## Does Internal Locus of Control Get You Out of Homelessness?\*

This paper examines the role of internal locus of control in shaping transitions into homelessness. The data is taken from a longitudinal Australian dataset drawn from a sample of vulnerable individuals. The results, based on a Wooldridge Conditional Maximum Likelihood (WCML) estimator, show that individuals high in internal locus of control are significantly less likely to enter a homeless episode.

**JEL Classification:** D31, I32, C23

#### 1. Introduction

One of the most exciting developments in Economics over recent years has been the recognition that non-cognitive skills are central to individual decision-making and success. Recent research shows that individuals with an internal locus of control (LOC) —one of the core non-cognitive skills in personality analysis— are more resilient (Etilé et al., 2021), expect higher returns from effort (Caliendo et al., 2022) and are more likely to engage in preventative behaviors (Bonsang and Costa-Font, 2022).

While these advances have improved our understanding of how personality is linked to individual outcomes, currently we know little about how LOC relates to primary achievements deemed necessary for a decent life, such as having an adequate shelter. Data paucity and the low prevalence of traumatic events in general population surveys are partially responsible for this gap. Paradoxically, socially-excluded groups are a population of special interest when studying interventions aimed at enhancing skills and alleviating social exclusion.

This paper takes a step towards this direction by examining whether internal LOC can account for transitions into an extreme form of poverty: homelessness. We hypothesize that individuals high in internal LOC are more prone to adaptive performance and aware of future needs, which prompts them to reduce housing risks. Homelessness has gained attention in the social agenda due to its consequences on social cohesion. In Australia, 50 out of every 10,000 people are actually homeless (Batterham et al., 2022).

We take the data from the Journeys Home (JH), a micro survey representative of the population experiencing disadvantages along all standard economic and social dimensions. The econometric approach is based on a Wooldridge Conditional Maximum Likelihood (WCML) estimator. The paper shows that individuals high in internal locus of control are significantly less likely to enter a homeless episode. This result is robust to several sensitivity checks, including controlling for the potential endogeneity of LOC and non-random attrition. Further details on the WCML approach and alternative estimation methods are given in the Appendix.

#### 2. Data and Methods

The JH is drawn from a broad spectrum of a disfavored population (Melbourne Institute, 2014). It has a panel structure, with respondents being interviewed six times at six-monthly intervals. We restrict the sample to participants aged between 20 and 59, noting that non-cognitive skills are relatively stable among adults (Borghans et al., 2008).

Our main explanatory variable of interest is LOC, which is assessed by seven questions inspired in Perlin and Schooler's (1978) questionnaire of coping efficacy. The responses are coded in a five-point Likert scale ranging from *Strongly agree* (1) to *Strongly disagree* (5), which yields a total score comprised between 5 and 35. After conducting a factor analysis, we extract a single latent factor and identify separate loadings for each item. These weights are used to construct a continuous measure interpretable as internal LOC. Those believing that life's outcomes are determined by their own decisions (external factors such as luck) score high (low) on our LOC

measure. The index is normalized to have zero mean and unit variance. Because this information is available only in wave 6 of the JH, we assume LOC is time-invariant over the estimation period.

The JH contains detailed information on the individual's housing situation. We adopt a narrow definition of homelessness according to which individuals are so if they are i) sleeping rough, in cars or squatting in an abandoned building ('primary' homelessness, as defined by the Australia Bureau of Statistics, ABS, 2011) or ii) living in emergency or crisis accommodation ('secondary' homelessness). This criterion applies to 9.4% of the JH sample and is closely aligned with much of the U.S. and Australia research evidence (Cobb-Clark et al., 2016).

#### 2.1 Empirical strategy

We model homelessness transitions as:

$$H_{it} = \mathbf{1} \, i \mathbf{f} \, (\rho H_{it-1} + X'_{it} \beta + \gamma LOC_i + c_i + u_{it} > 0) \tag{1}$$

 $(i=1,\ldots,N)$ ;  $(t=2,\ldots,T)$ , where  $H_{it}$  is a dummy variable that takes value one if the individual is homeless, zero otherwise,  $X_{it}$  is a set of relevant confounders,  $c_i$  stands for unobservable heterogeneity and  $u_{it}$  is a white noise. We deal with the initial condition problem following Wooldridge (2005) and defining an auxiliary distribution of the unobserved individual effect which is conditioned on the initial value  $H_{i1}$  and the within-means of the time-variant explanatory variables,  $\bar{X}_i$ ,

$$c_{i}|H_{i1}, X_{it} \sim N(\vartheta_{0} + \vartheta_{1}H_{i1} + \bar{X}'_{it}\vartheta_{2}, \sigma_{\xi}^{2})$$

$$c_{i} = \vartheta_{0} + \vartheta_{1}H_{i1} + \bar{X}'_{i}\vartheta_{2} + \xi_{i}$$

$$(2)$$

with  $\xi_i \sim N(0, \sigma_{\xi}^2)$ . A consistent estimation of Eq. (1) crucially relies on the correct specification of  $c_i$  and the assumption that  $E(H_{it-1}, u_{it}) = 0$ . In the Appendix we allow for less restrictive assumptions. Vector  $X_{it}$  includes the variables described in Table 1, which reports summary statistics and the marginal probability effects (MPEs) from the model.<sup>2</sup>

#### 3. Results

Homelessness is a self-perpetuating state, with the reference individual being about 5.9 percentage points (pp) more likely to be homeless at time *t* if he/she was homeless at *t-1*. This uncovers a strong homelessness trap among vulnerable individuals in Australia and is consistent with the negative duration dependence reported in earlier work (Cobb-Clark and Kettlewell, 2021). The coefficient of homelessness at the initial period is

<sup>&</sup>lt;sup>1</sup> Although the LOC measure may be subject to measurement error, we assume that the way individuals self-report such variables depends on individual traits or, in other words, that the individual fixed effect of the model absorbs the individual specific measurement error. Because the remaining measurement error is expected to produce attenuation bias, the estimates should be interpreted as a lower bound of the effect size.

<sup>&</sup>lt;sup>2</sup> The MPEs have been calculated at the means of covariates.

significantly greater than zero, which suggests that initial homelessness is due to an earlier history of chronic poverty and unobserved characteristics that hamper a person's life quality.

#### 3.1 Is LOC related to homelessness transitions?

Individuals high on LOC are less likely to suffer a homelessness spell. The estimate – a 1.3 pp decrease in the outcome probability for a one standard deviation increase in LOC – is non-negligible if we compare it with the sample average probability of being homeless (9.4%). The estimate is conditional on previous homelessness status, a condition that in our WCML setting captures the entire history of the right-hand-side variables, including those (employment, income, and schooling, among others) that may have been influenced by LOC at earlier stages of the individual's life.

The likelihood of homelessness is significantly lower among women and related to changes in marital status, with marriage representing a buffer against home loss. The coefficient of income has the expected sign yet is significant only at the 10% level.<sup>3</sup> The homelessness risk falls among those with a tertiary education and who have social support. Reversely, individuals living in an urban area and victims of physical or sexual harassment are more likely to be homeless. Variations in the regional employment rate fail to attract a significant coefficient, while individuals living in rich areas are more likely to be homeless, perhaps due to the relatively high prevalence of homelessness in large, wealthy cities (Sydney, Melbourne and Brisbane).<sup>4</sup>

--- Insert Table 1 here ---

#### 4. Discussion

#### 4.1 Endogeneity of LOC

The findings of the paper rely strongly on the assumption that LOC is a time-invariant attribute. There are reasons why this may be regarded a reasonable assumption. Firstly, the most relevant factor accounting for changes in non-cognitive skills is aging, with short-run variations in personality being very concentrated among the young or old (Borghans et al., 2008). We limit this channel by restricting the sample to adults and relying on the short time span offered in the JH (six semesters comprised between November 2011 and March 2014). Secondly, changes in LOC following life shocks, including illnesses, imprisonment, pregnancy and unemployment, among others, tend to be economically negligible (Cobb-Clark.and Schurer, 2013). These observations limit the risks of reverse causality in our setting.

<sup>&</sup>lt;sup>3</sup> The estimates shown in the table capture just the effect of variations in the explanatory variables. The effect of the time-averaged-value of all time-variant variables is embedded in the individual fixed effect.

<sup>&</sup>lt;sup>4</sup> The prevalence of homelessness in these cities more than doubles the sample average. Housing affordability pressures are higher in capital cities than in regional areas. Moreover, among the eight Australian capital cities, Sydney, Melbourne and Brisbane rank at least in the top four in a number of affordability measures, including the proportion of household income required to afford a median mortgage and the dwelling price to income ratio (CoreLogic Australia, 2018).

Notwithstanding, we consider the possibility that the LOC measure extracted from wave 6 of the panel may not fully represent the individual's LOC during the entire period. In Table 2 we limit the potential impact of life events on LOC by focussing on individuals who have never been exposed to potentially relevant life shocks, including i) unemployment episodes, ii) changes in educational attainment, iii) changes in marital status, iv) the death of a relative or family member, v) physical or sexual violence during the sample period and vi) a long term health/disability condition causing restrictions. In all cases the estimates are well-defined and do not depart much from the previous findings, which suggests that the extent of attenuation bias in the baseline estimates, if any, is very limited.

Given that LOC may differ across socio-economic groups, in the bottom part of the table we split the sample into gender, schooling and age categories. The association between LOC and homelessness remains negative and significant, particularly among women and individuals with a secondary education or more.

--- Insert Table 2 here ---

4.2 Potentially endogenous covariates, definition of homelessness, and additional controls

Table 3 presents results when variables potentially endogenous with LOC, such as income, labour status, schooling and health condition are dropped from the specification (Model 2), and when these and the remaining covariates are omitted (Model 3). These sensitivity analyses result in a slight increase in the effect size. We also examine the extent to which the results hold when granular controls for health and financial condition described in the Table- are included in the regressions (Model 4). In the next columns we show that, relative to the baseline model, the influence of LOC is reduced notably when accounting for the most severe form of homelessness, while it remains practically unchanged when we adopt a broad definition of homelessness.

--- Insert Table 3 here ---

#### 4.3 Non-random attrition

Although retention rates are remarkably high in the JH (yearly average = 96.5%), the non-random exit and entry of individuals for reasons related to homelessness is a potential concern. To investigate this issue, we regressed a dummy equal to 1 for individuals who attrit at wave t + 1 on homelessness and all the controls at wave t. Although dropouts are not significantly related with homelessness (p-value = 0.492), in Table 3 (last column) we report the results from a balanced panel in which the longitudinal weights provided by the JH have been used to limit potential biases arising from differential non-response.<sup>5</sup>

<sup>&</sup>lt;sup>5</sup> The longitudinal weights are calculated to correct for endogenous attrition. A full analysis of panel attrition and details of the construction of the balanced-panel weights can be found in the wave 6 technical report (Melbourne Institute, 2014). In our sample, gender (p-value = 0.04), singlehood (0.03) and divorce (0.02) correlate negatively with the probability of attrition.

#### 5. Conclusions

The evidence on how non-cognitive skills are related with the ability to fulfil primary needs among vulnerable populations (ex: having a home) is practically non-existent. This paper takes a step towards filling this gap. The results show that individuals high in internal locus of control are significantly less likely to enter a homeless episode. This result is robust to several sensitivity checks, including the inclusion of variables potentially endogenous with LOC, such as income, labour status, schooling and health. From a theoretical standpoint, this may lend support to the notion that the way people respond to housing stressors, namely through their choice of coping and problem-solving mechanisms, depends on LOC. Considering our results, an integrated approach that goes beyond financial assistance and considers the role of individual traits may prove useful to identify key risk groups. Moreover, interventions from very early ages aimed at reinforcing specific skills among families and individuals at risk of social exclusion may result in more targeted social policies.

#### 6. Appendix

The WCML estimator exhibits three main features, as it i) takes account of the unobserved heterogeneity that surrounds homelessness transitions; ii) controls for homelessness state dependence; and iii) addresses the 'initial conditions' problem, i.e., the possibility that housing status at the start of the observation period is endogenously determined by the past history of the individual. The auxiliary distributional assumption on the individual-specific effects allows the model to address two concerns, namely the potential correlation between i) the unobserved heterogeneity and the regressors of the model, i.e.,  $E(X_{it}, c_i) \neq 0$ , and ii) the unobserved heterogeneity and the initial value of the dependent variable, i.e.,  $E(H_{i1}, c_i) \neq 0$ 

Nonetheless, the WCML approach relies on the assumption that the lagged dependent variable is independent from the composite error process,  $E(H_{it-1}, u_{it}) = 0$ , a condition that may be violated. To address this concern, in this Appendix we present two complementary exercises. Firstly, we resort to Arellano et al.'s (1999) method of sequentially censored subsamples, according to which individuals without censored past observations  $(H_{it-1}=1)$  in our case) are exogenously selected for the purpose of estimating the dynamics of the dependent variable. Although the selection process is an issue, in the censored subsample  $E(H_{it-1}, u_{it}) = 0$ . The results, in the first column of Table A1, show that with this approach the LOC effect raises to -3.76 pp. Still, the estimate is significant only at the 10%, probably due to the small sample size.

The second exercise, based on a two-stage Generalized Method of Moments (GMM) estimation procedure, provides similar point estimates. We start by taking first differences of a linear version of Eq. (1) to purge the model from the individual-specific effect,

$$\Delta H_{it} = \rho \Delta H_{it-1} + \Delta X'_{it} \beta + \Delta u_{it} \tag{A1}$$

<sup>&</sup>lt;sup>6</sup> We thank José María Labeaga, one of the authors, for relevant discussions and comments.

Although this approach comes at the cost of abstracting from the binary nature of the dependent variable, it provides a venue for more flexible assumptions because it does not require a distributional assumption on  $c_i$ . Noting that in the resulting model there is still correlation between the differenced lagged variable and the disturbance process (the former contains  $H_{it-1}$  and the latter contains  $u_{it}$ ), we follow Arellano and Bond (1991) and instrument  $\Delta H_{it-1}$  with all lags of  $H_{it-j}$ , for  $j \geq 2$ . This requires that  $E(H_{it-j}\Delta u_{it}) = 0 \ \forall j \geq 2$  -a moment condition that can be tested- for the estimator to be unbiased and consistent.

However, this strategy is not directly applicable to our setting insofar as LOC is a time-invariant variable that disappears after taking first differences. Kripfganz and Schwarz (2019) propose a two-stage estimation procedure to identify the coefficients of invariant characteristics in the context of GMM models. This consists of estimating Eq. (A1) in a first stage and then regressing the first-stage residuals on the time-invariant regressors. Specifically,

$$H_{it} - \hat{\rho}H_{it-1} - X'_{it}\hat{\beta} = \gamma LOC_i + \epsilon_{it}, \text{ with } \epsilon_{it} = c_i + u_{it} - (\hat{\rho} - \rho)H_{it-1} - X'_{it}(\hat{\beta} - \beta)$$
 (A2)

where  $\hat{\rho}$  and  $\hat{\beta}$  are the first-stage estimates. In Table A1 we present the estimation results of Kripfganz and Schwarz's two-stage model with GMM-type instruments, standard instruments for the strictly exogenous regressors, and Windmeijer-corrected robust standard errors (endogenous regressors: lagged dependent variable, income and employment status; predetermined variables: education, marital status, number of children, health and addictions; strictly exogenous: the remaining variables). We include results with and without collapsed instruments, and under different moment conditions depending on whether they are linear or nonlinear as suggested by Chudik and Pesaran (2022). Although the first-stage estimates (not reported) vary by between 10% to 20% across specifications, the coefficients of LOC are practically identical across columns and approximately double the baseline estimate from the linear version of Eq. (1) (last column).

In the bottom part of the table the test for absence of serial correlation in the first-differenced errors of the first stage show that there is no second order serial correlation. We also report Hansen's J-test for the validity of the overidentifying restrictions for the first stage of the model with linear moment conditions (the second stage is exactly identified, while the test is not defined under non-linear conditions). The hypothesis that the instruments are not valid is rejected.

Notes: i) Source: JH, 6 waves; ii) Standard errors in parenthesis; \*p < 0.05, \*\*p < 0.01, \*\*\*p < 0.001. The set of controls include a set of binary indicators that capture whether the respondent i) has an addiction problem with drugs or alcohol, ii) can rely on networks of mutual support and community ties, iii) has experienced either physical or sexual violence in the last 6 months and iv) has ever experienced a homelessness episode before participating in the JH survey. This information captures life circumstances and non-observables that may impact an individual's financial strain and, ultimately, housing status. Regional per capita GDP, the unemployment rate and region and wave fixed effects are included to account for the stance of the business cycle and regional disparities.
