficiency and stability. It is vital to revisit the finance and growth literature because recent studies report that excessive financial development harms growth (Cecchetti and Kharroubi, 2012).

Using the updated well-known cross-country growth dataset by Fernandez et al. (2001), we find that traditional indicators of financial depth (and its squared terms) are not robustly related to long-term economic growth. The measures of financial depth and financial stability exhibit posterior inclusion probabilities well below 50%. However, our results suggest that bank efficiency, as proxied by the net interest margin, is crucial for long-term growth. The corresponding posterior inclusion probability is on average above 90%. This result is in line with theory, which indicates that the financial sector is essential in channeling resources from savers to borrowers. These results are robust to different parameter and model priors in Bayesian model averaging. The results are also robust once we address the endogeneity of financial indicators.

Overall, we find that the measurement of financial development is crucial in determining

the estimated effect of finance on growth. Based on our global sample, the results attribute a greater role to the banking sector and its efficiency in fostering economic growth. In terms of policy implications, our results indicate that the current wave of regulatory changes intended to safeguard financial stability should carefully analyze the consequences for the efficiency of financial intermediaries.

A1 Description of the Dataset

We use a commonly employed dataset on the determinants of growth developed by Fernandez et al. (2001). The dataset contains 41 explanatory variables that are potentially important for growth in 72 countries. Here, we describe the variables that do not assess financial development. Financial indicators, which we add to this dataset, are described in the main text.

We update the dataset by incorporating economic growth from new PWT, extending the time period considered from the former 1960-1992 to 1960-2011. Our dependent variable is the average growth of real output-based GDP per capita. The mean value of the growth rate across the dataset is 2.27% with a standard deviation of 1.45%. The regressors in the dataset comprise various measures of economic, political, geographic, demographic, social, and cultural factors. As many of the variables are endogenous with respect to growth, the data typically come from 1960 or before.

The economic variables primarily capture established factors from neoclassical growth theories. The initial level of GDP is included to capture conditional convergence, such that lower starting levels imply higher growth rates (Barro and Sala-i-Martin, 1992). Additionally, physical capital investment is considered, distinguishing between equipment investment (machinery) and non-equipment investment (other). This follows Long and Summers (1991), who find that the impact of the former is a stronger driver of long-term economic growth. Human capital enters through primary school enrollment, higher education enrollment and public education share from Barro (1996). Life expectancy is often assumed to capture human capital other than education; therefore, it is also included among the regressors. Exchange rate fluctuations, the black market premium, and the volatility of the black market premium account for the degree of economic uncertainty. Exchange rates can affect a country's foreign direct investments and net exports, subsequently influencing economic growth. The black market premium then reflects the surplus on the exchange rate over the official foreign exchange market. High discrepancy mirrors greater uncertainty, and in addition to high volatility, we expect it to decelerate growth. Moreover, a set of variables accounts for economic policies. Outward orientation based on an import-export structure reflects the potential impact of international competition on domestic production efficiency. Economic organization captures the degree of capitalism, using the classification developed by Hall and Jones (1999). The characteristic is measured on a six-degree scale ranging from "statist" to "capitalist" that depends on how much control the national government exerts over the economy. Finally, the degree of openness enters through the length of period that the country has experienced an open economy. All policy variables are assumed to be positively correlated with economic growth.

Geographic controls include dummy variables for Sub Saharan Africa, Latin America, total area, and absolute latitude. Spatial differences in economic growth have been established in the literature. The location of a country may influence growth through differences in transportation costs, disease burdens, or agricultural productivity (Gallup et al., 1999). A location farther from the equator should have a positive impact on growth.

The explanatory variables measuring political conditions within countries are colonial her-

itage, rule of law, indices for political rights, civil rights, and revolutions and coups. Political instability is further captured by war dummy, which equals 1 if the country suffered from war during 1960-1992. Acemoglu et al. (2001) note that colonial heritage is related to lower trust and malfunctioning institutions; therefore, former colonial status depresses growth. The rule of law is an established control in growth regressions, proxying for security, property rights, democratic government, and corruption (Haggard and Tiede, 2011). Civil liberties further accounts for the level of democracy and its relationship with income redistribution. If a large share of income is in the hands of a few, this may have consequences for economic agents' production incentives. Intuitively, revolutions and coups negatively affect growth by decreasing stability and infrastructure destruction.

The demographic characteristics of countries we use in our estimation are average age, religion, ethnolinguistic fractionalization, population growth, total labor force, ratio of workers in population, and language skills. Religion is found to be relevant to economic growth in Barro (1996). Population growth accounts for the neoclassical implication of a, *ceteris paribus*, decline in per capita growth with an increasing population. Language skills are approximated by the fraction of persons speaking English within a country and the fraction of persons speaking a foreign language. Hall and Jones (1999) demonstrate how better language skills are positively reflected in economic growth. They argue that this arises from facilitated internalization and the benefits of globalization. The full list of variable names and their abbreviations is presented below.

Additionally, PWT is missing observations on Algeria, Haiti, and Nicaragua. Therefore, we have to drop them from the sample. Furthermore, the GFDD does not include data on Taiwan. Ultimately, we have 68 observations, encompassing both developed and developing countries. The list of countries is as follows: Argentina, Australia, Austria, Belgium, Bolivia, Brazil, Botswana, Canada, Chile, Cameroon, Congo (Brazzaville), Congo Dem. Rep (Kinshasa), Colombia, Costa Rica, Cyprus, Denmark, Dominican Republic, Ecuador, El Salvador, Ethiopia, Finland, France, United Kingdom, Germany, Ghana, Greece, Guatemala, Hong Kong, Honduras, India, Ireland, Israel, Italy, Jamaica, Jordan, Japan, Kenya, South Korea, Sri Lanka, Morocco, Madagascar, Mexico, Malawi, Malaysia, Nigeria, Netherlands, Norway, Pakistan, Panama, Peru, Philippines, Portugal, Paraguay, Senegal, Singapore, Spain, Sweden, Switzerland, Thailand, Tunisia, Turkey, Tanzania, Uganda, Uruguay, United States, Venezuela, Zambia, and Zimbabwe.

Brit	British colony dummy
Buddha	Fraction Buddhist
Catholic	Fraction Catholic
CivLib	Civil liberties
Confucian	Fraction Confucian
EcoOrg	Degree of capitalism
English	Fraction of pop. speaking English
EquipInv	Equipment investment
EthnoL	Ethnolinguistic fractionalization
Foreign	Fraction speaking foreign language
French	French colony dummy
GDP60	GDP level in 1960
HighEnroll	High school enrollment
Hindu	Fraction Hindu
Jewish	Fraction Jewish
LabForce	Size of labor force
LatAmerica	Latin America dummy
LifeExp	Life expectancy
Mining	Fraction GDP in mining
Muslim	Fraction Muslim
NequipInv	Non-equipment investment
OutwarOr	Outward orientation
PolRights	Political rights
Popg	Population growth
PrExports	Primary exports
Privatecredit	Private credit
Protestants	Fraction Protestant
PrScEnroll	Primary school enrollment
PublEduPct	Public education share
RevnCoups	Revolutions and coups
RFEXDist	Exchange rate distortions
RuleofLaw	Rule of law
Spanish	Spanish colony dummy
stdBMP	SD of black market premium
SubSahara	Sub-Saharan dummy
WarDummy	War dummy
WorkPop	Ratio of workers to population
YrsOpen	Number of years of open economy
BankZscore	Bank Z-score
IntMargin	Net interest margin
MarketCap	Stock market capitalization to GDP
MarketTurn	Stock market turnover ratio
Privatecredit	Domestic credit to private sector

Table A2: Model diagnostics, private credit baseline estimation

Mean # regressors	Draws	Burn-ins	# models visited
19.09	1.5e+07	3e+06	9224946
Model space 2^K	% visited	% Top models	Corr PMP
4.4e+12	0.00021	0.3	0.5672
# obs	Model prior	g-prior	Shrinkage-Stats
68	uniform/21	hyper (a=2.029)	Av=0.909

Figure A1: Model comparison with private credit, Model 1=hyper-g, random model prior; Model 2=UIP, random model prior

Table A3: Model diagnostics, financial indicators baseline regression

Mean # regressors	Draws	Burn-ins	# models visited
