Abstract

We develop a numerical procedure that facilitates efficient likelihood evaluation in applications involving non-linear and non-Gaussian state-space models. The procedure approximates necessary integrals using continuous approximations of target densities. Construction is achieved via efficient importance sampling, and approximating densities are adapted to fully incorporate current information. We illustrate our procedure in applications to dynamic stochastic general equilibrium models.

Keywords: particle filter; adaption, efficient importance sampling; kernel density approximation; dynamic stochastic general equilibrium model.

Richard gratefully acknowledges research support provided by the National Science Foundation under grant SES-0516642. For helpful comments, we thank Chetan Dave, Jesus Fernandez-Villaverde, Hiroyuki Kasahara, Juan Rubio-Ramirez, Enrique Sentana, and seminar and conference participants at the Universities of Comenius, Di Tella, Texas (Dallas), Pennsylvania, the 2008 Econometric Society Summer Meetings (CMU), the 2008 Conference on Computations in Economics (Paris), and the 2008 Vienna Macroeconomics Workshop. We also thank Chetan Dave for assistance with compiling the Canadian data set we analyzed. Pseudo-code, GAUSS and MATLAB code, and data sets used to demonstrate implementation of the EIS filter are available at www.pitt.edu/~dejong/wp.htm
1 Introduction

Likelihood evaluation and filtering in applications involving state-space models requires the calculation of integrals over unobservable state variables. When models are linear and stochastic processes are Gaussian, required integrals can be calculated analytically via the Kalman filter. Departures entail integrals that must be approximated numerically. Here we introduce an efficient procedure for calculating such integrals: the EIS filter.

The procedure takes as a building block the pioneering approach to likelihood evaluation and filtering developed by Gordon, Salmond and Smith (1993) and Kitagawa (1996). Their approach employs discrete fixed-support approximations to unknown densities that appear in the predictive and updating stages of the filtering process. The discrete points that collectively provide density approximations are known as particles; the approach is known as the particle filter. Examples of its use are becoming widespread; in economics, e.g., see Kim, Shephard and Chib (1998) for an application involving stochastic volatility models; and Fernandez-Villaverde and Rubio-Ramirez (2005, 2009) for applications involving dynamic stochastic general equilibrium (DSGE) models.

While conceptually simple and easy to program, the particle filter suffers two shortcomings. First, because the density approximations it provides are discrete, associated likelihood approximations can feature spurious discontinuities, rendering as problematic the application of likelihood maximization procedures (e.g., see Pitt, 2002). Second, the supports upon which approximations are based are not adapted: period-$t$ approximations are based on supports that incorporate information conveyed by values of the observable variables available in period $t-1$, but not period $t$ (e.g., see Pitt and Shephard, 1999). This gives rise to numerical inefficiencies that can be acute when observable variables are highly informative with regard to state variables, particularly given the presence of outliers.

Numerous extensions of the particle filter have been proposed in attempts to address these problems. For examples, see Pitt and Shephard (1999); the collection of papers in Doucet, de Freitas and Gordon (2001); Pitt (2002); Ristic et al. (2004), and the collection housed at http://www-sigproc.eng.cam.ac.uk/smc/papers.html. Typically, efficiency gains are sought through attempts at adapting period-$t$ densities via the use of information available through period $t$. However, with the exception of the extension proposed by Pitt (2002), once period-$t$ supports are established they
remain fixed over a discrete collection of points as the filter advances forward through the sample, thus failing to address the problem of spurious likelihood discontinuity. (Pitt employs a bootstrap-smoothing approximation designed to address this problem for the specialized case in which the state space is unidimensional.) Moreover, as far as we are aware, no existing extension pursues adaptation in a manner that is designed to achieve optimal efficiency.

Here we propose an extension that constructs adapted period-t approximations, but that features a unique combination of two characteristics. The approximations are continuous; and period-t supports are adjusted using a method designed to produce approximations that achieve near-optimal efficiency at the adaption stage. The approximations are constructed using the efficient importance sampling (EIS) methodology developed by Richard and Zhang (RZ, 2007). Construction is facilitated using an optimization procedure designed to minimize numerical standard errors associated with the approximated integral.

Here, our focus is on the achievement of near-optimal efficiency for likelihood evaluation. Example applications involve the analysis of DSGE models, and are used to illustrate the relative performance of the particle and EIS filters. In a companion paper (DeJong et al., 2008) we focus on filtering, and present an application to the bearings-only tracking problem featured prominently, e.g., in the engineering literature.

As motivation for our focus on the analysis of DSGE models, a brief literature review is helpful. The pioneering work of Sargent (1989) demonstrated the mapping of DSGE models into linear/Gaussian state-space representations amenable to likelihood-based analysis achievable via the Kalman filter. DeJong, Ingram and Whiteman (2000) developed a Bayesian approach to analyzing these models. Subsequent work has involved the implementation of DSGE models towards a broad range of empirical objectives, including forecasting and guidance of the conduct of aggregate fiscal and monetary policy (following Smets and Wouters, 2003).

Prior to the work of Fernandez-Villaverde and Rubio-Ramirez (2005, 2009), likelihood-based implementation of DSGE models was conducted using linear/Gaussian representations. But their findings revealed an important caveat: approximation errors associated with linear representations of DSGE models can impart significant errors in corresponding likelihood representations. As a remedy, they demonstrated use of the particle filter for achieving likelihood evaluation for non-linear model representations. But as our examples illustrate, the numerical inefficiencies noted
above suffered by the particle filter can be acute in applications involving DSGE models. By eliminating these inefficiencies, the EIS filter offers a significant advance in the empirical analysis of DSGE models.

2 Likelihood Evaluation in State-Space Representations

Let $y_t$ be a $n \times 1$ vector of observable variables, and denote $\{y_j\}_{j=1}^{T}$ as $Y_t$. Likewise, let $s_t$ be a $m \times 1$ vector of unobserved ('latent') state variables, and denote $\{s_j\}_{j=1}^{T}$ as $S_t$. State-space representations consist of a state-transition equation

$$ s_t = \gamma(s_{t-1}, Y_{t-1}, u_t), \quad (1) $$

where $u_t$ is a vector of innovations with respect to $(s_{t-1}, Y_{t-1})$, and an observation (or measurement) equation

$$ y_t = \delta(s_t, Y_{t-1}, u_t), \quad (2) $$

where $u_t$ is a vector innovations with respect to $(s_t, Y_{t-1})$. Hereafter, we refer to $u_t$ as structural shocks, and $u_t$ as measurement errors.

The likelihood function $f(Y_T)$ is obtained by interpreting (1) and (2) in terms of the densities $f(s_t|s_{t-1}, Y_{t-1})$ and $f(y_t|s_t, Y_{t-1})$, respectively. Since the representation is recursive, $f(Y_T)$ factors sequentially as

$$ f(Y_T) = \prod_{t=1}^{T} f(y_t|Y_{t-1}), \quad (3) $$

where $f(y_1|Y_0) \equiv f(y_1)$. The time-$t$ likelihood $f(y_t|Y_{t-1})$ is obtained by marginalizing over $s_t$:

$$ f(y_t|Y_{t-1}) = \int f(y_t|s_t, Y_{t-1}) f(s_t|Y_{t-1}) ds_t, \quad (4) $$

where the predictive density $f(s_t|Y_{t-1})$ is given by

$$ f(s_t|Y_{t-1}) = \int f(s_t|s_{t-1}, Y_{t-1}) f(s_{t-1}|Y_{t-1}) ds_{t-1}, \quad (5) $$

and $f(s_{t-1}|Y_{t-1})$ is the time-$(t-1)$ filtering density. Advancing the time subscript by one period,
from Bayes’ theorem, \( f(s_t|Y_t) \) is given by

\[
f(s_t|Y_t) = \frac{f(y_t, s_t|Y_{t-1})}{f(y_t|Y_{t-1})} = \frac{f(y_t|s_t, Y_{t-1}) f(s_t|Y_{t-1})}{f(y_t|Y_{t-1})}. \tag{6}
\]

Likelihood construction is achieved by calculating (4) and (5) sequentially from periods 1 to \( T \), taking as an input in period \( t \) the filtering density constructed in period \( (t-1) \). In period 1 the filtering density is the known marginal density \( f(s_0) \), which can be degenerate as a special case; i.e., \( f(s_0|Y_0) \equiv f(s_0) \).

In turn, filtering entails the approximation of the conditional (upon \( Y_t \)) expectation of some function \( h(s_t) \) (including \( s_t \) itself). In light of (6) and (4), this can be written as

\[
E_t(h(s_t)|Y_t) = \frac{\int h(s_t)f(y_t|s_t, Y_{t-1}) f(s_t|Y_{t-1}) ds_t}{\int f(y_t|s_t, Y_{t-1}) f(s_t|Y_{t-1}) ds_t}. \tag{7}
\]

3 The Particle Filter and Leading Extensions

Since our procedure is an extension of the particle filter developed by Gordon, Salmond and Smith (1993) and Kitagawa (1996), we provide a brief overview here. The particle filter is an algorithm that recursively generates random numbers approximately distributed as \( f(s_t|Y_t) \). To characterize its implementation, let \( s_t^{r,i} \) denote the \( i \)th draw of \( s_t \) obtained from the conditional density \( f(s_t|Y_{t-r}) \) for \( r = 0, 1 \). A single draw \( s_t^{r,i} \) is a particle, and a set of draws \( \{s_t^{r,i}\}_{i=1}^N \) is a swarm of particles. The object of filtration is that of transforming a swarm \( \{s_t^{0,i}\}_{i=1}^N \) into \( \{s_t^{1,i}\}_{i=1}^N \).

The filter is initialized by a swarm \( \{s_0^{0,i}\}_{i=1}^N \) drawn from \( f(s_0|Y_0) \equiv f(s_0) \).

Period-\( t \) filtration takes as input a swarm \( \{s_t^{0,i}\}_{i=1}^N \). The predictive step consists of transforming this swarm into a second swarm \( \{s_t^{1,i}\}_{i=1}^N \) according to (5). This is done by drawing \( s_t^{1,i} \) from the conditional density \( f\left(s_t^{1,i}|s_t^{0,i}, Y_{t-1}\right) \), \( i = 1, ..., N \). Note that \( \{s_t^{1,i}\}_{i=1}^N \) can be used to produce an MC estimate of \( f(y_t|Y_{t-1}) \), which according to (4) is given by

\[
\hat{f}_N(y_t|Y_{t-1}) = \frac{1}{N} \sum_{i=1}^N f(y_t|s_t^{1,i}, Y_{t-1}). \tag{8}
\]

Next, \( f(s_t|Y_t) \) is approximated by re-weighting \( \{s_t^{1,i}\}_{i=1}^N \) in accordance with (6) (the updating
step): a particle $s_{t}^{1,i}$ with prior weight $\frac{1}{N}$ is assigned the posterior weight

$$w_{t}^{0,i} = \frac{f(y_{t}|s_{t}^{1,i}, Y_{t-1})}{\sum_{j=1}^{N} f(y_{t}|s_{t}^{1,j}, Y_{t-1})}.$$  

(9)

The filtered swarm $\{s_{t}^{0,i}\}_{i=1}^{N}$ is then obtained by drawing with replacement from the swarm $\{s_{t}^{1,i}\}_{i=1}^{N}$ with probabilities $\{w_{t}^{0,i}\}_{i=1}^{N}$ (i.e., bootstrapping).

Having characterized the particle filter, its strengths and weaknesses (well documented in previous studies) can be pinpointed. Its strength lies in its simplicity: the algorithm described above is straightforward and universally applicable.

Its weaknesses are twofold. First, it provides discrete approximations of $f(s_{t}|Y_{t-1})$ and $f(s_{t}|Y_{t})$, which moreover are discontinuous functions of the model parameters. The associated likelihood approximation is therefore also discontinuous, rendering the application of maximization routines problematic (a point raised previously, e.g., by Pitt, 2002).

Second, as the filter enters period $t$, the discrete approximation of $f(s_{t-1}|Y_{t-1})$ is set. Hence the swarm $\{s_{t}^{1,i}\}_{i=1}^{N}$ produced in the augmentation stage ignores information provided by $y_{t}$. (Pitt and Shephard, 1999, refer to these augmenting draws as “blind”.) It follows that if $f(y_{t}|s_{t}, Y_{t-1})$ - treated as a function of $s_{t}$ given $Y_{t}$ - is sharply peaked in the tails of $f(s_{t}|Y_{t-1})$, $\{s_{t}^{1,i}\}_{i=1}^{N}$ will contain few elements in the relevant range of $f(y_{t}|s_{t}, Y_{t-1})$. Thus $\{s_{t}^{1,i}\}_{i=1}^{N}$ represents draws from an inefficient sampler: relatively few of its elements will be assigned appreciable weight in the updating stage in the following period. This is known as “sample impoverishment”: it entails a reduction in the effective size of the particle swarm.

Extensions of the particle filter employ adaption techniques to generate gains in efficiency. An extension proposed by Gordon et al. (1993) and Kitagawa (1996) consists simply of making $N' \gg N$ blind proposals $\{s_{t}^{1,j}\}_{j=1}^{N'}$ as with the particle filter, and then obtaining the swarm $\{s_{t}^{0,i}\}_{i=1}^{N}$ by sampling with replacement, using weights computed from the $N'$ blind proposals. This is the sampling-importance resampling filter; it seeks to overcome the problem of sample impoverishment by brute force, and can be computationally expensive.

Carpenter, Clifford and Fearnhead (1999) sought to overcome sample impoverishment using a stratified sampling approach to approximate the prediction density. This is accomplished by
defining a partition consisting of $K$ subintervals in the state space, and constructing the prediction density approximation by sampling (with replacement) $N_k$ particles from among the particles in each subinterval. Here $N_k$ is proportional to a weight defined for the entire $k^{th}$ interval; also, $\sum_{k=1}^{K} N_k = N$. This produces wider variation in re-sampled particles, but if the swarm of proposals $\{s_t^{1,i}\}_{i=1}^{N}$ are tightly clustered in the tails of $f(s_t|Y_{t-1})$, so too will be the re-sampled particles.

Pitt and Shephard (1999) developed an extension that ours perhaps most closely resembles. They tackle adaption using an Importance Sampling (IS) procedure. Consider as an example the marginalization step. Faced with the problem of calculating $f(y_t|Y_{t-1})$ in (4), but with $f(s_t|Y_{t-1})$ unknown, importance sampling achieves approximation via the introduction into the integral of an importance density $g(s_t|Y_t)$:

$$f(y_t|Y_{t-1}) = \int f(y_t|s_t, Y_{t-1}) f(s_t|Y_{t-1}) g(s_t|Y_t) ds_t.$$  \hspace{0.5cm} (10)

Obtaining drawings $s_{t}^{0,i}$ from $g(s_t|Y_t)$, this integral is approximated as

$$\hat{f}(y_t|Y_{t-1}) \approx \frac{1}{N} \sum_{i=1}^{N} \frac{f(y_t|s_{t}^{0,i}, Y_{t-1}) f(s_{t}^{0,i}|Y_{t-1})}{g(s_{t}^{0,i}|Y_t)}.$$  \hspace{0.5cm} (11)

Pitt and Shephard referred to the introduction of $g(s_t|Y_t)$ as adaption. Full adaption is achieved when $g(s_t|Y_t)$ is constructed as being proportional to $f(y_t|s_t, Y_{t-1}) f(s_t|Y_{t-1})$, rendering the ratios in (11) as constants. Pitt and Shephard viewed adaption as computationally infeasible, due to the requirement of computing $f(s_{t}^{0,i}|Y_{t-1})$ for every value of $s_{t}^{0,i}$ produced by the sampler. Instead they developed samplers designed to yield partial adaption.

The samplers result from Taylor series approximations of $f(y_t|s_t, Y_{t-1})$ around $s_t = \mu^k_t = E\left(s_t|s_{t-1}^{0,k}, Y_{t-1}\right)$. A zero-order expansion yields their auxiliary particle filter; a first-order expansion yields their adapted particle filter. (Smith and Santos, 2006, study examples under which it is possible to construct samplers using second-order expansions.)

These samplers help alleviate blind sampling by reweighting $\{s_{t-1}^{0,i}\}$ to account for information conveyed by $y_t$. However, sample impoverishment can remain an issue, since the algorithm does not allow adjustment of the support of $\{s_{t-1}^{0,i}\}$. Moreover, the samplers are suboptimal, since $\mu^k_t$ is incapable of fully capturing the characteristics of $f(y_t|s_t, Y_{t-1})$. Finally, these samplers remain
prone to the discontinuity problem.

Pitt (2002) addressed the discontinuity problem for the special case in which the state space is unidimensional by replacing the weights in (9) associated with the particle filter (or comparable weights associated with the auxiliary particle filter) with smoothed versions constructed via a piecewise linear approximation of the empirical c.d.f. associated with the swarm \( \left\{ s^0_t \right\}_{i=1}^N \). This enables the use of common random numbers (CRNs) to produce likelihood estimates that are continuous functions of model parameters (Hendry, 1994).

4 The EIS Filter

EIS is an automated procedure for constructing continuous importance samplers fully adapted as global approximations to targeted integrands. Section 4.1 outlines the general principle behind EIS, in the context of evaluating (4). Section 4.2 then discusses a key contribution of this paper: the computation of \( f(s_t|Y_{t-1}) \) in (4) at auxiliary values of \( s_t \) generated under period-\( t \) EIS optimization. Section 4.3 discusses two special cases that often characterize state-space representations: partial measurement of the state space; and degenerate transition densities. Elaboration on the pseudo-code presented below is available at www.pitt.edu/~dejong/wp.htm.

4.1 EIS integration

Let \( \varphi_t(s_t) = f(y_t|s_t, Y_{t-1}) \cdot f(s_t|Y_{t-1}) \) in (4), where the subscript \( t \) in \( \varphi_t \) replaces \( (y_t, Y_{t-1}) \). Implementation of EIS begins with the preselection of a parametric class \( K = \{ k(s_t; a_t); a_t \in A \} \) of auxiliary density kernels. Corresponding density functions \( g \) are

\[
g(s_t; a_t) = \frac{k(s_t; a_t)}{\chi(a_t)}, \quad \chi(a_t) = \int k(s_t; a_t)ds_t. \tag{12}
\]

The selection of \( K \) is problem-specific; here we discuss Gaussian specifications; DeJong et al. (2008) discusses an extension to piecewise-continuous specifications. The objective of EIS is to select the parameter value \( \hat{a}_t \in A \) that minimizes the variance of the ratio \( \varphi_t(s_t) \frac{g(s_t)}{g(s_t|a_t)} \) over the range of integration.
Following RZ, a (near) optimal value \( \hat{a}_t \) is obtained as the solution to

\[
(\hat{a}_t, \hat{c}_t) = \arg \min_{a_t, c_t} \int \left[ \ln \varphi_t(s_t) - c_t - \ln k(s_t; a_t) \right]^2 g(s_t; a_t) ds_t,
\]

(13)

where \( c_t \) is an intercept meant to calibrate \( \ln(\varphi_t/k) \). Equation (13) is a standard least squares problem, except that the auxiliary sampling density itself depends upon \( a_t \). This is resolved by reinterpreting (13) as the search for a fixed-point solution. An operational MC version implemented (typically) using \( R << N \) draws, is as follows:

**Step** \( l + 1 \): Given \( \hat{a}_t^l \), draw intermediate values \( \{s^i_{t,l} \}_{i=1}^R \) from the step-\( l \) EIS sampler \( g(s_t; \hat{a}_t^l) \), and solve

\[
(\hat{a}_{t+1}^l, \hat{c}_{t+1}^l) = \arg \min_{a_t, c_t} \sum_{i=1}^R \left[ \ln \varphi_t(s^i_{t,l}) - c_t - \ln k(s^i_{t,l}; a_t) \right]^2.
\]

(14)

If \( K \) belongs to the exponential family of distributions, there exists a parameterization \( a_t \) such that the auxiliary problems in (14) are linear.

Three points bear mentioning here. First, the evaluation of \( \varphi_t(s_t) \) entails the evaluation of \( f(s_t|Y_{t-1}) \), which is unavailable analytically and must be approximated; this is discussed below in Section 4.2. Second, the selection of the initial value \( \hat{a}_1^l \) is important for achieving rapid convergence; Section 5 presents an effective algorithm for specifying \( \hat{a}_1^l \) in applications involving DSGE models (one step in each of the examples we consider). Third, to achieve rapid convergence, and to ensure continuity of corresponding likelihood estimates, \( \{s^i_{t,j} \} \) must be obtained by a transformation of a set of common random numbers (CRNs) \( \{u^i_t \} \) drawn from a canonical distribution (i.e., one that does not depend on \( a_t \); e.g., standardized Normal draws when \( g \) is Gaussian).

At convergence to \( \hat{a}_t \), the EIS filter approximation of \( f(y_t|Y_{t-1}) \) in (4) is given by

\[
\hat{f}_N(y_t|Y_{t-1}) = \frac{1}{N} \sum_{i=1}^N \omega(s^i_t; \hat{a}_t),
\]

(15)

\[
\omega(s^i_t; \hat{a}_t) = \frac{f(y_t|s^i_t, Y_{t-1}) f(s^i_t|Y_{t-1})}{g(s^i_t; \hat{a}_t)},
\]

(16)

where \( \{s^i_t \}_{i=1}^N \) are drawn from the (final) EIS sampler \( g(s_t; \hat{a}_t) \). This estimate converges almost surely towards \( f(y_t|Y_{t-1}) \) under weak regularity conditions (outlined, e.g., by Geweke, 1989). Violations of these conditions typically result from the use of samplers with thinner tails than those of
\( \varphi_t \). RZ offer a diagnostic measure that is adept at detecting this problem. The measure compares the MC sampling variances of the ratio \( \frac{\varphi_t}{g} \) under two values of \( a_t \): the optimal \( \hat{a}_t \), and one that inflates the variance of the \( s_t \) draws by a factor of 3 to 5.

Pseudo-code for implementing the EIS filter is as follows:

- At period \( t \), we inherit the sampler \( g(s_{t-1}; \hat{a}_{t-1}) \), and corresponding draws and weights \( \{s^{i}_{t-1}, \omega(s^{i}_{t-1}; \hat{a}_{t-1})\}_{i=1}^{N} \) from period \( t-1 \), where in period 0 \( g(s_0; \hat{a}_0) \equiv f(s_0) \).

- Using an initial value \( \hat{a}_t^1 \), obtain \( R \) draws \( \{s^{i,R}_{t}\}_{i=1}^{R} \) from \( g(s_t; \hat{a}_t^1) \), and solve (14) to obtain \( \hat{a}_t^2 \).
  
  Repeat until convergence, yielding \( \hat{a}_t \).

- Obtain \( N \) values \( \{s_{t}\}_{i=1}^{N} \) from the optimized sampling density \( g(s_t; \hat{a}_t) \), and calculate (15) and (16).

- Pass \( g(s_t; \hat{a}_t) \) and \( \{s^{i}_{t}, \omega(s^{i}_{t}; \hat{a}_{t})\}_{i=1}^{N} \) to period \( t+1 \). Repeat until period \( T \) is reached.

As we shall now explain, \( \{s^{i}_{t}, \omega(s^{i}_{t}; \hat{a}_{t})\}_{i=1}^{N} \) are passed from period \( t \) to \( t+1 \) to facilitate the approximation of the unknown \( f(s_t|y_{t-1}) \) appearing in (14) and (16).

### 4.2 Continuous approximations of \( f(s_t|y_{t-1}) \)

As noted, the EIS filter requires the evaluation of \( f(s_t|y_{t-1}) \) at any value of \( s_t \) needed for EIS iterations. Here we discuss three operational alternatives for overcoming this hurdle (a fourth, involving non-parametric approximations, is also possible but omitted here). Below, \( S \) denotes the number of points used for each individual evaluation of \( f(s_t|y_{t-1}) \).

*Weighted-sum approximations*

Combining (5) and (6), we can rewrite \( f(s_t|y_{t-1}) \) as a ratio of integrals:

\[
 f(s_t|y_{t-1}) = \frac{\int f(s_{t-1}, Y_{t-1}) f(y_{t-1}|s_{t-1}, Y_{t-2}) f(s_{t-1}|Y_{t-2}) ds_{t-1}}{\int f(y_{t-1}|s_{t-1}, Y_{t-2}) f(s_{t-1}|Y_{t-2}) ds_{t-1}}, \tag{17}
\]

where the denominator represents the likelihood integral for which an EIS sampler has been con-
structured in period $t - 1$. A direct MC estimate of $f(s_t|Y_{t-1})$ is given by

$$ \hat{f}_S(s_t|Y_{t-1}) = \frac{\sum_{i=1}^{S} f(s_{t|s_{t-1}^{i}, Y_{t-1}}) \cdot \omega(s_{t-1}^{i}; \hat{a}_{t-1})}{\sum_{i=1}^{S} \omega(s_{t-1}^{i}; \hat{a}_{t-1})}, \quad (18) $$

where $\{s_{t-1}^{i}\}_{i=1}^{S}$ denotes EIS draws from $g(s_{t-1}|\hat{a}_{t-1})$, and $\{\omega(s_{t-1}^{i}; \hat{a}_{t-1})\}_{i=1}^{S}$ denotes associated weights (both of which are carried over from period-$t - 1$).

Obviously $g(s_{t-1}|\hat{a}_{t-1})$ is not an EIS sampler for the numerator in (17). This can impart a potential loss of numerical accuracy if the MC variance of $f(s_{t|s_{t-1}, Y_{t-1}})$ is large over the support of $g(s_{t-1}|\hat{a}_{t-1})$. This would be the case if the conditional variance of $s_{t|s_{t-1}, Y_{t-1}}$ were significantly smaller than that of $s_{t-1}|Y_{t-1}$. But the fact that we are using the same set of draws for the numerator and the denominator typically creates positive correlation between their respective MC estimators, thus reducing the variance of their ratio.

**A constant weight approximation**

When EIS delivers a close global approximation to $f(s_{t-1}|Y_{t-1})$, the weights $\omega(s_{t-1}; \hat{a}_{t-1})$ will be near constants over the range of integration. Replacing these weights by their arithmetic means $\overline{\omega}(\hat{a}_{t-1})$ in (17) and (18), we obtain the following simplification:

$$ f(s_{t|Y_{t-1}}) \approx \int f(s_{t|s_{t-1}, Y_{t-1}}) \cdot g(s_{t-1}; \hat{a}_{t-1}) ds_{t-1}. \quad (19) $$

This substitution yields rapid implementation if additionally the integral in (19) has an analytical solution. This will be the case if, e.g., $f(s_{t|s_{t-1}, Y_{t-1}})$ is a conditional normal density for $s_{t|s_{t-1}}$, and $g$ is also normal. In cases for which we lack an analytical solution, we can use the standard MC approximation

$$ \hat{f}_S(s_t|Y_{t-1}) \approx \frac{1}{S} \sum_{i=1}^{S} f(s_{t|s_{t-1}^{0,i}, Y_{t-1}}). \quad (20) $$

**EIS evaluation**

Evaluation of $f(s_t|Y_{t-1})$ can sometimes be delicate, including situations prone to sample impoverishment (such as when working with degenerate transitions, discussed below). Under such circumstances, one might consider applying EIS not only to the likelihood integral (“outer EIS”),
but also to the evaluation of \( f(s_t|Y_{t-1}) \) itself ("inner EIS").

While outer EIS is applied only once per period, inner EIS must be applied for every value of \( s_t \) generated by the former. Also, application of EIS to (5) requires the construction of a continuous approximation to \( f(s_{t-1}|Y_{t-1}) \). Two obvious candidates are as follows. The first is a non-parametric approximation based upon a swarm \( \{s_{t-1}^i\}_{i=1}^S \):

\[
\tilde{f}_S(s_{t-1}|Y_{t-1}) = \frac{1}{Sh} \sum_{i=1}^S \kappa \left( \frac{s_{t-1} - s_{t-1}^i}{h} \right).
\]

The second is the period-(\(t-1\)) EIS sampler \( g(s_{t-1};\tilde{a}_{t-1}) \), under the implicit assumption that the corresponding weights \( \omega(s_{t-1};\tilde{a}_{t-1}) \) are near-constant, at least over the range of integration. It is expected that in pathological cases, significant gains in accuracy resulting from inner EIS will far outweigh approximation errors in \( f(s_{t-1}|Y_{t-1}) \).

### 4.3 Special cases

**Partial measurement**

Partial measurement refers to cases in which \( s_t \) can be partitioned (possibly after transformation) into \( s_t = (p_t, q_t) \), so that

\[
f (y_t|s_t, Y_{t-1}) \equiv f (y_t|p_t, Y_{t-1}). \tag{21}
\]

In this case, likelihood evaluation requires integration only with respect to \( p_t \):

\[
f (y_t|Y_{t-1}) = \int f (y_t|p_t, Y_{t-1}) f (p_t|Y_{t-1}) \, dp_t, \tag{22}
\]

and the updating equation (6) factorizes into the product of the following two densities:

\[
f (p_t|Y_t) = \frac{f (y_t|p_t, Y_{t-1}) f (p_t|Y_{t-1})}{f (y_t|Y_{t-1})}; \tag{23}
\]

\[
f (q_t|p_t, Y_t) = f (q_t|p_t, Y_{t-1}). \tag{24}
\]

Stronger conditional independence assumptions are required in order to produce factorizations.
in (5). In particular, if \( p_t \) is independent of \( q_t \) given \( (p_{t-1}, Y_{t-1}) \), so that

\[
f (p_t|s_{t-1}, Y_{t-1}) \equiv f (p_t|p_{t-1}, Y_{t-1}),
\]

(25)

then

\[
f (p_t|Y_{t-1}) = \int f (p_t|p_{t-1}, Y_{t-1}) f (p_{t-1}|Y_{t-1}) dp_{t-1}.
\]

(26)

Note that under conditions (21) and (25), likelihood evaluation does not require processing sample information on \( \{q_t\} \). The latter is required only if inference on \( \{q_t\} \) is itself of interest.

**Degenerate transitions**

When state transition equations include identities, corresponding transition densities are degenerate (or Dirac) in some of their components. This situation requires an adjustment to EIS implementation. Again, let \( s_t \) partition into \( s_t = (p_t, q_t) \), and assume that the transition equations consist of two parts: a proper transition density \( f (p_t|s_{t-1}, Y_{t-1}) \) for \( p_t \), and an identity for \( q_t|p_t, s_{t-1} \) (which could also depend on \( Y_{t-1} \), omitted here for ease of notation):

\[
q_t = \phi (p_t, p_{t-1}, q_{t-1}) = \phi (p_t, s_{t-1}).
\]

(27)

The evaluation of \( f (s_t|Y_{t-1}) \) in (5) now requires special attention, since its evaluation at a given \( s_t \) (as selected by the EIS algorithm) requires integration in the strict subspace associated with identity (27). Note in particular that the presence of identities raises a conditioning issue known as the Borel-Kolmogorov paradox (e.g., see DeGroot, 1975, Section 3.10). We resolve this issue here by reinterpreting (27) as the limit of a uniform density for \( q_t|p_t, s_{t-1} \) on the interval \( [\phi (p_t, s_{t-1}) - \varepsilon, \phi (p_t, s_{t-1}) + \varepsilon] \).

Assuming that \( \phi (p_t, s_{t-1}) \) is differentiable and strictly monotone in \( q_{t-1} \), with inverse

\[
q_{t-1} = \psi (p_t, q_t, p_{t-1}) = \psi (s_t, p_{t-1})
\]

(28)

we can take the limit of the integral in (5) as \( \varepsilon \) tends to zero, producing

\[
f (s_t|Y_{t-1}) = \int J (s_t, p_{t-1}) f (p_t|s_{t-1}, Y_{t-1}) f (p_{t-1}, q_{t-1}|Y_{t-1})|_{q_{t-1}=\psi (s_t, p_{t-1})} dp_{t-1},
\]

(29)
where with $\| \cdot \|$ denoting the absolute value of a determinant,

$$
J(s_t, p_{t-1}) = \| \frac{\partial}{\partial q_t^l} \psi(s_t, p_{t-1}) \|.
$$

(30)

Note that (29) requires that for any $s_t$, $f(s_{t-1}|Y_{t-1})$ must be evaluated along the zero-measure subspace $q_{t-1} = \psi(s_t, p_{t-1})$. This rules out use of the weighted-sum approximation introduced above, since the probability that any of the particles $s_i^{0,t-1}$ lies in that subspace is zero. Instead, we can approximate (29) by replacing $f(s_{t-1}|Y_{t-1})$ by $\pi_0(\alpha_{t-1}) g(s_{t-1}|\alpha_{t-1})$: \[ \hat{f}(s_t|Y_{t-1}) = \int J(s_t, p_{t-1}) f(p_t|q_{t-1}, Y_{t-1}) g(p_{t-1}, q_{t-1}|\alpha_{t-1}) |q_{t-1} - \psi(s_t, p_{t-1}) dp_{t-1}. \]

(31)

In this case, since $g(p_{t-1}, \psi(s_t, p_{t-1})|\alpha_{t-1})$ is not a sampler for $p_{t-1}|s_t$, we must evaluate (31) either by quadrature or its own EIS sampler.

One might infer from this discussion that the EIS filter is tedious to implement under degenerate transitions, while the particle filter handles such degeneracy trivially in the transition from $\{s_i^{0,t-1}\}$ to $\{s_i^{1,t-1}\}$. While this is true, it is also true that these situations are prone to significant sample impoverishment problems, as illustrated in the examples below.

5 Application to DSGE Models

As noted, the work of Fernandez-Villaverde and Rubio-Ramirez (2005, 2009) revealed that approximation errors associated with linear representations of DSGE models can impart significant errors in corresponding likelihood representations. As a remedy, they demonstrated use of the particle filter for achieving likelihood evaluation for non-linear model representations. Here we demonstrate the implementation of the EIS filter using two workhorse models. The first is the standard two-state real business cycle (RBC) model; the second is a small-open-economy (SOE) model patterned after those considered, e.g., by Mendoza (1991) and Schmitt-Grohe and Uribe (2003), but extended to include six state variables.

We analyze two data sets for both models: an artificial data set generated from a known model parameterization; and a corresponding real data set. Thus in total we consider four applications, each of which poses a significant challenge to the successful implementation of a numerical filtering
algorithm. Details follow.

5.1 Example 1: Two-State RBC Model

The first application is to the simple DSGE model used by Fernandez-Villaverde and Rubio-Ramirez (2005) to demonstrate implementation of the particle filter. The model consists of a representative household that seeks to maximize the expected discounted stream of utility derived from consumption \( c \) and leisure \( l \):

\[
\max_{c_t, l_t} U = E_0 \sum_{t=0}^{\infty} \beta^t \left( c_t^\varphi l_t^{1-\varphi} \right)^{1-\phi},
\]

where \((\beta, \phi, \varphi)\) represent the household’s subjective discount factor, degree of relative risk aversion, and the relative importance assigned to \( c_t \) and \( l_t \) in determining period-\( t \) utility.

The household divides its available time per period (normalized to unity) between labor \( n_t \) and leisure. Labor combines with physical capital \( k_t \) and a stochastic productivity term \( z_t \) to produce a single good \( \zeta_t \), which may be consumed or invested (we use \( \zeta \) in place of the usual representation for output – \( y \) – to avoid confusion with our use of \( y \) as representing the observable variables of a generic state-space model). Investment \( i_t \) combines with undepreciated capital to yield \( k_{t+1} \), thus the opportunity cost of period-\( t \) consumption is period-\((t + 1) \) capital. Collectively, the constraints faced by the household are given by

\[
\zeta_t = z_t k_t^\alpha n_t^{1-\alpha},
\]

\[
1 = n_t + l_t,
\]

\[
\zeta_t = c_t + i_t,
\]

\[
k_{t+1} = i_t + (1 - \delta)k_t,
\]

\[
z_t = z_0 e^{\delta t} e^{\omega_t}, \quad \omega_t = \rho \omega_{t-1} + \epsilon_t,
\]

where \((\alpha, \delta, g, \rho)\) represent capital’s share of output, the depreciation rate of capital, the growth rate of total factor productivity (TFP), and the persistence of innovations to TFP.

Optimal household behavior is represented in terms of policy functions for \((\zeta_t, c_t, n_t, l_t, i_t)\) in
terms of the state \((k_t, z_t)\). Given the policy function \(i(k_t, z_t)\), the state-transitions equations reduce to

\[
\left(1 + \frac{g}{1 - \alpha}\right) k_t = i(k_{t-1}, z_{t-1}) + (1 - \delta)k_{t-1}
\]

\[
\ln z_t = (1 - \rho) \ln(z_0) + \rho \ln z_{t-1} + \varepsilon_t, \quad \varepsilon_t \sim N(0, \sigma^2_z),
\]

and the observation equations are

\[
x_t = x(k_t, z_t) + u_{x,t}, \quad x = \zeta, i, n,
\]

\[
u_{x,t} \sim N(0, \sigma^2_x).
\]
polynomials is awkward, we approximate (36) and (37) using third-order polynomials in \((k_t, z_{t-1})\).

With the predictive density established, the time-\(t\) likelihood is standard:

\[
f(y_t|Y_{t-1}) = \int f(y_t|s_t, Y_{t-1}) f(s_t|Y_{t-1}) \, ds_t,
\]

(39)

where from (34)-(35),

\[
f(y_t|s_t, Y_{t-1}) \sim N_3(\mu(s_t), V), \tag{40}
\]

\[
\mu(s_t) = \begin{bmatrix} \zeta(s_t) \\ \delta(s_t) \\ n(s_t) \end{bmatrix}, \quad V = \begin{bmatrix} \sigma_y^2 & 0 & 0 \\ 0 & \sigma_l^2 & 0 \\ 0 & 0 & \sigma_n^2 \end{bmatrix}.
\]

To achieve likelihood evaluation in period \(t\), our approach is to construct a normally distributed EIS sampler \(g(s_t; a_t)\) for the integrand \(f(y_t|s_t, Y_{t-1}) \cdot f(s_t|Y_{t-1})\) in (39). In so doing, \(f(s_t|Y_{t-1})\) is represented using the constant-weight approach to approximation described above. That is, we use the time-\((t-1)\) sampler \(g(s_{t-1}; a_{t-1})\) as a stand-in for \(f(s_{t-1}|Y_{t-1})\), yielding

\[
f(s_t|Y_{t-1}) \simeq \int J(k_t, z_{t-1}) f(z_t|s_{t-1}) \, g(s_{t-1}; a_{t-1}) \, dz_{t-1} = \psi(k_t, z_{t-1}) \, dz_{t-1}. \tag{41}
\]

We initialize the process by constructing \(f(s_0)\) as the unconditional distribution of the Kalman filter associated with a linear approximation of the model. We proceed via forward recursion, taking \(g(s_{t-1}; a_{t-1})\) as an input, and passing \(g(s_t; a_t)\) to the subsequent period. Full details follow.

Consider first the evaluation of (41). Representing \(g(s_t; a_t)\) as

\[
g(s_t; a_t) \sim N_2(\mu, \Omega),
\]

and with \(f(z_t|s_{t-1})\) distributed as

\[
f(z_t|s_{t-1}) \sim N_1 \left( \begin{bmatrix} 0 \\ \rho \end{bmatrix} s_{t-1}, \, \sigma_z^2 \right),
\]

16
f (z_t|s_{t-1}) g (s_{t-1}; a_{t-1}) combines to form the joint density

\[
\begin{pmatrix}
  z_t \\
  s_{t-1}
\end{pmatrix}
\sim N_3 \begin{pmatrix}
  \begin{pmatrix}
    0 & \rho \\
    1 & 0 \\
    0 & 1
  \end{pmatrix}
  \mu, 
  V
\end{pmatrix},
\]

(42)

\[
V = \sigma_z^2 \begin{pmatrix}
  1 & 0 & 0 \\
  0 & 0 & 0 \\
  0 & 0 & 0
\end{pmatrix} + \begin{pmatrix}
  0 & \rho \\
  1 & 0 \\
  \rho & 0 & 1
\end{pmatrix} \Omega \begin{pmatrix}
  0 & 1 \\
  1 & 0
\end{pmatrix}.
\]

As (41) must be evaluated for each candidate \( s_t \) used to calculate (39), we must transform (42) into a distribution over \((s_t, z_{t-1})'\). Approximating (36) linearly as \( k_{t-1} = a_k k_t + b_k z_{t-1} \), which implies

\[
\begin{pmatrix}
  s_t \\
  z_{t-1}
\end{pmatrix} = A \begin{pmatrix}
  z_t \\
  s_{t-1}
\end{pmatrix},
\]

\[
A = \begin{pmatrix}
  0 & 1/a_k & -b_k/a_k \\
  1 & 0 & 0 \\
  0 & 0 & 1
\end{pmatrix}, \quad |A| = 1/|a_k|,
\]

we can express \((z_t, s_{t-1})'\) as a function of \((s_t, z_{t-1})'\). This expression, coupled with (42), yields the joint density

\[
f^* (s_t, z_{t-1}) \sim N_3 (m, \Sigma), \quad \Sigma = AA',
\]

(43)

\[
m = B \mu,
\]

\[
B = A \begin{pmatrix}
  0 & \rho \\
  1 & 0 \\
  0 & 1
\end{pmatrix}.
\]

Finally, we partition (43) into a product of two densities, one for \( s_t \) and one for \( z_{t-1}|s_t \):

\[
f^*_1 (s_t) \sim N_2 (m_1, \Sigma_{11}), \quad f^*_2 (z_{t-1}|s_t) \sim N_1 (m_{21} + \Delta_{21} s_t, \sigma_{22,1}),
\]

17
where
\[ m = \begin{pmatrix} m_1 \\ m_2 \end{pmatrix}, \quad \Sigma = \begin{pmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \sigma_{22} \end{pmatrix}, \]

with \( \Sigma_{11} \ 2 \times 2, \ \Sigma_{12} \ 2 \times 1, \ \Sigma_{21} \ 1 \times 2, \) and \( \sigma_{22} \ 1 \times 1, \) and

\[ \Delta_{21} = \Sigma_{21} (\Sigma_{11})^{-1}, \quad m_{21} = m_2 - \Delta_{21} m_1, \quad \sigma_{22.1} = \sigma_{22} - \Sigma_{21} (\Sigma_{11})^{-1} \Sigma_{12}. \]

Having accomplished these steps, (41) is approximately
\[ f (s_t | Y_{t-1}) \approx f_1^* (s_t) \int \frac{J (s_t, z_{t-1})}{|a_k|} f_2^* (z_{t-1} | s_t) \, dz_{t-1}, \tag{44} \]

where since
\[ |\Sigma|^{-1/2} = \frac{1}{|a_k|} |V|^{-1/2}, \]

the term \(|a_k|\) enters via the usual change-of-variables formula. For each candidate \( s_t \) that enters into the approximation of (39), we use \( f_2^* (z_{t-1} | s_t) \) as an EIS sampler, and approximate (44) as
\[ f (s_t | Y_{t-1}) \approx \left( \frac{f_1^* (s_t)}{|a_k|} \right) \frac{1}{S} \sum_{i=1}^S J (s_t, z_{t-1}^i), \tag{45} \]

where \( \{ z_{t-1}^i \}_{i=1}^S \) are simulated drawings from \( f_2^* (z_{t-1} | s_t) \).

Turning to the approximation of (39), this is straightforward once a reliable initial EIS sampler is constructed. To construct this initial sampler, we seek a close approximation of the integrand \( f (y_t | s_t, Y_{t-1}) \cdot f (s_t | Y_{t-1}) \). Towards this end, we use \( f_1^* (s_t) \) in place of \( f (s_t | Y_{t-1}) \), and construct a linear Gaussian approximation of \( f (y_t | s_t, Y_{t-1}) \). Recall from (40) that \( f (y_t | s_t, Y_{t-1}) \) is already Gaussian, but with a non-linear mean function, say \( \mu (s_t) \). Approximating this function as \( \mu (s_t) \approx r + P s_t \), we obtain
\[ f^* (y_t | s_t, Y_{t-1}) \sim N_3 (r + P s_t, \ V). \]
Combining these approximations, and letting \( Q = V^{-1}, H = \Sigma_{11}^{-1} \), we obtain the initial sampler

\[
    g\left(s_t; a_t^0\right) = f_1^* (s_t) f^* (y_t | s_t, Y_{t-1})
    \sim N(\mu^0, \Sigma^0),
    
    \mu^0 = (H + P'QP)^{-1} [H m_1 + P'Q (y_t - r)],
    
    \Sigma^0 = (H + P'QP)^{-1}.
\]

To summarize, EIS implementation is achieved for the two-state RBC model as follows.

**Model Representation**

- **Policy functions** \( x(k_t, z_t) = (\zeta, c, i, n, l) \), expressed as Chebyshev polynomials in \( s_t = [k_t \ z_t]' \), are constructed via the projection method.

- With the law of motion for capital given by \( k_t = i(k_{t-1}, z_{t-1}) + (1 - \delta)k_{t-1} \), we solve for \( k_{t-1} \) to obtain
  \[
  k_{t-1} = \psi(k_t, z_{t-1}), \quad J(k_t, z_{t-1}) = \frac{\partial}{\partial k_t} \psi(k_t, z_{t-1}),
  \]
  represented as third-order polynomials in \((k_t, z_{t-1})\). We also construct the linear approximation \( k_{t-1} = a_k k_t + b_k z_{t-1} \).

**Likelihood Evaluation**

- The EIS sampler \( g\left(s_{t-1}; \hat{a}_{t-1}\right) \) serves as an input in the construction of the period-\( t \) likelihood function. In period 1, \( g(s_0; \hat{a}_0) = \hat{f}(s_0) \) is constructed as the unconditional distribution of the Kalman filter associated with a linear approximation of the model.

- To approximate the integrand \( f(y_t | s_t, Y_{t-1}) \cdot f(s_t | Y_{t-1}) \) in (39), we construct the initial sampler \( g\left(s_t; a_t^0\right) \) as in (46):
  \[
  g\left(s_t; a_t^0\right) = f_1^* (s_t) f^* (y_t | s_t, Y_{t-1})
  \]

- Using drawings \( \{s_{t,0}^j\}_{i=1}^R \) obtained from \( g\left(s_t; a_t^0\right) \), we construct \( \hat{a}_t \) as the solution to (14).
This entails the computation of

\[ \varphi_t(s_t^i) = f(y_t|s_t^i, Y_{t-1}) f(s_{t-1}^i|Y_{t-1}), \]

where \( f(y_t|s_t, Y_{t-1}) \) is given in (40), and \( f(s_t|Y_{t-1}) \) is approximated as indicated in (45).

- Having constructed \( g(s_t; \tilde{a}_t) \), \( \tilde{f}(y_t|Y_{t-1}) \) is approximated as indicated in (15).
- The sampler \( g(s_t; \tilde{a}_t) \) is passed to the period-(\( t+1 \)) step of the algorithm. The algorithm concludes with the completion of the period-\( T \) step.

To demonstrate the performance of the EIS filter in this setting, we conducted Monte Carlo experiments using two data sets. The first is an artificial data set consisting of 100 realizations of \( \{\zeta_t, i_t, n_t\} \) generated from the RBC model. This was constructed by Fernandez-Villaverde and Rubio-Ramirez (2005) under the model parameterization presented in the second row of Table 1. The second consists of actual quarterly observations on \( \{\zeta_t, i_t, n_t\} \) used by Fernandez-Villaverde and Rubio-Ramirez to estimate the RBC model using the particle filter. The data are quarterly, span 1964:I-2003:II (158 observations), and were detrended using the Hodrick-Prescott filter. Posterior means of the estimates they obtained using this data set are presented in the third row of Table 1. Both data sets are available for downloading at

Each data set poses a distinct challenge to efficient filtering. In the artificial data set, note from Table 1 that the standard deviations of the measurement errors \( (\sigma_y, \sigma_i, \sigma_n) \) are small relative to \( \sigma_\varepsilon \), which as noted above can lead to problems associated with sample impoverishment. In the real data set, the investment series contains two outliers: the values at 1976:III and 1984:IV, which lie 7.7 and 4.7 standard deviations above the sample mean. Outliers can induce bias in likelihood estimates associated with the particle filter. Both of these challenges are overcome via implementation of the EIS filter, as we now demonstrate.
Using both data sets, we conducted a Monte Carlo experiment under which we produced 1,000 approximations of the likelihood function (evaluated at Table-1 parameter values) for both the particle and EIS filters using 1,000 different sets of random numbers. Differences in likelihood approximations across sets of random numbers are due to numerical approximation errors. Following Fernandez-Villaverde and Rubio-Ramirez, the particle filter was implemented using $N = 60,000$, requiring 40.6 seconds of CPU time per likelihood evaluation on a 1.8 GHz desktop computer using GAUSS for the artificial data set, and 63 seconds for the real data set. The EIS filter was implemented using $N = 20$, $S = R = 10$, with one iteration used to construct $\tilde{a}_i$; this required 0.22 seconds per likelihood evaluation for the artificial data set, and 0.328 seconds for the real data set.

Considering first the artificial data set, the mean and standard deviation of the 1,000 log-likelihood approximations obtained using the particle filter are $(1, 285.51, 33.48)$, and $(1, 299.81, 0.00177)$ using the EIS filter (the likelihood value obtained using the Kalman filter is 1,300.045). Thus the EIS filter reduces numerical approximation errors by four orders of magnitude in this application. Figure 1 plots the first 200 likelihood approximations obtained using both filters (in order to enhance visibility). Note that the particle-filter approximations (top panel) often fall far below the EIS sample mean of 1,299.81 (by more than 50 on the log scale in twenty instances, and by more than 100 in eight instances); this largely accounts for the distinct difference in sample means obtained across methods. But as the figure indicates, even abstracting from the occasional large likelihood crashes suffered by the particle filter, the EIS filter is extremely precise: the maximum difference in log-likelihood values it generates is less than 0.012 (bottom panel), while differences of 10 are routinely observed for the particle filter.

Hereafter, we shall refer to differences observed between sample means of log-likelihood values obtained using the particle and EIS filters as reflecting bias associated with the particle filter. This presumes that the values associated with the EIS filter closely represent “truth”. This presumption is justified in a number of ways, in this experiment and each of those that follow. First, the small numerical approximation errors associated with the EIS filter indicate virtual replication across sets of random numbers. Second, as we increase the values of $(N, R)$ used to implement the EIS filter, resulting mean log-likelihood approximations remain virtually unchanged, while numerical errors are inversely proportional to $N^{-1/2}$, as expected. Finally, when we implement the EIS filter using linear model approximations, the log-likelihood values we obtain match those produced by
the Kalman filter almost exactly (virtually to the limits of numerical precision).

Figure 2 provides an illustration and diagnosis of the problems faced by the particle filter in this application. The focus here is on a representative Monte Carlo replication generated as described above. The figure contains two panels, each of which represents a distinct scenario observed routinely across time periods within this replication. The top panel corresponds with \( t = 53 \); the bottom with \( t = 18 \).

Each panel contains two graphs, both of which depict \( z_t \) on the vertical axis and \( k_t \) on the horizontal axis. The measurement density \( f(y_t|s_t, Y_{t-1}) \) is the large thin ellipse depicted in both graphs (differences in vertical scales across graphs account for differences in its appearance). In the bottom graph, the swarm of dots comprises the particle-filter representation of \( f(s_t|Y_{t-1}) \), and the wide ellipse comprises the EIS representation of \( f(s_t|Y_{t-1}) \). In the upper graph, the swarm of dots comprises the particle-filter representation of \( f(s_t|Y_t) \); particles in the upper swarm were obtained by sampling repeatedly from the bottom swarm, with probabilities assigned by the measurement density. The upper graph also depicts the EIS representation of \( f(s_t|Y_t) \) (small ellipse).

Beginning with period 53, note that the vast majority of particles in the bottom graph are assigned negligible weight by the measurement density, and are thus discarded in the resampling step. Specifically, only 407 particles, or 0.68% of the total candidates, were re-sampled at least once in this instance. The average (across time periods) number of re-sampled particles is 350, or 0.58% of the total. This phenomenon reflects the sample impoverishment problem noted above. It results from the ‘blindness’ of proposals generated under the particle filter algorithm, and accounts for its numerical inaccuracy.

As noted, the small ellipse depicted in the upper graph is the EIS representation of \( f(s_t|Y_t) \). The difference between this and the corresponding particle-filter representation reflects a second problem suffered by the particle filter in this application: there is non-trivial bias in the filtered values of the state it produces. This also reflects the ‘blindness’ problem, coupled with the fact that alternative proposals for \( s_t \) cannot be re-generated in light of information embodied in \( y_t \). (Note from the figure that this bias is not easily eliminated through an increase in the number of particles included in the proposal swarm, since the probability that the proposal density will generate particles centered on the EIS representation of \( f(s_t|Y_t) \) is clearly miniscule.) As described above, under suitable initialization the EIS filter avoids these issues by generating proposals from an importance density
tailored as the optimal global approximation of the targeted integrand \( f(y_{t}\mid s_{t}, Y_{t-1}) \cdot f(s_{t}\mid Y_{t-1}) \).

Regarding period 18, note that the representations of both \( f(s_{t}\mid Y_{t-1}) \) and \( f(s_{t}\mid Y_{t}) \) generated using the particle filter are discontinuous in \( k_{t} \), a spurious phenomenon that occurs frequently through the sample. This exacerbates the bias associated with filtered values of the state, and contributes to a final problem associated with the particle filter illustrated in Figure 3.

Like its predecessor, Figure 3 was produced using a representative Monte Carlo replication. It depicts an approximation of the log-likelihood surface over \( \alpha \) obtained by holding the remaining parameters fixed at their true values, and varying \( \alpha \) above and below its true value. Three surfaces are depicted: those associated with the particle, EIS, and Kalman filters (the latter obtained using a linear model representation). The particle and EIS surfaces were produced with common random numbers, so that changes in \( \alpha \) serve as the lone source of variation in log-likelihoods.

Note that while the surfaces associated with the EIS and Kalman filters are continuous and peak at the true value of 0.4, the surface associated with the particle filter is discontinuous and has a slightly rightshifted peak. Thus in addition to being numerically inefficient and producing biased filtered values of the state, the particle filter generates likelihood surfaces that are spuriously discontinuous in the underlying parameters of the model, rendering as problematic the attainment of likelihood-based model estimates.

Turning to the experiment conducted using the actual data set, Table 2 reports average log-likelihood values and Monte Carlo standard deviations for four sets of estimates: the full sample, the first outlier period 1976:III in isolation, the second outlier period 1984:IV in isolation, and the partial sample from which the outliers were removed. Estimates obtained using the Kalman filter are also reported.

| Table 2. Monte Carlo Means and Standard Deviations, RBC Model, Actual Data Set |
|-------------------------------|-------------------|-------------------|-------------------|-------------------|-------------------|
|                              | Particle Filter   | EIS Filter        | Kalman Filter     |                  |
|                              | Mean              | Std. Dev.         | Mean              | Std. Dev.        | Filter            |
| Full Sample                  | 674.83            | 16.258            | 774.90            | 0.1089           | 763.74            |
| 1976:III                     | -248.93           | 17.926            | -122.02           | 0.0544           | -136.28           |
| 1984:IV                      | -24.92            | 0.626             | -25.14            | 0.0232           | -27.59            |
| Partial Sample               | 948.69            | 2.207             | 922.06            | 0.0645           | 927.61            |

23
Note first that unlike in the experiment conducted using the artificial data set, there are non-trivial differences between the log-likelihood values associated with the Kalman and EIS filters. The explanation for this is as follows. Since there are no outliers in the artificial data set, deviations from steady state are relatively small, thus the linear model approximations employed in implementing the Kalman filter are relatively accurate. However, accuracy breaks down when deviations from steady state are large (i.e., in the presence of outliers). Indeed, when the EIS filter is implemented using linear model approximations, differences in likelihoods produced by the EIS and Kalman filters virtually disappear (becoming at most 1.58e-9 in 1976:IV).

Here, the EIS filter yields MC standard deviations two orders of magnitude below those associated with the particle filter in the full sample (increasing \((N, R)\) from \((20, 10)\) to \((200, 100)\) increases the order-of-magnitude reduction from two to four, at the cost of increasing computation time from 0.328 to 3.28 seconds per function evaluation). But the striking aspect of this experiment is the large difference in log-likelihood means obtained using the two filters: 100, almost exactly. As the breakdown by dates indicates, the large outlier, 1976:III, accounts for the bulk of this difference.

As Figure 4 illustrates, the 1976:III outlier (time period 51) imparts significant bias in the approximations of the likelihood function \(f(y_t | Y_{t-1})\) and filtering density \(f(s_t | Y_t)\) produced by the particle filter; this accounts for the differences in log-likelihood means just noted. The construction of the figure mimics that of Figure 2. The top panel, constructed using time period 148, depicts a typical period in the sample for which the particle filter is relatively accurate and precise. In this case, there is considerable overlap between the representations of \(f(s_t | Y_{t-1})\) and \(f(s_t | Y_t)\) associated with both filters (although the particle-filter representations are slightly leftshifted). The bottom panel conveys an entirely different story.

Note from the lower graph in the bottom panel that the EIS and particle filter representations of \(f(s_t | Y_{t-1})\) are centered at roughly the same location in the sample space, far away from the location of \(f(y_t | s_t, Y_{t-1})\) due to the outlier. However, it is important to recognize a key difference in their supports. That of the particle filter representation is confined to the discrete support highlighted by the blue dots, and allows for no adjustments beyond this range. That of the EIS filter representation spans the entire plane, and thus allows for whatever adjustment is required given the location of \(f(y_t | s_t, Y_{t-1})\).

Casual inspection of this diagram suggests that the filtering density \(f(s_t | Y_t)\), which is the
product of \( f(s_t|Y_{t-1}) \) and \( f(y_t|s_t, Y_{t-1}) \), normalized by \( f(y_t|Y_{t-1}) \), ought to lie considerably above \( f(s_t|Y_{t-1}) \), as indeed is the case with the EIS representation of \( f(s_t|Y_t) \) in the top graph. However, since the representation of \( f(s_t|Y_t) \) produced by the particle filter is obtained by resampling with replacement from \( f(s_t|Y_{t-1}) \), it is not possible to achieve the dramatic relocation in the sample space required to successfully construct \( f(s_t|Y_t) \) in this case. Again, under the particle filter the support of \( f(s_t|Y_t) \) is fixed prior to the observation of \( y_t \), thus the representation it produces in the presence of an outlier is badly biased. As the figure makes clear, even a dramatic increase in the size of the particle swarms it employs cannot remedy the situation effectively.

Consider now the biased estimate of the likelihood function produced by the particle filter. Returning to the lower graph, recall that the likelihood function \( f(y_t|Y_{t-1}) \) is the integral of the product of \( f(s_t|Y_{t-1}) \) and \( f(y_t|s_t, Y_{t-1}) \). Once again, casual inspection suggests that this product lies considerably above \( f(s_t|Y_{t-1}) \). Thus, the optimal importance sampler for approximating \( f(y_t|Y_{t-1}) \) lies considerably above \( f(s_t|Y_{t-1}) \), and is not confined to the outer reaches of the state space as is the importance sampler associated with the particle filter (i.e., its discrete approximation of \( f(s_t|Y_{t-1}) \)). Indeed, since the EIS importance sampler \( g(s_t; \tilde{a}_t) \) is constructed as the normally distributed approximation of the filtering density \( f(s_t|Y_t) \), it is centered and shaped as the optimal normal distribution available for approximating \( f(y_t|Y_{t-1}) \). Thus to understand the source of bias in approximating \( f(y_t|Y_{t-1}) \) produced by the particle filter given this outlier, one merely needs to observe the difference between the particle-filter importance sampler (the discrete representation of \( f(s_t|Y_{t-1}) \) in the lower-right corner of the lower graph) and the EIS importance sampler (a normal approximation of \( f(s_t|Y_t) \) in the upper-right portion of the upper graph).

Returning to the biased approximation of \( f(s_t|Y_t) \) produced by the particle filter in this case (the small cluster of dots in the upper graph), in the following period this will impart bias in its approximations of \( f(s_{t+1}|Y_t) \) and \( f(y_{t+1}|Y_t) \) as well. This is due to the fact that the particle filter employs \( f(s_t|Y_t) \) as an importance sampler for computing the integral of \( f(s_{t+1}|s_t, Y_t) \cdot f(s_t|Y_t) \) in constructing \( f(s_{t+1}|Y_t) \); the bias in \( f(s_t|Y_t) \) thus imparts bias in \( f(s_{t+1}|Y_t) \). In turn, as \( f(s_{t+1}|Y_t) \) serves as the importance sampler in computing \( f(y_{t+1}|Y_t) \), it too will be biased. (Indeed the difference between log-likelihood means produced by the EIS and particle filters is 5.15 in period 1976:IV.)

As emphasized by RZ, it is important to distinguish between the numerical error associated with
a given approximation technique (quantified using the MC standard errors described above), and
the sampling error associated with the statistic being approximated (in this case, the log-likelihood
function). To characterize sampling error, we conducted two additional experiments. In both, we
constructed a data generation process (DGP) using a parameterization of the RBC model, and
generated 100 artificial data sets consisting of time-series observations of \((\zeta, i, n)\) of length \(T\). For
each artificial data set, we used the EIS filter implemented using \((N, R) = (200, 100)\) to obtain
100 approximations of the log-likelihood function. The standard deviation of the log-likelihoods
calculated in this manner serves as an estimate of the statistical sampling error associated with
this summary statistic.

The DGPs employed in the two experiments were tailored to the empirical applications described
above. The first was constructed using the parameters reported in the second row of Table 1, with
\(T = 100\); the second using the parameters reported in the third row of Table 1, with \(T = 158\).
The first yielded an estimated sampling error of 16.48; the second 20.45. For comparison, recall
that the corresponding MC standard errors associated with the particle filter are 33.48 and 16.26,
while those associated with the EIS filter are 0.00177 and 0.109. This comparison indicates that
the particle filter is an unreliable tool for assessing statistical uncertainty in this context, since its
associated numerical errors are first-order comparable to the associated statistical errors targeted
for approximation.

To conclude, tightly-distributed measurement distributions and sample outliers are troublesome
sources of numerical error and bias that can plague applications of the particle filter, but that can
be overcome via application of the EIS filter. We now demonstrate application of the EIS filter in
a second example model featuring an expanded state space.

### 5.2 Example 2: Six-State Small Open Economy Model

This application is to a small-open-economy (SOE) model patterned after those considered,
e.g., by Mendoza (1991) and Schmitt-Grohe and Uribe (2003). The model consists of a representa-
tive household that seeks to maximize

\[
U = E_0 \sum_{t=0}^{\infty} \theta_t \left[ c_t - \varphi \omega^{-1}\omega_t^{\omega} \right]^{1-\gamma} - 1, \quad \omega > 0, \quad \gamma \geq 0,
\]
where $\varphi_t$ is a preference shock that affects the disutility generated by labor effort (introduced, e.g., following Smets and Wouters, 2002). Following Uzawa (1968), the discount factor $\theta_t$ is endogenous and obeys

$$
\theta_{t+1} = \beta (\tilde{c}_t, \tilde{n}_t) \theta_t, \quad \theta_0 = 1,
$$

$$
\beta (\tilde{c}_t, \tilde{n}_t) = [1 + \tilde{c}_t - \omega^{-1} \tilde{n}_t^\omega]^{-\psi}, \quad \psi > 0,
$$

where $(\tilde{c}_t, \tilde{n}_t)$ denote average per capita consumption and hours worked. The household takes these as given; they equal $(c_t, n_t)$ in equilibrium. The household’s constraints are collectively

$$
d_{t+1} = (1 + r_t) d_t - \zeta_t + c_t + i_t + \frac{\phi}{2} (k_{t+1} - k_t)^2
$$

$$
\zeta_t = A_t \kappa^\alpha n_t^{1-\alpha}
$$

$$
k_{t+1} = \nu_t^{-1} i_t + (1 - \delta) k_t
$$

$$
\ln A_{t+1} = \rho_A \ln A_t + \varepsilon_{At+1}
$$

$$
\ln r_{t+1} = (1 - \rho_r) \ln \bar{r} + \rho_r \ln r_t + \varepsilon_{rt+1}
$$

$$
\ln \nu_{t+1} = \rho_{\nu} \ln \nu_t + \varepsilon_{\nu t+1}
$$

$$
\ln \varphi_{t+1} = \rho_\varphi \ln \varphi_t + \varepsilon_{\varphi t+1},
$$

where relative to the RBC model, the new variables are $d_t$, the stock of foreign debt, $r_t$, the exogenous interest rate at which domestic residents can borrow in international markets, $\nu_t$, an investment-specific productivity shock, and the preference shock $\varphi_t$.

The state variables of the model are $(d_t, k_t, A_t, r_t, \nu_t, \varphi_t)$; the controls are $(\zeta_t, c_t, i_t, n_t)$. In this application we obtain non-linear policy functions

$$
x_t = x(s_t), \quad x_t = (\zeta_t, c_t, i_t, n_t), \quad s_t = (d_t, k_t, A_t, r_t, \nu_t, \varphi_t)
$$

using a second-order Taylor Series approximation of the system of expectational difference equations associated with the model, following Schmitt-Grohe and Uribe (2004). Given these policy functions,
the state-transitions equations reduce to

\[
d_{t+1} = (1 + r_t) d_t - \zeta (s_t) + c (s_t) + i (s_t) + \frac{\phi}{2} (k_{t+1} - k_t)^2
\]

\[
k_{t+1} = \nu_t^{-1} i (s_t) + (1 - \delta) k_t
\]

\[
\ln A_{t+1} = \rho_A \ln A_t + \varepsilon_{At+1}
\]

\[
\ln r_{t+1} = (1 - \rho_r) \ln \bar{r} + \rho_r \ln rt + \varepsilon_{rt+1}
\]

\[
\ln \nu_{t+1} = \rho_v \ln v_t + \varepsilon_{vt+1}
\]

\[
\ln \phi_{t+1} = \rho_\phi \ln \phi_t + \varepsilon_{\phi t+1},
\]

and the observation equations are

\[
\ln (\frac{x_t}{x(s_t)}) = u_{x,t}, \quad x = \zeta, c, i, n,
\]

\[
u_{x,t} \sim N(0, \sigma_x^2).
\]

As with the RBC model, hereafter we represent state variables as logged deviations from steady state. In addition, given the form of (53), \(y_t\) is defined as \(y_t = [\ln \zeta_t, \ln c_t, \ln i_t, \ln r_t]'\). All subsequent formulas should be read in accordance with these representations.

Notice that (47) and (48) characterize a bivariate degenerate transition of the form

\[
q_t = \phi(p_{t-1}, q_{t-1}),
\]

where following the notation of Section 4.3, \(p_t = (A_t, r_t, v_t, \phi)\), and \(q_t = (d_t, k_t)\). Its inverse and corresponding linear approximation are denoted respectively as

\[
q_{t-1} = \psi(q_t, p_{t-1}), \quad q_{t-1} = \tilde{\psi}(q_t, p_{t-1}).
\]

The Jacobian associated with \(\psi\) is given by

\[
J (q_t, p_{t-1}) = \| \frac{\partial}{\partial q_t} \psi(q_t, p_{t-1}) \|.
\]

We achieve the inversion of (47) and (48) as follows. It turns out that the transition equation
for $k_t$ is independent of $d_t$, thus we exploit the triangular structure of the system by first solving for $k_{t-1}$, and then using this result to find $d_{t-1}$. Defining $s^1_{t-1} = [k_{t-1}, p_{t-1}]$, the second-order approximation to the law of motion of $k_t$ is given by

$$k_t = C_k + L_k s^1_{t-1} + \frac{1}{2} s^1_{t-1}' Q_k s^1_{t-1}, \quad (57)$$

which is a quadratic equation in $k_{t-1}$ with solutions

$$k_{t-1} = \frac{-b_k \pm \sqrt{b_k^2 - 4a_k c_k}}{2a_k}, \quad (58)$$

$$a_k = \frac{1}{2} Q^{11}_k, \quad (59)$$
$$b_k = L^1_k + Q^{12}_k p_{t-1}, \quad (60)$$
$$c_k = C_k + L^2_k p_{t-1} + \frac{1}{2} p_{t-1}' Q^{22}_k p_{t-1} - k_t, \quad (61)$$

$$Q_k = \begin{bmatrix} Q^{11}_k & Q^{12}_k \\ Q^{21}_k & Q^{22}_k \end{bmatrix}, \quad L_k = \begin{bmatrix} L^1_k \\ L^2_k \end{bmatrix}.$$

As the capital stock evolves slowly, the solution to (57) we seek is chosen as

$$k^*_{t-1} = \arg \min \left[ |(k^1_{t-1} - k_t)|, |(k^2_{t-1} - k_t)| \right], \quad (62)$$

where $k^1_{t-1}$ and $k^2_{t-1}$ are the roots (58).

Having obtained $k^*_{t-1}$, the solution of $d_{t-1}$ proceeds as follows. Substituting (48) for $k_{t+1}$ in (47), the second-order approximation to the law of motion of $d_t$ is given by:

$$d_t = C_d + L_d s_{t-1} + \frac{1}{2} s_{t-1}' Q_d s_{t-1},$$

which is a quadratic equation in $d_{t-1}$ with solutions

$$d_{t-1} = \frac{-b_d \pm \sqrt{b_d^2 - 4a_d c_d}}{2a_d},$$
\[ a_d = \frac{1}{2} Q_{d}^{11}, \quad (63) \]

\[ b_d = L_d^2 + Q_{d}^{12} s_{t-1}^1, \quad (64) \]

\[ c_d = C_d + L_d^2 s_{t-1}^1 + \frac{1}{2} s_{t-1}^1 Q_{k}^{22} s_{t-1}^1 - d_t, \quad (65) \]

\[ Q_d = \begin{bmatrix} Q_{d}^{11} & Q_{d}^{12} \\ Q_{d}^{21} & Q_{d}^{22} \end{bmatrix}, \quad L_d = \begin{bmatrix} L_d^1 \\ L_d^2 \end{bmatrix}. \]

Again we select the solution \( d_{t-1}^* \) following (62).

The sequence of operations just described effectively transforms a triangular inverse transformation into a diagonal transformation. The corresponding Jacobian is given by

\[ J(q_t, p_{t-1}) = (b_k^2 + 4a_k c_k)^{-\frac{1}{2}} \cdot (b_d^2 + 4a_d c_d)^{-\frac{1}{2}}. \]

Having achieved inversion, implementation of the EIS filter proceeds precisely as with the RBC model, with the following straightforward modifications:

- \( J(k_t, z_{t-1}) \) in (37) is replaced by \( J(d_t, k_t, p_{t-1}) \) in (56).

- The predictive density \( f(s_t|Y_{t-1}) \) in (41) becomes

\[
f(s_t|Y_{t-1}) \simeq \int J(q_t, p_{t-1}) f(p_t|s_{t-1}) g(s_{t-1}; \hat{a}_{t-1}) |_{q_{t-1} = \psi(q_t, p_{t-1})} dp_{t-1},
\]

where

\[
f(p_t|s_{t-1}) = N_4 \begin{bmatrix} 0 & 0 & \rho_{\varphi} & 0 & 0 \\ 0 & 0 & 0 & \rho_r & 0 \\ 0 & 0 & 0 & 0 & \rho_v \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \sigma_{\varphi}^2 \\ \sigma_r^2 \\ \sigma_v^2 \\ 0 \end{bmatrix} \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \sigma_{\varphi}^2 \end{bmatrix}.
\]
With $y_t$ now defined as $y_t = [\ln \zeta_t \quad \ln c_t \quad \ln i_t \quad \ln n_t]^T$, the measurement density becomes

$$f (y_t|s_t, Y_{t-1}) \sim N_3 (\mu(s_t), V),$$

$$\mu(s_t) = \begin{bmatrix}
\ln \zeta(s_t) \\
\ln c(s_t) \\
\ln i(s_t) \\
\ln n(s_t)
\end{bmatrix}, \quad V = \begin{bmatrix}
\sigma_y^2 & 0 & 0 & 0 \\
0 & \sigma_c^2 & 0 & 0 \\
0 & 0 & \sigma_i^2 & 0 \\
0 & 0 & 0 & \sigma_n^2
\end{bmatrix}.$$

We demonstrate the performance of the EIS filter with two Monte Carlo experiments patterned exactly after those used in working with the RBC model. We again work with two data sets: an artificial data set consisting of 100 realizations of $\{\zeta_t, c_t, i_t, n_t\}$ generated using the parameterization of the model given in Table 3; and a Canadian data set consisting of quarterly real per capita observations on $\{\zeta_t, c_t, i_t, n_t\}$, spanning 1976:I-2008:IV (132 observations), and detrended using the Hodrick-Prescott filter. The latter was obtained from Statistics Canada; both are available for downloading at www.pitt.edu/~dejong/wp.htm.

Aside from the parameters that characterize the sources of stochastic uncertainty in the model, the artificial data were generated using the parameter values calibrated by Schmitt-Grohe and Uribe (2003) to match the summary statistics on Canadian data reported by Mendoza (1991): parameter values are listed in their Table 1 (and our Table 3), and the summary statistics in their Table 3. The parameters that characterize the sources of stochastic uncertainty in the model were chosen as those that minimized the sum of squared differences between Mendoza’s summary statistics (excluding the trade balance) and the statistics implied by the model; the statistics consist of standard deviations of $\{\zeta_t, c_t, i_t, n_t\}$, first-order serial correlations, and contemporaneous correlations with output. Finally, the standard deviations of all measurement errors were set at 0.5%. The same parameters used to generate the data were also used to evaluate the likelihood function in the MC experiment.

The parameters used to evaluate the likelihood function associated with the actual data are posterior modes estimated using the prior specification indicated in Table 3. The prior consists of independent normal distributions specified for each parameter. Aside from parameters that characterize stochastic uncertainty, prior means were set at the values specified by Schmitt-Grohe.
and Uribe, and prior standard deviations were set to reflect non-trivial uncertainty over these specifications. (Note that the specifications of $\delta$ and $\tau$ chosen by Schmitt-Grohe and Uribe are appropriate for annual data, and thus were translated under our prior into specifications appropriate for the quarterly observations we employ.) The priors over AR parameters were centered at 0.8 (s.d. 0.2); and with two exceptions along ill-behaved dimensions ($\sigma_r$ and $\sigma_i$), the priors over $\sigma'$s were centered at 0.5% (s.d. 0.5%). The likelihood function implies strong negative correlation between $\sigma_r$ and $\rho_r$, thus $\sigma_r$ was set so that the posterior mode of $\rho_r$ lied near its prior mean. Also, the posterior mode of $\sigma_i$ was difficult to pin down, so its prior mean was centered at 0.5% like its counterparts, while its standard deviation was set to pin down the posterior mode at this value.

Results from the two MC experiments we conducted are presented in Table 4. Due to the increased dimensionality of the state space, we set $N$ to 150,000 in working with the particle filter (requiring 128.59 and 169.66 seconds per function evaluation in the artificial and real data sets), and $(N,R)$ to (50,30) in working with the EIS filter (requiring 5.02 and 6.65 seconds per function evaluation).

To begin, note that in this case there are significant differences between the likelihood values produced by the EIS and Kalman filters in both data sets. Relative to the RBC model, this reflects the added sources of non-linearity featured in the SOE model: e.g., the captial-adjustment cost term \( \frac{\theta}{2} (k_{t+1} - k_t)^2 \) in (47), and the endogenous discount factor \( \theta_t \) featured in the household’s objective function. Once again, when the EIS filter is implemented using linear model approximations, differences in log-likelihoods produced by the EIS and Kalman filters virtually disappear (becoming at most 6.3e-11 across data sets and all time periods). Thus there is clearly a significant payoff in the implementation of a non-linear model representation in this application.

It is also interesting to note that in this application the artificial data set is the more challenging of the two. This is evident along two dimensions. First, MC standard deviations obtained using the artificial data set are relatively high for both filters. Second, the bias suffered by the particle filter is more substantial in the application involving the artificial data set. Specifically, the difference in mean log-likelihood approximations generated by the particle and EIS filters is more than 9 in working with the artificial data set, compared to less than 5 in working with the actual data set.

As opposed to the applications involving the RBC model, the explanation for these differences across data sets does not lie in the behavior of associated measurement errors: variances of measurement errors are closely comparable across data sets in this case. Instead, these differences stem primarily from differences in the volatility and persistence of the model’s structural shocks. In particular, with the model parameterization associated with the artificial data set calibrated to annual data, and the parameterization associated with the real data set estimated using quarterly observations, structural shocks are far less persistent, and generally more volatile, in the former case. The upshot of this difference is that in working with the actual data, the state variables are relatively easy to track, and in general the construction of likelihood approximations is less problematic.

Comparing the EIS and particle filters, as noted, the particle filter once again suffers non-trivial
bias, on scales similar to those observed in working with the RBC model. Regarding MC standard errors, these differ by two orders of magnitude in the artificial data set, but by only one order of magnitude in the actual data set. These results indicate that increases in the dimensionality of the state space do not necessarily amplify the numerical problems suffered by the particle filter: outliers and narrow measurement densities are far more important sources of difficulty.

We conclude our analysis of the SOE model by reporting sampling errors associated with the log-likelihood estimates reported in Table 4. Following the procedure described above in working with the RBC model, we estimate these errors to be 25.55 using the parameterization associated with the artificial data set, and 17.92 using the parameterization associated with the actual data set. Comparing these estimates with the MC standard errors reported in Table 4, we see that the particle filter serves as a better potential gauge of statistical uncertainty than was the case in the applications involving the RBC model. In particular, its MC standard errors are only 1/13th and 1/36th the size of their associated sampling errors in this case, while recall that in working with the RBC model, these ratios were roughly 2 and 4/5ths. The ratios associated with the EIS filter are 1/354th and 1/376th in this case, compared with roughly 1/10,000 and 1/200 in working with the RBC model.

6 Conclusion

We have proposed an efficient means of facilitating likelihood evaluation in applications involving non-linear and/or non-Gaussian state space representations: the EIS filter. The filter is adapted using an optimization procedure designed to minimize numerical standard errors associated with targeted integrals. Resulting likelihood approximations are continuous in underlying likelihood parameters, greatly facilitating the implementation of ML estimation procedures. Implementation of the filter is straightforward, and the payoff of adoption can be substantial.
