Does sorting matter for learning inequality?

Evidence from East Africa

Paul Anand,¹ Jere R. Behrman,² Hai-Anh H. Dang,³ and Sam Jones⁴

December 2019

Abstract: Inequalities in children’s learning are widely recognized to arise from variations in both household- and school-related factors. While few studies have considered the role of sorting between schools and households, even fewer have quantified how much sorting contributes to educational inequalities in low- and middle-income countries. We fill this gap using data on over one million children from three countries in Eastern Africa. Applying a novel variance decomposition procedure, our results indicate that sorting of pupils across schools accounts for at least 8 per cent of the total test-score variance and that this contribution tends to be largest for children from families at either end of the socio-economic spectrum. Empirical simulations of steady-state educational inequalities reveal that policies to mitigate the consequences of sorting could substantially reduce inequalities in education.

The United Nations University World Institute for Development Economics Research provides economic analysis and policy advice with the aim of promoting sustainable and equitable development. The Institute began operations in 1985 in Helsinki, Finland, as the first research and training centre of the United Nations University. Today it is a unique blend of think tank, research institute, and UN agency—providing a range of services from policy advice to governments as well as freely available original research.

The Institute is funded through income from an endowment fund with additional contributions to its work programme from Finland, Sweden, and the United Kingdom as well as earmarked contributions for specific projects from a variety of donors.

Katajanokanlaituri 6 B, 00160 Helsinki, Finland

The views expressed in this paper are those of the author(s), and do not necessarily reflect the views of the Institute or the United Nations University, nor the programme/project donors.

1 Introduction

Education plays a vital role in building human capital, helping individuals make a productive contribution to the economy and to live a fulfilled life. The international community has recently issued a joint call for all children to have access to free and equitable education up to the end of secondary level by 2030. To achieve this ambitious goal, it is useful to have a better understanding of the complex process that determines educational achievement, thereby stimulating more effective policies to reduce education inequalities.

A vast literature attests that both household and school factors are key determinants of educational achievement (e.g. Björklund and Salvanes 2011; Bowles 1970; Hanushek and Rivkin 2012). Thus, unequal learning opportunities at either home or school can be expected to contribute to inequalities in final educational achievement. Moreover, these two factors are unlikely to be independent. Both theoretical and empirical evidence suggest that children from disadvantaged families disproportionately attend lower-quality schools (Hsieh and Urquiola 2006; Nechyba 2006). Also, a range of evidence indicates that teachers serving schools in socio-economically deprived areas are often less experienced or less qualified, potentially limiting learning outcomes (Clotfelter et al. 2011; Jackson 2009; OECD 2018; Sass et al. 2012). In this way, sorting between households and schools is likely to accentuate educational inequalities. Consequently, policies to mitigate sorting may help narrow the education gap between rich and poor households.

The vast bulk of evidence regarding educational sorting comes from richer countries. However, in these contexts the significance of these processes remains unsettled. Kremer (1997) argues that eliminating neighbourhood segregation would decrease long-run educational inequality in the USA by less than 2 per cent. In contrast, Fernández and Rogerson (2001) develop a model in which enhanced sorting can have much larger effects on inequality (see also Fernandez 2003); also, empirical evidence from Canada suggests that elimination of sorting either by home language or by parental education could reduce test-score variance as much as 40 per cent in some subjects, at least in locations where school segregation is substantial (Friesen and Krauth 2007).

To our knowledge, hardly any study has sought to quantify the contribution of sorting to educational inequalities in developing countries. But this is not because educational outcomes are highly equal. In fact, large achievement gaps running along socio-economic lines between pupils within developing countries have been extensively documented (e.g. Watkins 2012); also, (low-cost) private schools have expanded rapidly in many developing countries over recent decades, expanding possibilities for school choice (Heyneman and Stern 2014). To fill the gap in the literature, we show how estimates of the variance contribution of sorting can be derived on the basis of separate estimates of the lower-bound contributions of household and school factors. We present and apply this approach to a large-scale database of test scores covering over 1,000,000 school-aged children from three East African countries (Kenya, mainland Tanzania, and Uganda). Not only do we find a relatively high degree of segregation along socio-economic lines across communities, but we also find the contribution of sorting of children across schools within communities is positive and accounts for around 8 per cent of the total test-score variance. As such, almost one-fifth of the joint variation in test scores due to school, community, and household circumstances (referred to in the literature as inequality of opportunities, or IEO) can be attributed to sorting. Further analysis of heterogeneity suggests that the same sorting contribution tends to be larger among families at both the top and bottom ends of the socio-economic distribution, among those sending their children to private schools, as well as in specific locations.

To reflect on the long-run implications of these results, we construct simulations of how educational inequality evolves over time. These show that for the average district in the region, the steady-state level of educational inequality would fall by around 10 per cent if sorting were to be fully eliminated. While

this may not seem large at first glance, we show this is equivalent to around a 15 per cent decline in the magnitude of the intergenerational persistence of education. Moreover, in a material number of districts, the reduction in inequality from eliminating sorting would be over 20 per cent of the total variance and over 40 per cent of IEO. As such, this suggests that policies that take sorting into account, and even actively counteract it, merit attention.

This paper consists of six sections. In the next section, we outline a simple conceptual framework that guides our discussion of educational inequalities and points to the primitive components of the corresponding test-score variance decomposition. In Section 3, we show how these primitives can be estimated using standard econometric techniques, incidentally also yielding upper- and lower-bound estimates for the household and school components. For the purposes of validation of these estimates we go on to extend the estimation approach of Altonji and Mansfield (2018), which constitutes a more direct strategy to estimate the sorting component based on a set of constructed proxy variables. In Section 4 we describe the data; Section 5 presents the results, showing highly comparable results across the estimation methods; and Section 6 concludes.

2 Conceptual framework

A conventional point of departure for the analysis of inequality in education splits the proposed test-score generating process into the effect of given circumstances (opportunities) and the effect of other factors (idiosyncratic effects, efforts, preferences, etc.). This implies an educational production function of the following form:

$$t_{ijk} = f(h_j, s_k) + e_{ijk} \quad (1)$$

where t is a measure of educational achievement (e.g. test scores), and indices $i = (1, 2, \dots, N)$, $j = (1, 2, \dots, H)$, and $k = (1, 2, \dots, S)$ refer to individual children, families, and schools respectively. Following Bowles (1970) and others, h_j can be considered a comprehensive metric of the contribution of all factors shared by children in the same household (hereafter sibs) to test scores; and s_k is a comprehensive metric of the contribution of the given school to their learning. Finally, e_{ijk} represents the remaining individual or idiosyncratic variation, which we assume is orthogonal to the household- and school-effects—that is, $E(e_{ijk}|s_k, h_j) = 0$.

To make this framework tractable for empirical analysis, two main elaborations are required. The first is to select a specific metric of inequality. While a variety of measures have been employed in the literature (e.g. Hanushek and Wößmann 2006), we use the test-score variance. As Ferreira and Gignoux (2014) note, unlike other popular inequality measures, the variance is ordinally invariant to standardization procedures often used to express test scores on a comparable scale. Furthermore, the linear additive nature of the variance makes it straightforward to isolate the contributions of individual factors (Shorrocks 1982), and the variance also has the attractive property of sub-group decomposability (Chakravarty 2001).

Second, we must place some structure on $f(\cdot)$, specifying how the school and household factors plausibly relate. With respect to the levels expression in Equation (1), we adopt a simple additive linear model. Critically, however, this specification does not pin down the (co)variance structure without further assumptions. To show this, Table 1 describes four main cases of the relationship between h and s , where each row invokes more specific assumptions about the level *and* variance of t . In the first row we assume the household and school factors make independent, additive contributions to outcomes. So, in terms of the associated variance, this imposes the assumption: $E(s_k' h_j) = 0$, which rules out any correlation between the two factors.

Table 1: Summary of alternative test-score data-generating processes

Model	Score level	Score variance	Description
1 Restricted linear	$h_j + s_k + e_{ijk}$	$\sigma_h^2 + \sigma_s^2 + \sigma_e^2$	Independent households and schools
2 Unrestricted linear	$h_j + s_k + e_{ijk}$	$\sigma_h^2 + \sigma_s^2 + 2\Sigma_{hs} + \sigma_e^2$	Correlated household and school factors
3 Household upper-bound	$h_j + \gamma \bar{h}_{jk} + \nu_k + e_{ijk}$	$(1 + \gamma)^2 \sigma_h^2 + \sigma_\nu^2 + \sigma_e^2$	Household effects partly absorb school effects
4 School upper-bound	$s_k + \theta \bar{s}_{kj} + \omega_j + e_{ijk}$	$(1 + \theta)^2 \sigma_s^2 + \sigma_\omega^2 + \sigma_e^2$	School effects partly absorb household effects

Notes: score variance in Rows 3 and 4 assume $\sigma_h^2 \equiv \text{Var}(h_j) \approx \text{Var}(\bar{h}_{jk})$ and $\text{Var}(s_k) \approx \text{Var}(\bar{s}_{kj})$

Source: authors' compilation.

The zero-covariance assumption embedded in row 1 of Table 1 is restrictive. With respect to education, various sorting processes, including residential segregation, school choice (by parents), and teacher allocation rules, have been identified as potential material determinants of schooling outcomes (e.g. Fernandez 2003; Hanushek and Yilmaz 2007; Nechyba 2006). In such cases, the restriction in row 1 becomes untenable, and an unrestricted linear model may apply (row 2), in which any such sorting is captured via the covariance between household and school effects.

An interpretation consistent with the unrestricted linear (sorting) model is that the household and school factors have no direct mutual effects—that is, both effects are separately predetermined but become correlated through *ex post* processes of sorting or assortative matching. However, this is not the only mechanism that could generate a correlation between these factors. Some part of the school effect may reflect the causal effect of (average) constituent households, such as when households make direct financial or time commitments to school functioning. This kind of mechanism is also suggested by versions of cream-skimming models, where average peer quality in a school (or class) is driven by household characteristics, which in turn directly influences individual achievement (Walsh 2009). An extreme version of this is captured in the third row of Table 1, which assumes s can be partitioned into a component that is oblique or parallel to h (by construction) and an orthogonal component ν , with own variance σ_ν^2 :

$$s_k = \gamma \frac{1}{N_k} \sum_{\forall j|K=k} h_{jK} + \nu_k = \gamma \bar{h}_{jk} + \nu_k \quad (2)$$

and with $E(\bar{h}'_{jk} \nu_k) = 0$.

Applying this expression to the unrestricted linear model, row 3 gives a strict upper bound on the variance contribution due to households. The corollary is given in row 4, where household effects are assumed to be (partial) reflections of given school effects, plus an orthogonal component. Note that in both of these cases, the observed covariance between household and school effects is attributed wholly to one of the factors and no remaining sorting is allowed (by construction). As such, and as we clarify further below, the models in rows 2–4 of Table 1 provide bounds on the variance components of interest, including an absolute upper bound on sorting.

Reflecting on the set of models described in Table 1, existing literature has frequently estimated IEO via some variant of the household upper-bound model. Concretely, various studies treat family effects as a single fixed unobserved factor and omit any consideration of school effects. Björklund and Salvanes (2011) describe this approach and show how, under this set-up, the relative variance contribution of households equals the correlation in outcomes between siblings. They summarize estimates of sibling correlations in various developed countries, ranging from 0.24 in former East Germany to over 0.60 in the USA. While many of these estimates are based on grades of completed schooling, Mazumder (2011) estimates sibling correlations across learning domains for children in the USA. His estimates are of the same broad magnitude, ranging from approximately 0.35 to 0.50. For the UK, Nicoletti and Rabe (2013) analyse results from compulsory national tests and find somewhat larger sibling correlations (>0.50). Estimates of sibling correlations in developing countries are scarce, mainly reflecting data constraints. An exception is Behrman et al. (2001), who find the sibling correlation across Latin American countries, in terms of completed years of schooling, lies between around 0.30 and 0.60; and Emran and Shilpi (2015),

who find a sibling correlation of around 60 per cent in years of schooling among children in India (see also Hertz et al. 2007).

Variation in school (or teacher) effects point to differences in school quality. Many studies seek to assess the magnitude of these effects (e.g. Hanushek and Rivkin 2006; Pritchett and Viarengo 2015; Sass et al. 2012), in some cases also controlling for the contribution of family background to avoid confounding. For instance, Freeman and Viarengo (2014) use PISA data to investigate the (sources of) variance in school effects. They report that a regression of test scores on school dummies alone (as per the school upper-bound model) explains around two-thirds of the variation in the data, while a limited set of observed family background variables accounts for just one-third, after controlling for school effects. Dang and Glewwe (2018) find that schools and communities explain around 40 per cent of the variation in either test scores or years of schooling among Vietnamese children. However, studies of this sort remain rare for low-income contexts and hardly any explicitly estimate the complete variance contributions of *both* schools and households, including their covariance (for an exception, see Carneiro 2008).¹ As such, the direction and magnitude of sorting—defined generically as the factor covariance—has been largely neglected.

3 Decomposition

3.1 Methods

To address the gap in the literature, we propose a multi-factor variance decomposition. The aim is to identify the main components of educational inequalities, which amounts to apportioning the variance across households and schools without imposing any particular covariance structure a priori. In doing so, and following Gibbons et al. (2014), we seek to identify bounds on the variance contributions of households and schools, plus the sorting component.

The main analytical insight, from which the empirical methods flow, is that the various models set out in Table 1 can all be (re)stated in terms of a set of primitive quantities. As we explain further below, this means it is not necessary to estimate the correlated variance components (σ_h^2, σ_s^2) directly. To see this, note that in relation to Equation (1), the lower-bound or uncorrelated variance contribution of any given factor directly relates to its raw or unadjusted contribution via the pairwise-correlation coefficient (ρ_{sh}). For example, using the upper-bound household model, the lower bound on the school component can be rewritten as: $\sigma_v^2 = (1 - \rho_{hs}^2)\sigma_s^2$ (see Appendix A for derivation). In other words, the uncorrelated or lower-bound contribution due to schooling is proportional to 1 minus the square of the correlation coefficient between the two factors.²

Using this insight, we can then rewrite the unrestricted linear model as:

$$\sigma_t^2 = \frac{\sigma_\omega^2 + \sigma_v^2 + 2\rho_{hs}\sigma_\omega\sigma_v}{1 - \rho_{hs}^2} + \sigma_e^2 \quad (3a)$$

$$\Leftrightarrow 2\rho_{hs}\sigma_\omega\sigma_v = (1 - \rho_{hs}^2)(\sigma_t^2 - \sigma_e^2) - (\sigma_\omega^2 + \sigma_v^2) \quad (3b)$$

It follows that once three specific quantities are known—namely, the two uncorrelated variance shares and the total variance jointly attributable to the two latent factors given by $(\sigma_t^2 - \sigma_e^2)$ —then the unknown

¹ By ‘complete’, we refer to both observed and unobserved aspects of each factor. In this sense, where studies rely on a limited set of observed proxies for any single effect, the observed component only can be expected to represent a part of the overall variance associated with the factor of interest (Ferreira and Gignoux 2014), thereby constituting a lower bound.

² An equivalent expression relates the lower-bound and raw-variance contributions of the household factor.

correlation coefficient can be obtained as the root to Equation (3b). Furthermore, and as summarized in Appendix Table C1, *any* of the variance decomposition components of interest, including the contribution of sorting, can be calculated from the three primitives ($\sigma_o^2, \sigma_v^2, \rho_{hs}$). Thus, the empirical objective of the variance decomposition is to estimate these primitives.

Before proceeding to implementation, it is important to note that households and schools are encountered in the same locations and, thus, may share a common community (neighbourhood) component. To capture this explicitly, the household and school effects need to be operationalized as follows:

$$z_{jkl} = c_l + h_{jl} + s_{kl} \quad (4)$$

where z represents the joint contribution of schools and households in location l and c is the location-specific effect. Admittedly, the nature and magnitude of these types of effects remains controversial (e.g. Oreopoulos 2003). However, there is growing evidence that the quality of local environments can have a material influence on child development trajectories (Chetty and Hendren 2018; Chetty et al. 2016). Moreover, ignoring the contribution of the latter term would mean they are simply absorbed by the upper-bound household or school effect estimates, in turn muddying the interpretation of the variance decomposition components. Consequently, as detailed below, in our empirical implementations we estimate the implied community effects separately. In doing so, we impose that the estimated household/school effects are orthogonal to the community effects, implying the estimates of sorting will not be confounded by selection of households or schools *across* communities. As such, the estimated contribution of sorting (defined above) should be interpreted in a narrow or within-community sense.

3.2 Implementation

In order to estimate the primitives presented above, we first adopt a simple indirect approach. As hinted by Table 1, the uncorrelated (lower-bound) school and household variance contributions can be obtained from household and school upper-bound models, respectively. In fact, following Solon et al. (2000) (also Raaum et al. 2006), a regression of the test scores on a set of household dummies (only) will capture not just the stand-alone household effect, but also the effect of all unobserved variables correlated with this factor, including sorting—that is, the household dummies will absorb the joint contribution of h_j and \bar{h}_{jk} . Based on these estimates, residual variation aggregated to the school level will be orthogonal to all included factors by construction, giving the uncorrelated (lower-bound) school variance contribution of interest (σ_v^2). Using a set of school dummies, the same approach provides estimates for the uncorrelated (lower-bound) household variance contribution and the associated contribution of sorting is calculated on the basis of Equation (3b). Step-by-step details of this procedure are set out in Appendix A3.

A drawback of using such fixed-effects procedures is that estimates of latent factors generally include measurement error, meaning the corresponding raw-variance shares will be upwards biased (Koedel et al. 2015). To address this, we use empirical Bayes shrinkage, which involves adjusting each estimated effect towards a common prior by a factor proportional to the estimated noise-to-signal ratio in the original estimates. Following Stanek et al. (1999), we shrink each estimated fixed effect (e.g. \hat{h}_j) towards a global mean as follows:

$$\tilde{h}_j = \bar{h}_j + \psi(\hat{h}_j - \bar{h}_j) \quad (5)$$

with shrinkage factor $0 < \psi = \frac{\sigma_{\hat{h}}^2}{\sigma_{\hat{h}}^2 + \alpha^2/N_j} < 1$

where N_j is the effective degrees of freedom available to estimate each of the j effects; $\sigma_{\hat{h}}^2$ is the raw variance of the estimated household fixed effect; α^2 is the estimated overall residual variance; and \bar{h}_j is the sample fixed-effect mean, typically zero under conventional normalization restrictions.

A second approach to dealing with the presence of sorting is suggested by Altonji and Mansfield (2018) (hereafter AM18). Motivated by a concern that sorting on unobserved variables may bias estimates of the

effects of group-level inputs, such as schools, these authors show that where households with different characteristics also have differing effective preferences (willingness-to-pay) for underlying school or community amenities, group averages of observed household or pupil characteristics can be employed as control functions. Inclusion of these generated variables, henceforth referred to as sorting proxies, in a regression model thus permits identification of a lower bound on the unique (variance) contribution of school factors. In this set-up, the specification of interest becomes:

$$t_{ijkl} = h'_{O,j}\beta + \bar{h}'_{O,k}\gamma + [h_{jl}] + [s_{kl}] + e_{ijkl} \quad (6)$$

where $h_{O,j}$ are observed household-level covariates; $\bar{h}_{O,k}$ are the set of sorting proxies; and the terms in brackets represent the (uncorrelated) household and school random effects.

An advantage of this more direct procedure is that it relies on a single estimation equation. A drawback is that the random effects are assumed to be orthogonal to the set of included covariates, implying Equation (6) may be mis-specified.³ Furthermore, while the variances of the random effects are estimated as model parameters, their associated best-linear-unbiased predictors (BLUPs or conditional modes) typically do not share the same variance–covariance structure as the estimated population-level moments (see Morris 2002). Consequently, the BLUPs may not be reliable for the purposes of investigating systematic patterns in the random effects (e.g. subgroup heterogeneity).⁴ Consequently, as an additional validation procedure, we extend the AM18 approach to incorporate fixed- as opposed to random-effects terms. As described in Appendix A3, this involves modifying the indirect estimation procedure whereby the sorting proxies are used to account for variation in test scores before estimation of the (one-way) household and school fixed effects.

Finally, it merits clarification why we do *not* seek to estimate the (correlated) variance components from the outset (σ_h^2, σ_s^2). While this might seem more straightforward, these factors cannot be identified easily. Treating them as conventional random effects requires imposing a zero pairwise covariance restriction, ruling out the presence of sorting. This limitation is not shared by two-way fixed-effects models, but a downside of these methods is that the pairwise correlation of the estimated fixed-effects vectors tends to be biased downwards (Abowd et al. 2002). As Andrews et al. (2008) demonstrate, this is driven by a quasi-mechanical relation, whereby if one factor (e.g. household effects) is overestimated then, on average, the other factor (e.g. schools) will be underestimated (see also Andrews et al. 2012).⁵ Furthermore, while methods to correct for the negative covariance bias in two-way fixed-effects estimators have been proposed (see Gaure 2014), they remain work in progress.

4 Data

Since 2010, the Uwezo initiative has undertaken large-scale household-based surveys of academic achievement in Kenya, mainland Tanzania, and Uganda.⁶ The surveys target children residing in households aged between the official school-starting age and 16, and are representative at both national

³ For households, a ‘tighter’ lower-bound variance share is obtained by adding the estimated variance of the fitted observed component to the variance of the random component.

⁴ Estimation of high-dimensional mixed-effects models is also highly computationally intensive and prone to convergence problems. In the present case we use the `lme4` package in R for estimation (Bates 2010).

⁵ Intuitively, this reflects the general problem of model over-parameterization, and the magnitude of bias tends to be larger where fewer observations are available to estimate each effect, which is particularly relevant here as the latent effects are highly granular (e.g. households).

⁶ The approach adopted by Uwezo has been inspired by exercises carried out in India by the Assessment Survey Evaluation Research Centre (ASER). For further details and comparison to other regional assessments, see Uwezo (2012) and Jones et al. (2014).

and district levels. Excluding the initial surveys, five rounds of the Uwezo surveys are publicly available (2011–15) and used here. For each household, the surveys collected information covering general characteristics, as well as the demographic and educational details of resident children (e.g. age, gender, whether or not they were attending school). Also, all children of school age were individually administered a set of basic oral literacy and numeracy tests that were tailored to each country and varied by survey round based on a common template to reflect competencies stipulated in the national curriculum at the grade 2 level.

The literacy and numeracy tests (the Uwezo tests) are described in detail in Jones et al. (2014). The literacy tests refer to national languages of instruction in which pupils are tested at the end of primary school—that is, English and Kiswahili in Tanzania and Kenya, and just English in Uganda. Importantly, the Uwezo tests are not adapted to the children’s ages or their completed level of schooling. Given that they focus on basic competencies, it is thus unsurprising there are strong age-related differences, which affect both the level and variance of scores between age cohorts. From the present perspective, this between-cohort variation can be considered unwanted noise (see Mazumder 2008). As a result, so as to construct an overall metric of achievement, we transform the raw integer scores on the individual tests in two steps. First, we apply a graded response IRT (item response theory) model to the suite of tests answered by each child, yielding an estimated achievement score (the empirical Bayes mean of the latent trait).⁷ Next, to place the scores on a comparable scale, we standardize them to take a mean of 0 and standard deviation of 1 within each survey, country, and age group. This removes all unwanted variation in the score levels that would add noise to the decomposition; also, since the same Uwezo test forms are administered to children of all ages in each household, it accounts for the fact that the raw score standard deviation is not constant across age groups.

Table 2 reports regional means and standard deviations of the test scores for the sample used in the present analysis, pooling data from different rounds. Note that due to the relatively basic competency levels assessed by the Uwezo tests, we exclude children above 14 years old, as they tend to perform at the upper end of the tests (and show much lower variance). The analytical sample also excludes observations that can be perfectly predicted using either household or school fixed effects—that is, singletons have been removed. Column 1 of the table reports weighted means of the raw competency tests (ordinal scores); column 2 reports the IRT scores standardized by country and round, but not age; and column 3 reports the final measures, including age standardization. As can be seen, movement from the second to the third metric constitutes a simple monotone transformation. Also, as per the methodological discussion of Section 3, the analytical focus is on the variance components of the test score; there is no evidence to suggest these dropped observations are distributed in a systematic pattern over regions or districts. The (sample) standard deviations of the test scores are reported in parentheses in the table.⁸

⁷ Further details are available on request. Due to differences in test forms between countries and across years, we estimate these models separately by country and survey round. Also, in a small number of cases the graded response model did not converge and, instead, we used a partial credit model. The test scores derived from the IRT procedure are extremely highly correlated with those constructed from a conventional standardization.

⁸ In line with Ferreira and Gignoux (2014), the rank position of each region according to its test-score variance is largely preserved, regardless of the transformation applied.

Table 2: Metrics of achievement (test scores), by country and region

Country and region		Raw score		IRT		IRT std	
		Mean	Std dev.	Mean	Std dev.	Mean	Std dev.
KE	Central	4.68	(1.63)	0.38	(0.86)	0.45	(0.83)
	Coast	3.71	(2.04)	-0.10	(1.01)	-0.12	(1.01)

To implement the decomposition procedures, household and school indices must be defined. The former is trivial—unique indices are ascribed to all siblings in the same household (in each year).⁹ The school effects are less straightforward. In the present data, limited information about schools is provided. Nonetheless, we know the kind of school attended (none, public, or private) and whether or not the child attends the main public school in their local community (catchment area). Consequently, for each enumeration area, we categorize children into four school categories: (1) those not attending school; (2) those attending the specific (known, matched) local public school; (3) those attending other public schools; and (4) those attending private school. The advantage of this procedure is that, within each household, children can be associated to different school effects—that is, the school and household effects are crossed. A downside is that for the last two school categories we do not identify specific schools; as such, these effects capture average school quality of a given type.

Further descriptive statistics for the dataset are reported in Table 3. This shows the number of unique children (i), households (j), and school effects (k) covered in the dataset. Additionally, the table reports summary statistics, including average child characteristics and schooling status indicators (those out of school, the share attending the specific matched public school, and those attending a private school). Overall, these indicate the sample is comprehensive and balanced (by age and gender).¹⁰ It also reveals

⁹ The Uwezo surveys are cross-sectional in nature and no attempt is made to track the same children over time.

¹⁰ Average ages are higher in Tanzania as the school-starting age is seven, compared to six in the other countries.

there are systematic differences in schooling between countries as well as across regions within each country—for example, in all countries enrolment rates differ substantially across regions (e.g. from 96.5 to 80 per cent in Kenya), as does the number of children attending private school.

Table 3: Descriptive statistics, by country and region

5 Results

5.1 Spatial clustering

We begin with a preliminary review of the degree of spatial clustering or segregation—that is, the extent to which similar types of children are found in the same schools or communities. To do so, we compare the correlation between individuals within different aggregate units, which is equivalent to the proportion of the variance attributable to the between-group structure of the data (for similar exercises, see Emran and Shilpi 2015; Friesen and Krauth 2007, 2010; Fryer and Levitt 2004; Lindahl 2011). The magnitude of the correlation across members of the same group, and how quickly this falls as we move to higher levels of aggregation, thus indicates the extent to which variables are spatially segregated (clustered). For instance, if local communities only contained households with the exact same socio-economic status, then the proportion of variance in socio-economic status accounted for by communities would be equal to that accounted for by households, indicating a very high degree of clustering.

Results from this exercise are reported in Table 4, covering a range of variables. As might be expected, assuming child gender is approximately random, the between-group variance share accounted for by

households is extremely low. For the remaining variables, however, clustering by households, schools, or communities is much higher. For instance, more than two-thirds of the variation in access to clean water is accounted for both by schools and by communities. Overall, a little more than half of the total variation in aggregate socio-economic status (SES) in the region is attributable to (average) differences between distinct communities, implying substantial levels of residential clustering or economic segregation.

Table 4: Percentage of between-group variance attributable to alternative grouping structures

Group level →		Household	School	Village	District	Region	Ratios	
Variable		(a)	(b)	(c)	(d)	(e)	(b)/(a)	(c)/(b)
Female	0.5	3.0	3.0	1.7	0.1	0.0	1.01	0.56
Household has electricity	0.2	100.0	54.0	47.5	19.1	7.4	0.54	0.88
Household has clean water	0.4	100.0	70.5	66.9	13.4	2.8	0.70	0.95
Household owns phone	0.7	100.0	38.9	33.0	10.3	5.4	0.39	0.85
Mother's education	4.4	100.0	52.7	46.4	13.6	6.7	0.53	0.88
Aggregate SES index	-0.1	100.0	58.6	51.8	22.5	9.4	0.59	0.88
Enrolled	0.9	40.6	100.0	27.7	8.2	3.2	2.46	0.28
Highest grade	-0.0	50.2	42.9	31.1	11.8	5.2	0.85	0.72
Math achievement (IRT)	0.0	42.6	31.9	25.4	7.3	2.9	0.75	0.80
Literacy achievement (IRT)	0.0	45.0	34.4	28.2	10.7	5.0	0.76	0.82
Overall achievement (IRT)	-0.0	48.8	37.5	30.2	10.6	4.6	0.77	0.81

Note: cells in columns (a)–(e) report the correlation between children within the same grouping unit (e.g. households, schools), which is the adjusted R^2 from a one-way fixed-effects model, without covariates; for the highest grade, this correlation is calculated conditioning on child age; the final two columns report ratios.

Source: authors' compilation.

Turning to the education outcomes at the bottom of the table, we observe somewhat lower magnitudes of clustering across communities and schools, partly reflecting the presence of variation between children within households.¹¹ In terms of achievement on the Uwezo tests as measured by the age-adjusted IRT scores, the correlation between siblings is almost 50 per cent, which is highly comparable to magnitudes found in a range of other countries (Section 2). More notably, however, the correlation between pupils attending the same schools, as well as between children in the same communities, is only moderately lower. Nearly 40 per cent of the overall variation in achievement is accounted for by schools, and 30 per cent between distinct residential locations. Although the definition of communities is not equivalent across studies, these latter magnitudes appear to be a factor larger than encountered in developed countries. For example, for pupils in the UK, Nicoletti and Rabe (2013) find a sibling correlation (the household upper-bound variance share) in achievement of around the same order of magnitude, but a neighbour correlation of less than 15 per cent (among children at Key Stages 2 and 4); in the USA, Solon et al. (2000) find a sibling correlation of around 50 per cent in educational attainment, but a neighbour correlation of under 20 per cent. In this light, the degree of clustering of both economic and education outcomes in East Africa appears comparatively large.

5.2 Aggregate variance bounds

Turning to the variance decomposition, Table 5 reports estimates of the three primitives required to calculate the within-community sorting component (also shown). Together these form the basis for calculation of the variance bounds, which are set out in Table 6 and cover the household upper-bound model (HUB), the unrestricted linear model (ULM), and school upper-bound model (SUB). In both tables we present estimates on a pooled (all East Africa) basis from each of the three procedures described in Section 3—namely, our own indirect fixed-effects approach (FEi), as well as the mixed-effects model

¹¹ Of course, enrolment is fully accounted for by school-level variation; but there is within-household variation in enrolment.

(MLM) and the direct fixed-effects (FE_d) procedures based on AM18.¹² The tables also report results based on absolute variance shares, given in standard deviation units ($\times 100$), and relative variance shares, given in per cent. The relative contribution of the relevant components to overall inequality of opportunity, which effectively refers to the systematic components above the level of the individual, are further illustrated in Figure 1.

Table 5: Primitive components of variance decomposition, all East Africa

		Absolute			Relative		
		FE _i	MLM	FE _d	FE _i	MLM	FE _d
Household	σ_ω	45.1 (0.2)	46.0 (0.3)	45.1 (0.2)	20.3 (0.3)	21.1 (0.3)	20.3 (0.3)
School	σ_ν	14.3 (0.2)	27.6 (0.1)	21.2 (0.2)	2.1 (0.1)	7.6 (0.1)	4.5 (0.1)
Correlation	ρ_{hs}	0.41 (0.01)	0.40 (0.02)	0.30 (0.01)	0.41 (0.01)	0.40 (0.02)	0.30 (0.01)
\Rightarrow Sorting	$2\Sigma_{hs}$	25.3 (0.3)	34.5 (1.0)	24.9 (0.3)	6.4 (0.2)	11.9 (0.6)	6.2 (0.2)

Note: columns indicate the outcome transformation and decomposition method; ‘absolute’ refers to standard deviation units ($\times 100$); ‘relative’ is as a percentage of the total variance; standard errors (in parentheses) are calculated via a clustered bootstrap procedure.

Source: authors’ compilation.

Five points stand out. First, the three decomposition methods yield consistent results for all primitives and, hence, the variance bounds. While there are some differences in precise magnitudes, discussed further below, the pattern of estimates is highly comparable across all three procedures. This suggests the results are robust to the method of estimation (e.g. mixed- versus fixed-effects) and, specifically, that the indirect approach performs adequately. Second, we find a positive correlation between the household and school effects, ranging between 0.30 and 0.41. Consequently, the derived within-community sorting component is material—for example, it is always larger than the stand-alone (lower-bound) contribution of schools. As such, within-community sorting makes a non-trivial contribution to the total variance in test scores.

Third, although the stand-alone contribution of sorting may not appear so large, particularly when viewed in relative terms (between 12 and 6 per cent), this must be put in context. According to the Uwezo data, an additional year of schooling is associated with an approximate 0.18 standard deviation increase in a child’s test score *ceteris paribus*. Thus, the contribution of sorting to the variance in test scores is roughly equivalent to around half a year of schooling. Additionally, sources of inequality of educational opportunity outside the household, including sorting, are substantial. Considering the ULM results in Table 6, the combination of schools, communities, and sorting is always greater than the household contribution alone; and the same insight derives from the SUB, where the contributions of schooling and communities then exceed that of households.¹³

Fourth, the stand-alone contribution of schools also is fairly moderate, representing no more than 10 per cent of the total variance under the ULM estimates. Necessarily, this limits the overall contribution of sorting; in this sense, were variation between schools to increase, one would expect the contribution of

¹² For the MLM results, variance components are calculated from the estimated BLUPs plus their standard error, which match the population second moments. We also clean the school and household BLUPs of cross-correlation with the random community effects, such that they are comparable to the uncorrelated variance terms (primitives) required to estimate the sorting effect.

¹³ Another way of interpreting the magnitude of the sorting contribution is in terms of the gap between the lower- and upper-bound contributions of schools and households. Following Table C1, the smaller the correlation coefficient, the smaller the gap. But for both effects, the gap is relatively wide—based on the direct method, the school effect ranges from 4.2 to 11.3 per cent of the variation in achievement.

Table 6: Decomposition of variation in achievement across East Africa

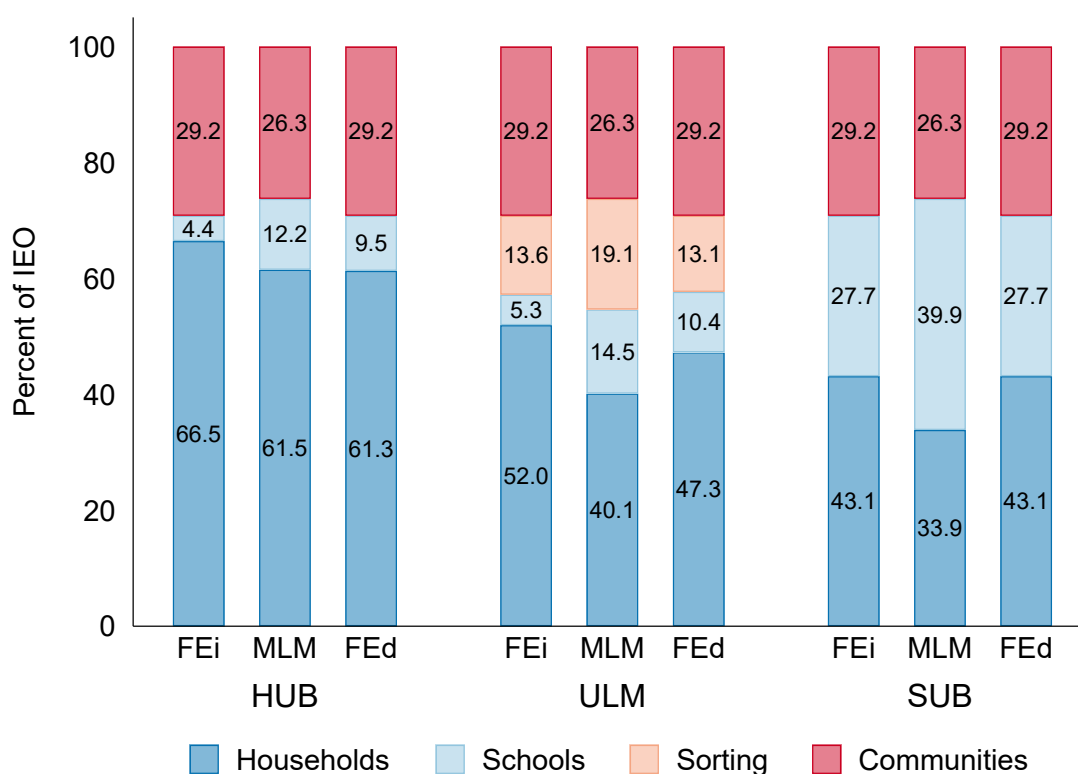

Method →	FEi			MLM			FEd		
Model →	HUB	ULM	SUB	HUB	ULM	SUB	HUB	ULM	SUB

Note: super-columns indicate the decomposition method and sub-columns the assumed variance components model, which are the HUB, the ULM, and the SUB; standard errors (in parentheses) are calculated via a clustered bootstrap procedure.

Source: authors' compilation.

sorting also to be larger (assuming the same correlation holds). In comparative terms, however, these magnitudes are not especially small. For example, AM18 estimate that school *and* community effects jointly explain around 5 per cent of the variation in high school graduation rates (lower bounds). Here, schools alone account for roughly the same amount of variation in achievement; but, when combined with community effects, the joint contribution is at least 15 per cent (Table 6). Similarly, the joint contribution of schools and communities taken from the school upper-bound estimates, which are generally more comparable to estimates found elsewhere (e.g. Freeman and Viarengo 2014) are hardly trivial. Our estimates for East Africa place this joint effect at around 25 per cent (at least), which is similar to the average school-effect variance contribution calculated by Pritchett and Viarengo (2015) for a range of countries. So, while the present results do point to some similarities in the respective variance contributions of different components between East Africa and elsewhere, the material contribution of residential location within the joint school–community effect is noteworthy.

Figure 1: Variance components (in percentage of IEO), alternative methods, and models, East Africa pooled

Notes: bars indicate the percentage contribution of each factor to IEO, which is the variance accounted for by systematic supra-individual factors (households, schools, communities, and their covariance).

Source: authors' compilation based Table 6.

Fifth, differences in estimates between the three decomposition methods appear to derive from two main sources. On the one hand, some of the differences for the correlation and sorting components simply reflect the sensitivity of calculations based on Equation (3b). Recall that we estimate ρ_{hs} from the household- and school-effect lower bounds. Thus, even minor differences here, such as slightly larger values under the MLM approach, are magnified in the estimates for the correlation term (as it is their product that is of interest for sorting). On the other hand, the mixed- and fixed-effects approaches treat the community effects in a slightly different fashion. In the latter case, community effects are removed from the joint fixed effect (households plus schools) in the first of the series of orthogonal projections (see Appendix A3). As such, and in similar fashion to the upper-bound models discussed in Section 2, the estimated community variance contribution will capture *both* the direct effect of shared community-level factors on outcomes (e.g. via environmental conditions) plus any covariance with either household or school factors. Thus, any possible sorting of households (or teachers) across different communities will be absorbed by the community effect.¹⁴ In the mixed-effects approach, all terms are estimated simultaneously, meaning that a strict distinction between within- and between-community components is not enforced *ex ante*. Although we implement a correction for this to obtain the uncorrelated school and household components (see above), this methodological difference is likely to explain the (small) disparities in our estimates of the community effect and the uncorrelated variance components.

¹⁴ Since we do not observe the same households (or teachers) across different communities, we are not able to distinguish between the direct and sorting effects associated with residential location.

5.3 Subgroup heterogeneity

Averages can often hide substantial heterogeneity. Thus, to look behind the pooled results, we take advantage of the properties of the variance and calculate the decomposition for specific sub-groups. These results are presented in Table 7, where we stratify individuals along various dimensions—gender, age group, schooling status, school type, and SES quintile. For simplicity, and given the broad consistency across the empirical procedures, hereafter we only present results for the direct fixed-effects method. This is chosen as it gives the most conservative estimates for both the correlation coefficient and sorting component (see Table 5). For reference, Appendix Table C2 presents the identical subgroup decomposition in absolute magnitudes, and Tables C3 and C4 present the same relative and absolute results based on the mixed-effects method, which provides the largest estimates of the sorting component among the three methods.

Table 7: Sub-group variance decomposition (as a percentage of total variance)

Group	Level	Individual σ_x^2	Household σ_h^2	School σ_s^2	Sort $2\Sigma_{hs}$	Community σ_c^2	Residential σ_e^2	Total σ_t^2	Correlation ρ_{hs}
Female	No	0.9 (0.0)	22.4 (0.5)	5.0 (0.1)	13.8 (0.3)	6.4 (0.2)	51.6 (1.0)	100.0 –	0.30 (0.01)

Note: the table reports direct fixed-effects variance decomposition estimates, based on the unrestricted linear model representation; standard errors (in parentheses) are calculated via a clustered bootstrap procedure.

Source: authors' compilation.

Focusing on the main insights, there are no systematic difference in the variance components by gender or age. However, there are moderate differences between socio-economic groups. In particular, lower quintiles display comparatively larger contributions due to both households and schools, as well as a higher correlation coefficient, leading to a larger sorting component (5.4 versus 3.7 per cent). In other words, IEO is larger among the less advantaged. Even more critical differences emerge between children who are in and out of school. Recall that the school effect treats all children within each community who are not enrolled as a separate category (effect). Thus, when we undertake the decomposition for *all*

children, the school and sorting effects not only refer to specific schools (for those enrolled), but also the effect of the local environment (for children out of school), including the general quality of available schools. In this sense, the overall variance decomposition (e.g. Table 6) refers to both the extensive and intensive margins of engagement in the school system.

Understood in this light, the variance decomposition for the sub-group of enrolled children only captures variation at the intensive margin within the formal school system; and the variance decomposition for the sub-group of non-enrolled children only captures variation at the intensive margin outside of the schooling system. Since we note that the household–school–effect correlation is considerably lower within these two sub-groups (<15 per cent versus 24 per cent overall), mechanically this means that the group-specific averages of both effects must not only diverge considerably from the overall means, but they do so in the same direction as the correlation coefficient. That is, out-of-school children face both lower household *and* lower (general) school effects. In turn, much of the contribution due to sorting is at the extensive margin, reflecting differences in conditions faced by children attending school and those who do not. Plausibly, some of this may be due to a causal effect of poor-quality local schools faced by less-advantaged children on the decision to attend; but we cannot prove this here.

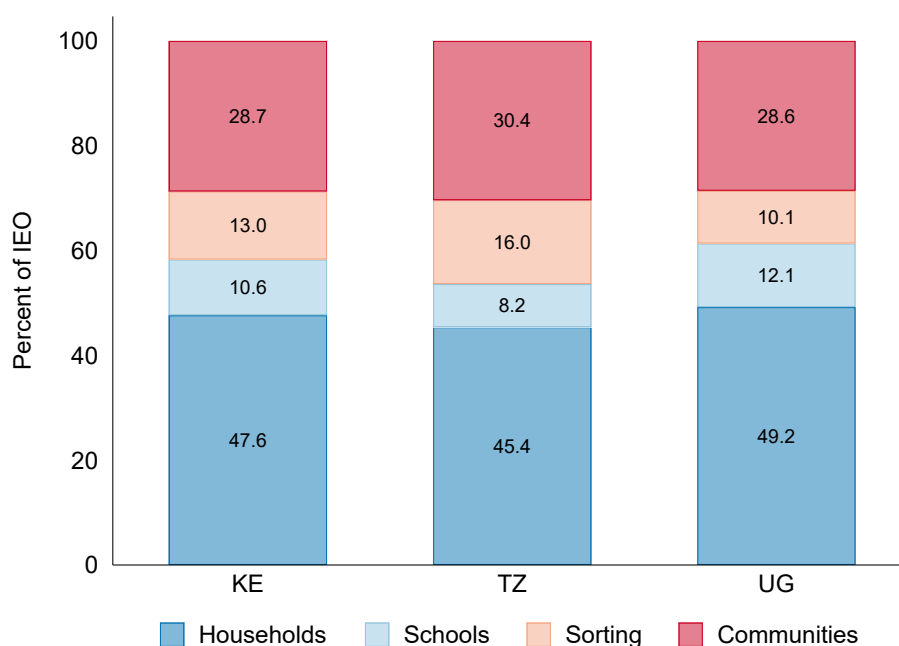

The final sub-group distinction in Table 7 points to differences between school types within the schooling system. In particular, we find a larger household–school–effect correlation and (correspondingly) a larger relative contribution of sorting among children attending private school compared to those attending public school (16 versus 12 per cent). We also note that the contribution of variation between schools is moderately larger in the private sector. This may well reflect differences associated with lower- and higher-cost private schools, where these segments serve children of quite different backgrounds. Also, and consistent with previous literature, this suggests that where there is greater scope for school choice, processes of sorting tend to be larger.

5.4 Spatial heterogeneity

A related form of heterogeneity relates to geographical locations. Arguably, this is particularly relevant from the perspective of policy as it speaks to the possibility of targeted interventions. A spatial perspective is also motivated by educational differentials within each country, as shown in Table 2. These indicate large differences in both the average level and variance of test scores across regions of each country. Retaining our focus on the unrestricted linear model presentation estimated via the direct (fixed-effects) method, Figure 2 illustrates the relative variance components for each country, and Tables C5–C7 report results at the regional level within each country.

As in the previous subsection, we find substantial heterogeneity in the size and relative importance of the different factors. Between countries, the structure of (relative) IEO appears most distinct in Tanzania, where the contribution of communities and sorting is generally larger. Within countries, the absolute variance contribution of different components can vary by a factor of around three. For instance, in Kenya the absolute contribution of sorting in the Central region is 0.11 standard deviation units versus 0.33 in the North Eastern region. Similarly, we see large differences in the variance contribution of schools, ranging from 0.13 (Central) to 0.30 units (North Eastern). In relative terms, such differences are somewhat less pronounced; but, even here there remain material differences in the contributions of schools and sorting between regions. We also note that regions containing the capital city in each country (defined here as Central in Kenya and Uganda, and Dar Es Salaam in Tanzania) tend to display comparatively lower absolute test-score inequalities, as well as somewhat smaller variation due to schools and sorting. This is consistent with an interpretation that capital cities tend to provide more equal access to schools of a similar quality.

Figure 2: Variance components (as a percentage of IEO), unrestricted linear model, by country

Note: bars indicate the percentage contribution of each factor to inequality of educational opportunity (IEO), which is the variance accounted for by systematic supra-individual factors (households, schools, communities, and their covariance); estimates are taken from the direct fixed-effects variance decomposition procedure, based on the unrestricted linear model representation; KE is Kenya; TZ is Tanzania (mainland); and UG is Uganda.

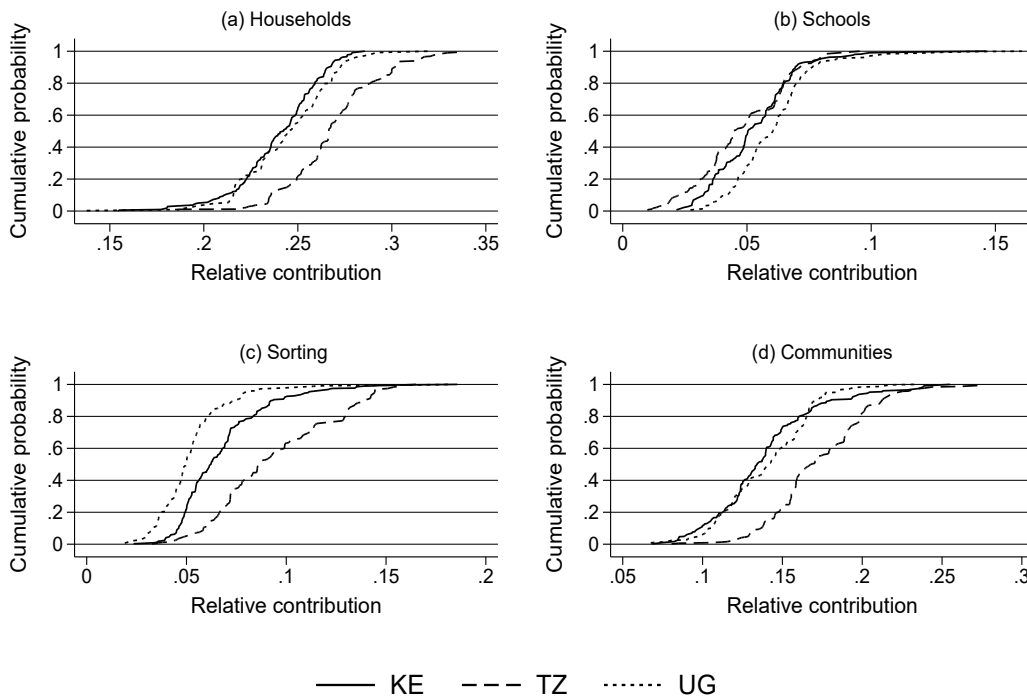

Source: authors' compilation.

An advantage of the Uwezo data is that we can run the same analysis at the district level. Figure 3 plots the cumulative empirical district-level distributions of the relative variance shares for the four main IEO components taken from the preferred estimates, by country. These confirm substantial variations across all components within each country, but country-specific differences continue to be evident—that is, the distribution functions display (approximate) first-order dominance in all cases. Variation in the magnitude of sorting across countries is confirmed in Figure 4, which shows the cumulative distribution of the estimates for ρ_{hs} across districts, based on both the direct and MLM procedures. This underlines that the correlation between household and school effects is substantially larger in Tanzania—for example, for the median district the correlation in Tanzania is almost twice that in Uganda. But within each country, movement from the 10th to the 90th percentile of the district-level distribution is associated with at least a 15 percentage point increase in the correlation coefficient. In other words, spatial heterogeneity in sorting is material.

5.5 Long-run inequalities

Finally, following the spirit of Kremer (1997), we consider the implications of sorting for long-run (steady-state) educational inequalities. The key idea here is that in the presence of positive educational sorting, children from more advantaged families receive a double benefit that can be expected to exacerbate inequalities over time. Such children benefit both from family circumstances and from higher-quality schooling, which has a multiplicative effect across generations.

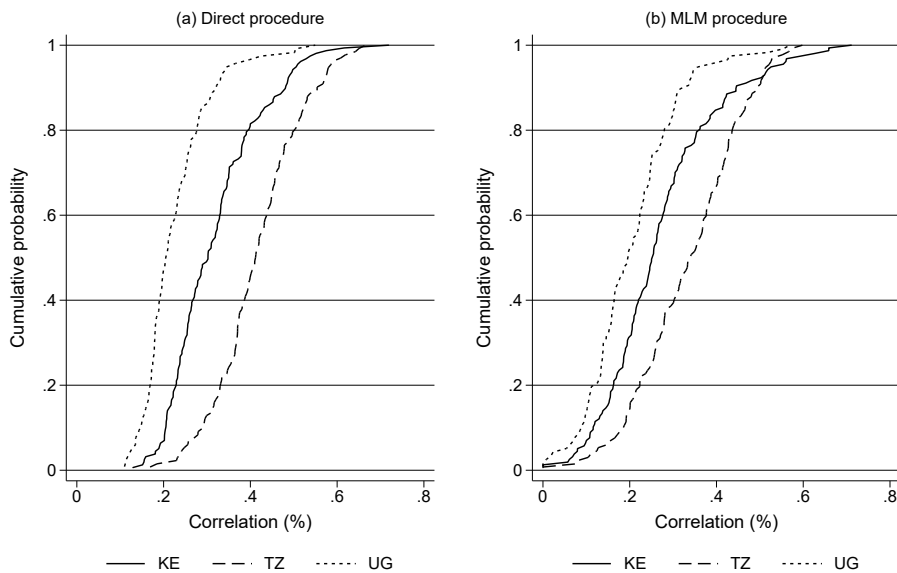

Figure 3: Cumulative distribution of variance components (in per cent) across districts, by country

Note: lines indicate the cumulative distribution of relative contributions of each factor to total test-score variance; estimates taken from the direct fixed-effects variance decomposition procedure, based on the unrestricted linear model representation.

Note: lines indicate the cumulative distribution of estimates for the household–school pairwise-correlation coefficient under different decomposition procedures (MLM and FE), based on the unrestricted linear model representation.

Source: authors' compilation.

In order to quantify the potential magnitude of these effects, we move to a dynamic or intergenerational setting. Furthermore, we adopt the simple formulation that household effects (h) are directly proportional to parental achievement, reflecting both parental capacity to support learning and other characteristics that flow from their educational level. Indexing generations by g , and using previous notation, these assumptions imply $h_{jg} \approx h_{j0} + \delta t_{j,g-1}$, which in turn means:

$$\delta^2 = \frac{\sigma_{h_g}^2}{\sigma_{t_{g-1}}^2} = \frac{\sigma_{\omega_g}^2}{(1 - \rho_{hs,g}^2)\sigma_{t_{g-1}}^2} = \frac{\bar{\delta}^2}{1 - \rho_{hs,g}^2} \quad (7)$$

where $\bar{\delta} = \sigma_{\omega_g}^2 / \sigma_{t_{g-1}}^2$ is the sorting-invariant or raw intergenerational persistence parameter. From this, we can then solve for the long-run steady-state level of educational inequality:

$$\sigma_t^2 = \frac{\sigma_v^2 + 2\bar{\delta}\rho\sigma_v\sigma_t + (\sigma_c^2 + \sigma_e^2)(1 - \rho^2)}{1 - \rho^2 - \bar{\delta}^2} \quad (8)$$

where σ_c^2 is the upper-bound variance contribution associated with residential location (which we treat as exogenous, for simplicity). (See Appendix A for the derivation).

To simulate this model, a value for the raw persistence parameter needs to be chosen. To do so, we opt for a data-driven approach and make the assumption that currently observed inequality is approximately at the steady state (i.e. $\sigma_t^2 = \sigma_t^2$), allowing us to solve for $\bar{\delta}$ using Equation (A3c) based on previously estimated values of the primitives. This gives us the magnitude of the persistence parameter that would maintain achievement inequality at current levels. Fixing $\bar{\delta}$ at this level also means that simulations based on changes to (other) primitives in the model can be interpreted directly with reference to the current magnitude of achievement inequality. Appendix Figure D1 plots the resulting district-level cumulative distributions of the inequality-constant persistence parameter, which range from 0.30 to 0.56; and the corresponding pooled overall coefficient is 0.46. Notably, these magnitudes are broadly consistent with estimates of intergenerational regression coefficients in educational attainment found elsewhere. For instance, Hertz et al. (2007) estimate an average persistence parameter of 0.42 for a range of mostly developed countries. However, existing estimates for (low-income) developing countries typically point to somewhat larger values. For instance, Emran and Shilpi (2015) find a persistence parameter of around 0.50 in India, and in a sample of African countries, Azomahou and Yitbarek (2016) find an average persistence of 0.66. These values are generally larger than our own estimates, implying a higher steady-state level of educational inequality than observed today.¹⁵ In other words, our baseline assumption is likely to be conservative.

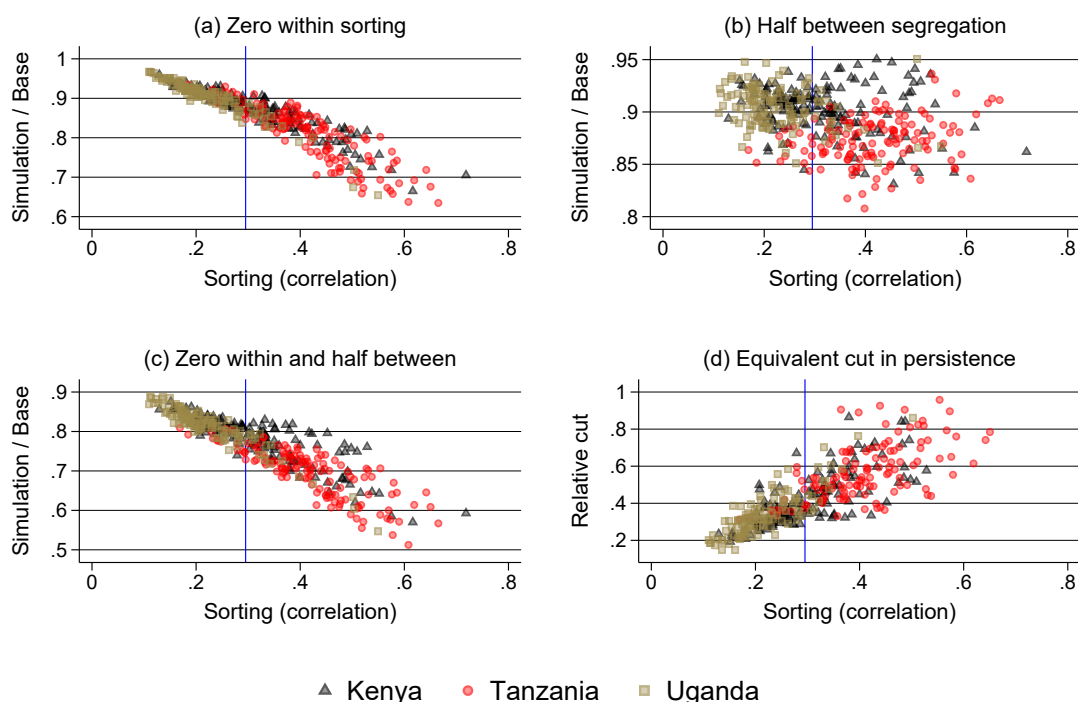

With the constant-inequality persistence parameter in hand, we now use Equation (A3c) to simulate the steady-state level of inequality under alternative assumptions for other inputs. First, we set the sorting correlation coefficient ρ to zero, under which the same equation simplifies to $\sigma_t^2 = (\sigma_v^2 + \sigma_c^2 + \sigma_e^2) / (1 - \bar{\delta}^2)$. Figure 5(a) plots the results of this exercise, taking districts as the unit of observation, and where the magnitudes of the primitives entering each unit-level calculation are taken from the earlier FEd estimates. At the average magnitude of the sorting coefficient, indicated by the blue vertical lines, steady-state inequality falls by about 12 per cent relative to the baseline; however, in a non-trivial number of districts the reduction is more than 20 per cent. In light of earlier results, this reveals that eliminating educational sorting would lead to a substantially larger reduction in long-run inequality than might be suggested by the relative variance contribution of sorting itself (Figure 3). Indeed, the relative variance contribution due to sorting is roughly only half the expected proportional decline in inequality if sorting were to be reduced.

Eliminating within-community sorting does not address segregation of either households or teachers (schools) by residential location, as captured by the community effect. Our earlier results indicated this

¹⁵ Employing the alternative assumption: $\delta = \bar{\delta} \sqrt{1 - \rho_{hs}^2} = 0.66 \sqrt{1 - \rho_{hs}^2}$, we find steady-state inequality is expected to be 40 per cent larger than at present (for the region as a whole).

term was material, potentially reflecting significant barriers to internal mobility in the East African context. To look at the implications of this more general form of sorting for long-run educational inequality, Figure 5(b) estimates the unique impact of halving the variance contribution due to community effects. For the average district, the reduction in inequality compared to the baseline is similar to the first simulation, falling by 10 per cent. Combining these two scenarios equates to more than a 20 per cent fall in long-run inequality, on average—see Figure 5(c). To put this magnitude of reduction in inequality in context, it is equivalent to a very substantial fall in the intergenerational persistence of educational achievement. Figure 5(d) reports the percentage reduction in the persistence parameter required to match the effect of both eliminating within-community sorting and halving between-community segregation. On average, the equivalent reduction is over 40 per cent, implying a required persistence parameter of 0.27 (versus 0.42 in the baseline).

Figure 5: Simulations of steady-state inequality

Note: panel (a) plots the ratio of long-run inequality to present inequality, assuming sorting were eliminated; and panel (b) indicates the reduction in the intergenerational persistence parameter required to achieved the same fall in long-run inequality (e.g. 0.1 implies a 10 per cent reduction); the vertical blue line is the pooled correlation coefficient, given in the x -axis.

6 Conclusions

There is continued debate regarding the extent to which sorting exacerbates inequalities, including in educational attainment and achievement. We add to this debate by undertaking a variance decomposition, treating sorting as the contribution of the covariance between household and school effects to variation in educational outcomes. We quantify the contribution of sorting to learning inequalities among over 1,000,000 children in three East African countries: Kenya, mainland Tanzania, and Uganda.

To estimate the contribution of sorting, we propose three complementary approaches. First, we show how an indirect procedure, based on separate one-way fixed-effects estimators, can identify the lower-bound or uncorrelated variance contributions of both schools and households, which are necessary primitives to derive the sorting component. Second, we adopt the approach of AM18, who show how group

means of observed factors can absorb confounding effects of sorting on unobserved characteristics. This helps isolate the independent contributions of the factors of interest, from which lower-bound variance contributions can be estimated using mixed-effects estimators. Third, we extend the AM18 approach to allow for fixed as opposed to random effects, which is both computationally more tractable and better suited to exploring sub-group heterogeneity.

Empirically, all three estimation procedures indicate positive sorting of pupils across schools that accounts for up to 8 per cent of the total test-score variance and almost one-fifth of the joint variation in test scores due to schools, communities, and households. The sorting contribution tends to be larger among families at the top and bottom ends of the socio-economic distribution, among those sending their children to private schools, as well as in specific locations.

To explore the implications of these results, we conduct simulations of how learning inequality evolves over time. These show that for the average district in the region, the steady-state level of educational inequality would fall by around 10 per cent if sorting were to be fully eliminated. Moreover, in a number of districts, the reduction in inequality from eliminating sorting would be over 20 per cent of the total variance and over 40 per cent of IEO. As such, this suggests that policies that take sorting into account, and even actively counteract it, merit consideration.

Appendix A Derivations

A1 Correlated and uncorrelated components

To show the relationship between the uncorrelated and correlated school component, we start with the household upper-bound model from Table 1:

$$\sigma_v^2 = \sigma_t^2 - (1 + \gamma)^2 \sigma_h^2 - \sigma_e^2 \quad (\text{A1a})$$

$$= \sigma_h^2 + \sigma_s^2 + 2\Sigma_{hs} - (1 + \gamma)^2 \sigma_h^2 \quad (\text{A1b})$$

$$= \sigma_h^2 + \sigma_s^2 + 2\rho_{sh}\sigma_h\sigma_s - (1 + \gamma)^2 \sigma_h^2 \quad (\text{A1c})$$

$$= \sigma_s^2 - \gamma^2 \sigma_h^2 \quad (\text{A1d})$$

$$= (1 - \rho_{hs}^2) \sigma_s^2 \quad (\text{A1e})$$

where σ_t^2 is the total variance to be decomposed. Movement from the third to the fourth line derives from the definition of the covariance term, using Equation (2), as: $\text{Cov}(h_j, s_k) \equiv \Sigma_{sh} = \gamma \text{Var}(h_j)$; and movement from the fourth to the final line uses the fact that γ defines the slope of the (approximate) linear relation between \bar{h} and s : $\gamma = \rho_{hs}(\sigma_s/\sigma_h)$.

A2 Steady-state inequality

Based on the unrestricted linear model of Table 1, combined with Equations (4) and (7), education inequality evolves as follows:

$$\sigma_t^2 = \delta^2 \sigma_{t_{g-1}}^2 + \sigma_s^2 + 2\delta\rho\sigma_s\sigma_{t_{g-1}} + \sigma_c^2 + \sigma_e^2 \quad (\text{A2})$$

In long-run equilibrium it must hold that $\forall n > 0$: $\sigma_{t_{g+n}}^2 = \sigma_{t_g}^2 = \sigma_{\bar{t}}^2$, thus:

$$\sigma_{\bar{t}}^2(1 - \delta^2) = \sigma_s^2 + 2\delta\rho_{hs}\sigma_s\sigma_{\bar{t}} + \sigma_c^2 + \sigma_e^2 \quad (\text{A3a})$$

$$\sigma_{\bar{t}}^2(1 - \delta^2) = \frac{\sigma_v^2}{1 - \rho^2} + \frac{2\delta\rho\sigma_v\sigma_{\bar{t}}}{\sqrt{1 - \rho^2}} + \sigma_c^2 + \sigma_e^2 \quad (\text{A3b})$$

$$\sigma_{\bar{t}}^2 = \frac{\sigma_v^2 + 2\delta\bar{\rho}\sigma_v\sigma_{\bar{t}} + (\sigma_c^2 + \sigma_e^2)(1 - \rho^2)}{1 - \rho^2 - \bar{\delta}^2} \quad (\text{A3c})$$

A3 Empirical steps

Following Section 3, we recognize that estimates of separate fixed effects (e.g. household and schools) in a two-way setting are expected to be biased from a mechanical negative pairwise covariance. As such, and excluding the distinct issue of measurement error, there is no reason to suspect this concern affects estimates of their joint contribution. In light of this, to undertake the variance decompositions we begin by running a full model with multiple fixed effects. Then we apply a sequence of orthogonal projections to identify the uncorrelated components of the estimated joint effect.

Concretely, for the indirect procedure we proceed as follows:

1. Use the fully specified model to obtain the joint contribution of the latent factors (z_{jkl}).
2. Project \hat{z}_{jkl} on the location indices to obtain the (upper-bound) location-specific effect.
3. Separately project the household- and school-effect indices on the fitted residual joint factor from Step 2, ($\hat{z}_{jkl} - \hat{c}_l$), in each case obtaining their corresponding upper-bound contributions.
4. Separately project the household- and school-effect indices on the relevant residuals from Step 3 to obtain their lower-bound contributions (e.g. the school lower bound is estimated from the residual from the household upper bound: $\hat{z}_{jkl} - \hat{c}_l - \hat{h}_k^*$, $h_k^* = h_j + \gamma \bar{h}_{jk}$).

For the extension of the AM18 approach to allow for fixed effects we proceed as follows:

1. Estimate a fully specified model, including two-way fixed effects, to obtain the joint contribution of the latent factors (z_{jkl} ; see Equation 4).
2. Project \hat{z}_{jkl} on the location indices to obtain the (upper-bound) location-specific effect (\hat{c}_l).
3. Project the residual from step 2 ($\hat{z}_{jkl} - \hat{c}_l$) on the set of sorting proxies ($\bar{h}'_{O,k}$).¹⁶
4. Project the school indices (only) on the residual component of the joint factor obtained from step 3 ($\hat{z}_{jkl} - \hat{c}_l - \bar{h}'_{O,k} \hat{\beta}$) to obtain the uncorrelated school contribution.
5. Project the household indices (only) on the final residual taken from step 4 to obtain the uncorrelated household lower-bound contribution ($\hat{\omega}_k$).

In both of the above approaches, the sequential orthogonal projections ensure that the primitives of interest are not only mutually uncorrelated, but also uncorrelated with any observed variables that enter the model, including the sorting proxies. Furthermore, any such additional control variables can be entered in a straightforward manner. For instance, individual-specific observed variables would enter the fully specified model in step 1 of each procedure. Also, observed household (school) characteristics are added in step 3 of each procedure, thereby tightening the one-way estimates of the school (household) effects (see Raum et al. 2006).

¹⁶ Where, $\bar{h}'_{O,k}$ refer to school-level means derived from observed household- and pupil-level variables.
