Abstract

Populist far-right politicians are increasingly successful across the globe. However, we know little about the personal characteristics of rank-and-file far-right politicians and what part of their success is due to these characteristics. We use hand-collected data on more than 41,000 political candidates for local council elections in the German state of Saxony to study the characteristics and electoral outcomes of *Alternative für Deutschland* (AfD) politicians. We find that AfD candidates are new entrants to local politics rather than turncoats from other parties. AfD candidates also differ in observable characteristics from candidates of more established parties. However, “characteristics space” demand estimations show that AfD candidates’ electoral success is due to voters’ strong preference for the AfD “party brand”. In fact, voters evaluate (the observed traits of) AfD candidates more negatively than most other parties’ candidates. We decompose the party brand effect into distinct policy dimensions and identify the AfD’s stance on refugees and gender issues as particularly salient to voters.

Keywords: Populism, political selection, local councils, demand estimation, BLP model

We are grateful for funding from the German National Science Foundation (DFG): project “Political selection in Germany” (Grant no. DFG-405960810). We thank Tom Berwe, Kristin Binner, Benedikt Feldkamp, Matthias Gähl, Lina Grunow, Ekaterina Komarova, Yannick Ollesch, Nina Peschick, Antonio Scarpino, Hanna Schömann, Anna Schouten, Alexander Stöcker, and Anna Weinforth for excellent research assistance. We have benefited from helpful comments and suggestions offered by participants at the EPCS conference in Vienna, the EEA conference in Bordeaux, the MPI Workshop on Local Public Finance in Berlin, the Public Finance Workshop in Osnabrück, the ZEW Public Finance Conference in Mannheim, the Spring Retreat of the RTG “Regional Disparities and Economic Policy” and the RGS Econ Jamboree in Essen, and the Economics Department Seminar of the University of Heidelberg. The usual disclaimer applies.

1 Introduction

Contemporary politics is defined by the growing popularity of populist right-leaning movements that only a few years ago were at the fringes of the political landscape (Guriev and Papaioannou, 2022; Morelli, 2025). The crawl of formerly fringe ideologies into the halls of power is a global phenomenon, with prominent examples including the “Make America Great Again” movement led by Donald Trump in the US, right-wing populist leaders in South America, and the increasingly successful populist and nativist parties across Europe.

Why are far-right populists successful? This question can be analyzed from different angles. We emphasize the distinction between populist politicians and their parties. Are far-right populists successful because voters are dissatisfied with traditional political elites and desire a new slate of political leaders with different characteristics? Or are populist politicians successful because the voters are drawn to the broad policies they and their parties have come to symbolize (e.g., “no immigration”, “traditional gender roles”, “patriotism”)?

Our contribution is to disentangle and quantify the contribution of political candidates’ personal traits vs. “party brand” effects for the success of far-right populism. The scarcity of existing evidence on this question is arguably due to data and methodological limitations. While the traits of prominent, national-level populist (and mainstream) politicians are well-known, it is difficult to disentangle the impact of party brands vs. politicians’ traits at the national level due to small samples and the relative importance of country-specific idiosyncracies. While larger samples are available at the local level, comprehensive data on relevant traits of local-level politicians are sparse. In addition, even where such data is available, specific features of the electoral system often impede the implementation of suitable empirical designs.

We hand-collect data on more than 41,000 political candidates for local elections across more than 400 municipalities in the German federal state of Saxony. Our data includes

personal, non-political characteristics of candidates (gender, occupation, academic titles) as well as political and electoral information (party, incumbency, list placement, votes received). Saxony is an ideal setting to study the role of candidates vs. party brands for the success of far-right populists. In Saxony, the *Alternative für Deutschland* (AfD), Germany’s dominant populist far-right party, has been particularly successful and fielded from the local elections in 2014 onwards candidates across the state. As such, the Saxonian electoral setting offers a large amount of variation that can be harnessed to study the success of populist politicians. Second, the local electoral system in Saxony, unlike in other German states, does not allow for list votes and thereby forces voters to cast their votes exclusively for candidates.

This particular feature of the Saxonian electoral system implies that the choice a voter has regarding for whom to vote resembles a consumer’s decision regarding which product to buy. Drawing on this similarity, we make use of established approaches for demand estimation in “characteristics space” from Industrial Organization (Berry, 1994a; Berry et al., 1995; Berry and Haile, 2021) to estimate voter preferences and to disentangle the relative contributions of party brands vs. personal (i. e., non-political) candidate traits for candidates’ electoral performance.

We first descriptively explore the traits of AfD candidates vs. the traits of candidates of other parties. In terms of observable personal characteristics, AfD candidates indeed represent a new and different selection. AfD candidates are new entrants to politics rather than turncoats from other parties. They are also more likely male and self-employed and less likely to hold academic titles (i. e., Dr. or Professor). Nevertheless, demand estimations indicate that voter preferences for the observable traits of AfD candidates are no higher than for candidates of other parties. In fact, aggregate candidate quality of AfD candidates from the perspective of voters is lower than the quality of candidates running for most other parties. Why do AfD candidates nonetheless obtain high vote shares? Our results indicate that AfD candidates benefit strongly from their party brand: the AfD brand has a higher value than that of all other major parties.

These findings have important policy implications. They indicate that more established parties cannot mimic the AfD's success by fielding candidates that are more similar to AfD candidates. Relatedly, one reason why the perceived quality of AfD candidates is low is that they are less likely to hold academic titles, while voters display a preference for such titles. It has been argued that populists are successful because voters are dissatisfied with traditional (notably "academic") elites (Guriev and Papaioannou, 2022). However, this does not appear to be the explanation for populists' success in our setting. As such, fielding candidates that do not resemble "traditional elites" may not be a promising strategy for non-populist parties, either. Instead, to poach voters from the AfD, other parties ostensibly have to address "party brand" effects, by either improving their own brand, or diminishing that of the AfD, or both.

What is reflected by the party brand? According to Keller and Lehmann (2006), brands reflect "the complete experience that customers have with products". One important aspect of the experience that a local voter has with parties' brands consists of their stance on nationally salient policy issues. In the Saxonian context, we find that refugee inflows and local gender (im-)balances are significantly related to the local strength of the AfD brand, indicating that the AfD's positioning on immigration and gender issues are particularly relevant to voters.

This paper contributes to a recent literature in Political Economy on the success of far-right populist policy makers. As discussed, this question can be approached from different angles, and thus different explanations have been explored in the literature. One important strand perceives populist parties essentially as an option that voters choose if they are confronted by shocks and macroeconomic developments beyond their control, e. g., globalization, immigration, economic crises. Fremerey et al. (2024), for example, find that in Germany, the inflow of refugees increases the vote share of far-right parties at the county level (but not at lower levels of government). Similarly, Edo et al. (2019) find that immigration increases the vote share of far-right parties at the departmental level in France. Gabriel et al. (2023) show that austerity in the wake of fiscal consolidations

increases the vote share of extremist parties. Similar evidence for the importance of economic insecurity using survey and voting data for Europe is offered by Guiso et al. (2024) and Gozgor (2022), respectively. Relatedly, Rodrik (2021) argues that globalization is one of the main drivers of populism. We complement this literature by focusing on whether voters respond to such outside events by voting for far-right populists because populist politicians are more preferred than mainstream politicians, or because their parties stand for policies that are particularly appealing to voters.

Another strand of literature, typically relying on survey data, emphasizes incremental changes in voter preferences as explanations for populists' electoral success. For example, Danieli et al. (2023) find that changes in voter priorities, i. e., which policy dimensions voters value, are the main driver of populist success across Europe: cultural issues have ostensibly become important to voters, which appears to drive populist voting. Koch et al. (2023), in contrast, identify increasing "dissatisfaction with democracy" as another explanation. Relatedly, Bellodi et al. (2024) argue that declining trust of voters in government causes a shift toward "commitment policies", which benefits populists. Other related contributions in this strand of literature are, e. g., Kollberg et al. (2025), Hangartner et al. (2019), Bonikowski (2017), Guethner and Nunnari (2025), and Ballard-Rosa et al. (2021). We relate to this literature by estimating voter preferences with observed voting behavior instead of survey data.

Political selection within populist parties has received little attention in the Economics literature. Bó et al. (2022) comes closest to addressing to what extent populist success is driven by the entry of new and possibly different types of candidates into the political arena. They study the characteristics of candidates running on the ticket of the Sweden Democrats. Drawing on administrative data, they conclude that Sweden Democrat candidates are more likely to be economic and social outsiders. They also show that the voters of Sweden Democrats have characteristics that are similar to those of their candidates. This finding implies that at least part of the success of the Sweden Democrats

is due to the traits of their candidates. However, Bó et al. (2022) do not attempt to quantify the effect of candidate characteristics vs. party brand effects.¹

With respect to methodology, our paper is also related to a recent literature in Political Economy that uses approaches from Industrial Organization to structurally estimate voter preferences for characteristics, party brands, and policy positions of political candidates. For example, Iaryczower et al. (2024) use demand estimation in “characteristics space” to study whether the non-ideological characteristics and policy positions of candidates supplied by the political system in Brazil adequately reflect voter preferences. Another example is Kawai and Sunada (2025), who adapt approaches developed for production function estimations to estimate the valence of candidates running in US House elections.²

2 Background

2.1 Municipalities in Germany

Germany is a federal country with three main tiers of administration: the federation, states, and communes. The communes are responsible for the day-to-day lives of their residents and are subdivided further into counties and municipalities, with each county – being the larger territorial unit – comprising several municipalities. Counties are mainly responsible for services that are considered to be supra-local (e. g., public transportation, hospitals, vocational schools). In contrast, municipalities are responsible for local services

¹There are further contributions suggesting that (populist and mainstream) policy makers are elected for their unique traits. Poertner (2023), for example, finds that candidates in Mexico who share traits with underrepresented groups increase engagement and electoral participation of these groups. However, these contributions tend to focus on the importance of specific traits. They also neither attempt to disentangle the relative contributions of these traits nor to isolate party brand effects. While there is a literature in Political Science that studies candidate selection by populist parties, these contributions tend to focus on specific political traits that are important mainly within the political context of the country in question. For example, Kamenova (2023) finds that the AfD strategically selects candidates for the European Parliament in view of their ability to avoid accusations of racism.

²Other methodologically related approaches have been implemented by Longuet-Marx (2025), Ujhelyi et al. (2021), Albuquerque et al. (2025), Magesan et al. (2024), and Montero (2025).

and constitute, as the lowest tier of administration, the part of the state that is closest to citizens. They provide, e. g., public child care, maintain local roads, and engage in land-use planning (Rellecke, 2019). A few large municipalities are “county-free” and provide both municipality- and county-level services.

2.2 Municipalities and local councils in Saxony

Saxony is one of the six federal states located in East-Germany and has about 4 million inhabitants. As other eastern states, it has suffered crippling economic decline and sustained depopulation after reunification. While there are by now some growing and economically prosperous urban centers, the rural areas have never recovered economically and faced substantial outflows of (primarily young) inhabitants.

As of January 1st 2024, Saxony has 418 municipalities. Three large municipalities (Dresden, Leipzig, Chemnitz) are county-free while the remaining 415 are organized into ten counties. The governing body of municipalities is the local council.³ The council has several elected members and holds ultimate political authority over all matters concerning the municipality. The main responsibility of the local council is the approval of the municipal budget. The council also passes statutes regulating municipal matters.

The size of a council is determined prior to a local election and depends on the number of inhabitants. Local council size varies from 8 councilors in municipalities with up to 500 inhabitants to 70 councilors for municipalities exceeding 400,000 inhabitants (Rellecke, 2019). The office of local councilor is an honorary position. However, councilors receive a monthly allowance and a financial compensation for each meeting they attend.

³The second important local political institution is the mayor. The mayor is the chief executive and oversees the administration of the municipality. She is directly elected by the residents of her municipality. Mayor elections are not synchronized across municipalities. The tenure of a mayor is seven years and mayors can be re-elected.

2.3 Local council elections

Local council elections take place every five years on the same day for all municipalities. In every municipality, parties and local voter initiatives submit lists of candidates. Candidates can be nominated by political parties or voter initiatives by secret ballot in a members' assembly. Every voter has three votes which she can cast either individually for up to three candidates (*panaschieren*) or jointly for one single candidate (*kumulieren*). Unlike in other states, voters vote for individual candidates and cannot cast their vote for a list as a whole.

Seats are assigned to parties according to a proportional rule: if the candidates on a particular list have jointly won 25% of all votes, the party fielding the list is entitled to about 25% of all seats. Which candidates ultimately win a seat is determined by their within-list rank, which is based on the number of personal votes they have received (open list system). If parties have not fielded a sufficient number of candidates to fill all seats they have won, the seat remains empty. The council thus becomes effectively smaller than originally intended.

Except for the three county-free municipalities, each municipality has only one electoral district whose boundaries overlap with the municipality boundaries. The three county-free municipalities are divided into electoral districts (up to 13 in the case of Dresden, the largest city in Saxony). In the county-free municipalities, parties field a separate list for each electoral district and thus, in effect, a separate election is held in each district.

2.4 The rise of the AfD

While other European countries have had strong far-right populist parties for decades – e. g., Austria (*Austrian Freedom Party (FPÖ)*), Italy (*Lega Nord*), or Finland (*True Finns*)–, such parties have traditionally struggled and had been marginalized in Germany. However, this changed when the AfD entered the scene.

The AfD was founded in 2013. The impetus for its founding was the payment of bailout transfers to Southern European countries in the wake of the 2010 European debt crises. Besides opposition against these bailout payments, the AfD emphasized “conservative” values, notably free-market policies as well as traditional family and gender roles. With this political program, it obtained 4.7% of the votes in the federal election of 2013 and thus performed well for a new party. However, it failed to clear the electoral threshold of 5% and thus did not receive any seats in the federal parliament (“Bundestag”).

While its original leaders presumably intended the AfD to become a more conservative and EU-skeptical alternative to the (at the time) ruling Christian Democrats, inner-party conflicts soon erupted. Over time, the original leadership was pushed out, and the party moved progressively further to the right. It is now considered to be the German variant of the populist “alt-right” movements that have emerged in the US and elsewhere in Europe. Besides rhetorical opposition against “elites” and “mainstream parties”, its main policy positions include the restriction of immigration as well as opposition against “liberal” policies (e. g., policies that facilitate female employment or DEI policies).

With its tilt toward the far-right, the AfD had remarkable success in subsequent elections. In the 2017 federal election, it received 12.6% of the votes and entered the federal parliament as the third largest party. While it stagnated in the 2021 federal election with a vote share of 10.3%, it increased its vote share to 20.6% in the 2025 snap election.

2.5 Local politics in Saxony

In local elections, the major national parties as well as local voter initiatives and fringe parties run for council seats. The traditional national parties include the Christian Democrats (CDU, conservative), the Social Democrats (SPD, center-left), Greens (environmentalist), Free Democrats (FDP, market-liberal), and Left-Party (Linke, far-left). As of 2014, the AfD started to field candidates in local elections as well.

The voter initiatives in Saxony have different names. Many participate under the label “Free Voters” (*Freie Wähler*). In addition, there are voter initiatives with municipality-

specific names such as “Zukunft Sebnitz” (*Future Sebnitz*), “Wv Tourismus” (*Voter Initiative Tourism*), or “Regionalbauernverband Erzgebirge” (*Regional Farmers’ Association Erzgebirge*). Finally, there are a number of fringe parties that are generally unimportant at the federal or state level, but manage to win a few seats in local councils.

While local politics is traditionally considered to be less ideological than state or federal politics and focused on day-to-day issues, members of far-right parties have generally been kept at arm’s length by mainstream parties. In practice, this meant that the mainstream parties would not rely on far-right parties to obtain majorities in the council. This was possible as these parties had only limited representation in local councils and could thus be easily isolated. With the success of the AfD in the 2019 local election, however, this strategy has become more difficult. While the official position of the mainstream parties towards the AfD continues to be one of non-cooperation, it remains unclear what rank-and-file councilors do on the ground.⁴

Figure 1 shows the development of aggregate turnout and vote shares for the major parties across Saxony from 2009 to 2024. Turnout has jumped from 2014 (49%) to 2024 (68%). Another remarkable development is the rise of the AfD from only 2% in 2014 to 21% in 2024. In descriptive terms, this rise appears to come mainly at the expense of the conservative CDU, which dropped from a vote share of 33% to 22%, and the market-liberal FDP, which dropped from 8% to 2%. However, left-wing parties have lost considerably as well, notably the Left Party from 15% to 6% and the SPD from 11% to 7%. The vote share of the voter initiatives (FW), on the other hand, has remained more or less stable.⁵

⁴See, e. g., <https://taz.de/Brandmauer-in-saechsischen-Kommunen/!6064675/>.

⁵While Figure 1 shows the aggregate vote share across Saxony, we report in Appendix Figure C.1 the average vote shares gained by each party in municipalities where they contested. The numbers vary as parties do not contest in all municipalities. This is particularly relevant for the AfD, which competed only in 14 municipalities in 2014. Across these 14 municipalities, its average vote share was 10%. Also, average vote shares are higher for the voter initiatives in municipalities where they contest than their Saxony-wide aggregate vote shares. Nevertheless, overall patterns are similar for average and aggregate vote shares.

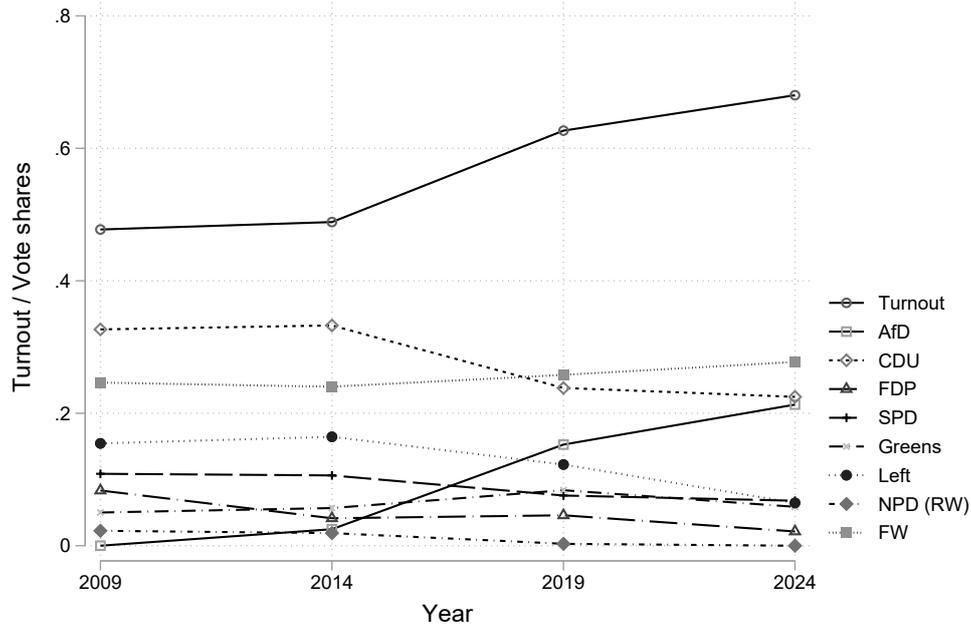

Figure 1: Development of turnout and party vote shares in Saxonian local elections. This figure shows the development of aggregate vote shares and turnout across Saxony.

3 Data

3.1 Hand-collected local election data

We hand-collect candidate-level data for local council elections held in 2014-2024 in Saxony as this data is not available from official sources. To collect this data, we rely on the official websites of municipalities, local newspapers, old editions of "Gemeindeblätter", etc. (see Online Appendix A for details on the data collection).

Appendix Figure C.2 shows the coverage of the candidate characteristics data. As this is hand-collected data, we do not have the universe of municipalities, but coverage is high for the elections in 2019 (90%) and 2024 (97%). For the 2014 election, coverage is about 50%, but this lower coverage is less problematic as the AfD only participated in 14 municipalities in 2014, and we have data on 11 of these municipalities.⁶

⁶Appendix Table C.3 compares population size and electoral outcomes (party vote shares, turnout) of the municipalities for which we were able to collect candidate-level data with the remaining set of municipalities in Saxony. While municipalities with missing data tend to be smaller, other differences, notably electoral outcomes, are minor.

Overall, we have information on 9,710 candidates in 2014, 15,125 candidates in 2019, and 16,823 candidates in 2024. With respect to AfD candidates, our data covers 97 candidates in 2014, 909 in 2019, and 1,562 in 2024. This candidate-level data includes the names of candidates and their occupation. Using this information, we can infer gender, academic titles, employment characteristics, and incumbency status. Our data also covers their initial list rank (as determined by their parties) as well as the number of votes received, their final list rank (as determined by their personal votes), and whether or not they have won a seat.⁷

As the data we retrieve is not standardized and has to be cleaned by us manually, it might be less accurate than administrative data. However, it has the major advantage that it essentially covers the same information that is observed by voters. While some voters might have private information about specific candidates, all voters observe their names and occupations on the ballot.

3.2 Descriptives on candidate characteristics

3.2.1 Are AfD candidates new or old candidates?

Are AfD candidates new entrants to local politics or are they “turncoats”, i. e., political veterans poached from other parties? To study this question, we identify turncoats by matching the names of candidates across elections (see Section A.4 in the Appendix for details on the matching procedure). That is, we study whether in a given municipality, the same name (given name and surname) appears on different party lists in two consecutive

⁷When estimating voter preferences below, we use a smaller sample of municipalities and candidates as candidate-level votes are not available in some elections. That is, we only include elections where we have vote data for the full set of candidates in the regressions. See Appendix Figure C.3 for the coverage of this sample. Table C.4 compares the population size and electoral outcomes (party vote shares, turnout) of the municipalities included and missing in the regression sample. There are only minor differences.

elections.⁸ Appendix Table C.1 reports a matrix with defections from and to different parties between the 2014 and 2019 (Panel A) and between the 2019 and 2024 (Panel B) election.

Turncoats are ostensibly rare in Saxonian local politics. Only 279 of the 15,125 candidates in our sample in 2019 were turncoats. Similarly, there were only 602 turncoats in 2024 (out of 16,823 candidates). Reflecting the low number of turncoats overall, the number of turncoats among AfD candidates is low as well. Only 40 (of 909) AfD candidates were turncoats from other parties in 2019 and 52 (of 1,562) in 2024.⁹

We confirm that AfD candidates are indeed more likely to be “new” candidates by regressing a recontesting dummy on party dummies while accounting for municipality fixed effects. That is, we estimate for the elections of 2019 and 2024 the following linear probability model:

$$\text{recontesting}_{i,m} = \alpha_m + \sum_p \alpha_p \mathbf{P} + \epsilon_{i,m}, \quad (1)$$

with i denoting a candidate and m the municipality. P is a set of dummies indicating the party of the candidate.

Appendix Figure C.4 visualizes the coefficient estimates. AfD candidates are, both in 2019 and 2024, less likely to be recontesting candidates than the candidates of all other parties.

⁸Note that in the three county-free cities, the boundaries of electoral districts can change between elections. As such, we identify turncoats at the municipality rather than the electoral district level for the county-free cities, even if separate lists are fielded within each electoral district.

⁹In Appendix Table C.2, we explore the electoral success of turncoats using OLS regressions with the vote share of a given candidate i as dependent variable. On the right-hand side, we include a dummy on whether or not she is a turncoat, an interaction with a dummy indicating AfD party affiliation, and further individual controls. We find that, conditional on other observable traits (Model 3), turncoats who switched to the AfD receive significantly higher vote shares. Turncoats who switched to other parties, on the other hand, do not fare better than non-turncoats. The estimated coefficient of AfD turncoats is 0.018. Thus, compared to the mean vote share of candidates (2.6%), being a turncoat for the AfD increases the vote share of a candidate by almost 70%.

3.2.2 Characteristics of AfD candidates

While AfD candidates are new candidates, are they also different candidates? We compare observable characteristics of the AfD and other parties' candidates. As indicated in Section 3.1, we collect information on observable candidates' characteristics from official election announcements. These announcements include, in particular, the name and the occupation of candidates. These are also the two pieces of information voters observe on the ballot.

From their names, we can infer candidates' gender and academic titles (in particular PhDs).¹⁰ Regarding occupations, there is no standardized list. We thus match the stated occupations using regular expressions to keywords to identify whether a candidate is (likely) self-employed, a pensioner, employed in the public sector, and whether she is an employee. We describe our classifications in more detail in Section A in the Appendix.

Appendix Table C.5 shows averages of the above-mentioned characteristics of all candidates (Panel A) and elected candidates (Panel B) across parties. AfD candidates differ across several observable characteristics from candidates of most other parties. Only 16.5% of AfD candidates are women, which is less than the share of women in all other major parties. AfD candidates are also less likely to hold academic degrees and more likely to be self-employed. They are also the party with the second-highest share of pensioners (only the Left Party has a higher share of pensioners).

Parties generally do not field candidates in all municipalities. The characteristics of candidates might also have changed over time within parties. As such, the simple comparison in Table C.5 might be confounded by municipality- and election-year-specific differences. We therefore estimate linear probability models of the following form to account for election-specific differences between AfD and other parties:

¹⁰We identify gender manually and academic titles from names using regular expressions that search for keywords such as "Professor" or "Dr."

$$\text{trait}_{i,e} = \alpha_e + \sum_p \alpha_p \mathbf{P} + \epsilon_{i,e}, \quad (2)$$

with $\text{trait}_{i,e}$ a dummy indicating each of the traits mentioned above and P a set of party dummies. α_e are election (municipality \times election year) fixed effects. We report the estimates in Appendix Figure C.5 and find that they in line with the summary statistics reported in Table C.5.¹¹

4 Estimation of voter preferences

We estimate voter preferences for party brands and candidate traits using techniques developed for demand estimation in Industrial Organization (Berry, 1994a; Berry et al., 1995). Following this literature, the utility a voter i obtains from voting for candidate j in her municipality m in a given election year is modeled as follows¹²:

$$u_{i,j} = \sum_p \alpha_p P_{j,p} + \sum_k \beta_k X_{j,k} + \zeta_j + \epsilon_{i,j}. \quad (3)$$

In this equation, $P = (P_{(j,1)}, \dots, P_{(j,P)})$ indicates a set of dummy variables with $P_{j,p} = 1$ for the party of candidate j and 0 for all other parties. $X = (X_{(j,1)}, \dots, X_{(j,K)})$ is a set of observable candidate characteristics (gender, age, occupation-related traits). ζ_j denotes candidate characteristics that may be known to voters but unobserved by us (e.g., charisma or “valence”, as well as policy positions on municipality-specific issues). $\epsilon_{i,j}$ is an i.i.d shock distributed according to a Type-I Extreme Value distribution with mean zero.¹³

¹¹The corresponding figures for elected candidates are available in Appendix Figure C.6.

¹²Technically, elections are held within electoral districts rather than municipalities. For simplicity, we refer in the following to electoral districts as municipalities. For all but the three county-free cities, municipal and electoral district boundaries overlap.

¹³Our formulation of voter utility deviates from those in, e.g., Iaryczower et al. (2024) and Longuet-Marx (2025) in that we do not estimate preferences for candidate-specific policy positions. In fact, the variable that operationalizes candidate-specific policy positions assumes the role of prices in demand

Voters vote for the candidate j who provides the highest utility, as in standard multinomial choice models. Then with voter utility specified as in Equation (3), it is well known that in models of multinomial choice, the probability voter i votes for candidate j can be expressed as

$$Prob_j^i = \frac{\exp(\Gamma_j)}{1 + \sum_j \exp(\Gamma_j)}. \quad (4)$$

Γ_j represents the “mean-utility” of candidate j and is given by:

$$\Gamma_j = \sum_p \alpha_p P_{j,p} + \sum_k \beta_k X_{j,k} + \zeta_j. \quad (5)$$

Drawing on the analogy between the probability that voter i selects candidate j and the vote share obtained by the candidate in a given election, the parameters reflecting voter preferences in Equation (2), (α, β) , can be estimated non-linearly from aggregate (“market-level”) data by replacing $Prob_j^i$ with the vote share S_j obtained by candidate j . This is facilitated by the assumption that voters only vary in the idiosyncratic shocks $\epsilon_{i,j}$ received from each candidate j , but not in how they assess candidate traits or party brands.

Berry (1994a) derives an “inversion” of choice probability expressions such as in Equation (4) that circumvents the need for non-linear estimation. Specifically, after replacing $Prob_j^i$ with S_j , Equation (4) can be transformed as follows:

$$\log(S_j) - \log(S_0) = \sum_p \alpha_p P_{j,p} + \sum_k \beta_k X_{j,k} + \zeta_j. \quad (6)$$

estimation and is thus perceived as endogenous in the above papers. Estimating voter preferences for candidate-specific policy positions on *local* issues is difficult since different issues are salient across municipalities. However, it is also less relevant in our context as our goal is to disentangle the effect of innate candidate traits vs. party brands. The important assumption in our context is that candidates’ policy positions on local issues are not systematically correlated with their party brands. We discuss this assumption in more detail in Section 5.1.

This equation is simply a linear model with the log odds between candidate j 's choice probability (proxied by her vote share) and the choice probability of the “outside option” (whose utility is normalized to 0) as dependent variable. In our electoral context, the natural “outside option” is the rate of abstention (1- turnout). ζ_j , the unobserved candidate characteristic, is the error term.

However, the specification of voter utility in Equation (2), upon which the “Berry-inversion” relies, is restrictive in that it does not allow for heterogeneous voter preferences. This implies that potentially unreasonable substitution patterns are imposed. The formulation in Equation (2) neglects, in particular, the possibility, that from voters’ perspective, parties might belong to separate political camps. A voter who has a strong preference for the AfD party brand might like the CDU as a party more than the SPD, for example.

A more general specification would allow for random and thus potentially correlated coefficients. In robustness tests, we therefore assume that voters vary in their preferences for party brands. This allows us to account for correlation of tastes across parties. More specifically, we decompose voter i 's taste for party brands as follows:

$$\boldsymbol{\alpha}_i = \boldsymbol{\alpha} + \boldsymbol{\Sigma}\mathbf{v}_i, \tag{7}$$

with $\boldsymbol{\alpha}$ a vector with the mean preferences (across all voters) for party $p = (1, \dots, P)$ and $\mathbf{v}_i \sim i.i.d. \ N(0, 1)$ a vector of taste shocks for each voter i , with each element referring to a party p . $\boldsymbol{\Sigma}$ is a symmetric matrix with up to $P \times P$ non-zero parameters. By multiplication with this matrix, each component of \mathbf{v}_i can be allowed to have different variances and to be correlated with other components.

The “Berry-inversion” cannot be applied to Equation (3) when coefficients are assumed to be random, as the choice probability for candidate j involves integration over the distribution of \mathbf{v}_i , i. e.,

$$Prob_j^i = \int \frac{\exp(\Gamma_j)}{1 + \sum_j \exp(\Gamma_j)} f(\mathbf{v}_i) d\mathbf{v}_i. \quad (8)$$

Two approaches have been pursued in the literature to resolve this complication. First, more structure could be ex-ante imposed on Σ . In particular, following Berry (1994a), if we group “similar” candidates into “nests” g , we can allow for correlation in voter tastes for candidates belonging to the same nest by writing $\epsilon_{i,j}$ in Equation (3) as follows:

$$\epsilon_{i,j} = \bar{\epsilon}_{i,g(j)} + (1 - \rho)\bar{\epsilon}_{i,j}, \quad (9)$$

with ρ capturing to what extent voter i prefers the nest to which candidate j belongs rather than specifically candidate j . For this nested-logit-type specification of voter utility, we can derive the following inversion following Berry (1994a):

$$\log(S_j) - \log(S_0) = \sum_p \alpha_p P_{j,p} + \sum_k \beta_k X_{j,k} + \rho \log(S_j/S_g) + \zeta_j, \quad (10)$$

with S_g denoting the aggregated vote share of all candidates belonging to nest g . This is again a linear model. However, as $\log(S_j/S_g)$, the relative vote share of candidate j within her nest g , is clearly endogenous, we need to instrument for this variable.

The advantage of the nested logit model is that it represents a straightforward extension of the plain logit model in Equation (7) and can be estimated by TSLS. However, one limitation is that nests have to be defined ex-ante. This is particularly unfortunate in our context as it is not clear whether AfD candidates belong to any particular “nest” (political camp) in the first place, and if yes, then whether they compete primarily with candidates of local voter initiatives (whose voters were ostensibly not attached to any of the major parties previously), candidates of the more mainstream right-wing parties (CDU, FDP), or candidates of certain left-wing parties (Linke, SPD).

Berry et al. (1995) introduce a non-linear estimation approach, often referred to as BLP, to explicitly estimate (the parameters in) Σ as defined in Equation (8), in addition to (α, β) . The idea is to estimate the linear and non-linear parameters of the model in

two steps. First, for an initial guess of Σ , the BLP-algorithm solves for the values of Γ_j – the “mean utility” for each candidate– that make candidate j ’s predicted vote shares match her actual vote shares. This is the inner loop of the algorithm. Since there is no closed form solution to Equation (8), a contraction mapping is applied at this stage.

Given the Γ_j ’s determined in the inner loop, predicted candidate-specific errors $\hat{\zeta}_j = S_j - Prob_j(\Gamma)$ can be calculated. Given $\hat{\zeta}_j$, we can estimate the structural parameters of the model with GMM, using a set of exogenous instruments. This is the outer loop.

With the estimates of Σ obtained in the outer loop, the inner and outer loops can then be run again to obtain a new set of parameter estimates. This procedure is repeated until convergence is achieved, i. e., the GMM criterion is minimized. The outer loop ensures that parameters are estimated consistently, while the inner loop ensures that parameter estimates correspond to the actual candidate vote shares.

One disadvantage of the BLP approach is that it requires at least as many “instruments” as elements in Σ to identify all parameters. It is not straightforward to obtain strong instruments that “target” each of the elements in Σ . In practice, restrictions have to be imposed ex-ante on Σ to avoid noisy or unreliable parameter estimates.

The nested logit and BLP approaches address the important concern of correlated preferences, but face limitations when it comes to implementation. Since they are thus not necessarily preferable to plain logit, we use the plain logit as baseline given its simplicity and flexibility. However, we report nested logit and BLP estimations as robustness tests.

5 The value of party brand and candidate traits: estimation

5.1 Identifying assumptions

We estimate the plain logit model as specified in Equation (7) with OLS. The identifying assumption is that ζ_j , the unobservable traits of candidate j , are uncorrelated with ob-

servable traits. In particular, we require ζ_j to be uncorrelated with the party dummies. In standard demand estimations, it is typically assumed that product characteristics are exogenous (the key endogenous variable in these models is the price of a product). However, the exogeneity of party brands and possibly other candidate characteristics is an important concern in our setting.

Exogenous party brands imply, *inter alia*, that AfD candidates do not systematically adopt policy positions or have unobserved traits that are more or less popular with voters *beyond* what is reflected by the AfD party brand. That is, AfD candidates most likely espouse views regarding, e. g., immigration that are popular with many voters in Saxony. They might also have distinct socio-economic backgrounds. However, in doing so they are in line with the policy positions and brand image of the AfD as an anti-immigration and anti-establishment party. Thus, such effects on voter utility is legitimately captured by the AfD dummy.

What would complicate the interpretation of the estimates is if AfD candidates systematically adopted, relative to candidates of other parties, more or less popular positions on local issues on which the AfD as a party has no official stance, or if AfD candidates had traits that matter to voters but which are not commonly associated with the AfD as a party. There is no indication that there are such systematic differences between AfD and non-AfD candidates. Nevertheless, we address such concerns further in Section 5.3 with robustness tests.¹⁴

¹⁴The non-political candidate traits are arguably not exogenous either (Marshall, 2024). For example, being a pensioner conveys more to voters than simply a particular employment status. Pensioners might be older and have lower incomes. Gender may also convey further information about a candidate. For example, female candidates might be perceived as having more time constraints as councilors due to family duties (Baskaran and Hessami, 2022). A negative voter bias against women might thus not be due to gender *per se*, but rather arise because voters assume that female candidates will perform less well as councilors due to such time constraints (statistical discrimination). However, the purpose here is not to establish the causal effect of traits on vote shares, but rather to establish how voters make use of the explicit and implicit information conveyed by a trait about the “quality” of a particular candidate.

Another related consideration is that parties may strategically decide what type of candidate to run in a particular election. In fact, as not all parties participate across the entire state, it might be that parties strategically enter the election in a municipality based on the types of candidates available locally and

5.2 Logit estimations

We collect the results from estimating Equation (7) in Table 1. The “outside option” is the abstention rate, i. e., candidates’ vote shares are defined relative to total eligible votes (not actual votes). In Model (1), we include dummies for all major parties as well as non-political traits of candidates. As the party dummies are mutually exclusive, we omit the “minor” parties and voter initiatives. That is, independents as well as minor national parties (for simplicity, we refer to the minor parties as independents as well), are the reference category and the estimates for the party dummies capture to what extent voter preferences for party p deviate from preferences for the minor parties.

To account for election-specific (i. e., market-level) differences, we extend Model (1) by additionally controlling for “election” fixed effects (municipality \times election year in regular municipalities, and electoral district \times election year in the three county-free cities). Model (2) thus estimates voter preferences for parties and traits within each election. In Model (3), we add as further controls “electoral” characteristics of candidates, i. e., whether she is a top-three ranked candidate on her list and whether or not she is an incumbent.

Across all specifications, the results suggest that AfD candidates benefit from a strong party brand. While we discuss the marginal effects of AfD membership based on the estimated coefficients in Table 1 in Appendix B.1, the magnitude of the effect in our preferred specification (Model 3), 0.770, can already be assessed by comparing it to the estimates for incumbency, 0.740. As in other contexts, incumbency advantages are known to be large in German local politics, i. e., voters show a strong preference for incumbents (Baskaran et al., 2023). Our estimates suggest that a non-incumbent candidate is viewed as positively as an incumbent if she runs for the AfD, i. e., the AfD’s party brand is sufficient to cancel out the disadvantage of non-incumbency. Similarly, being on an AfD list on any list position gives about the same premium as being placed on a top-three

the perceived local value of the party brand. While candidate selection and party entry is thus possibly endogenous (Magesan et al., 2024), we do not account for this explicitly in this paper. However, we show in Section 5.3 that our estimates are robust when we consider only elections in which the AfD participated, and that the results do not vary with the number of AfD candidates available.

spot on another party’s list, i. e., it is preferable to be a backbencher for the AfD than a front man or woman for another party.

The other party brands have either much lower or even negative (compared to independents) effects on voter utility. The CDU, for example, is viewed positively as well by voters, but to a much smaller degree than the AfD. The CDU coefficient, albeit significant, is only 0.105. In contrast, the FDP as a party brand is strongly disliked. An incumbent candidate loses more than her incumbency advantage if she runs on an FDP list. The fringe right-wing extremist parties have a negative brand as well (compared to independents). Voters who vote for the candidates of fringe parties tend to vote for them despite their association with these parties. For the AfD, it is the other way around.

We also observe strong preferences regarding selected non-political traits of candidates. Women receive a small penalty (-0.039), pointing toward an anti-female bias on part of voters. Candidates with academic degrees, in contrast, are strongly preferred by voters. Self-employed candidates are also preferred by voters, in contrast to employees and pensioners.

Based on the estimates in Table 1, we can calculate a score for each candidate reflecting her non-ideological “quality”, i. e., the aggregated utility voters have from the observable personal traits of each candidate (excluding incumbency and list placement). We plot the distribution of candidate scores across parties in Figure 2. While FDP candidates have on average the highest observable quality among all candidates (subfigure a), among elected candidates, average observable candidate quality is highest for the Greens (subfigure b). This is arguably due to the high proportion of elected candidates with academic titles and low proportion of pensioners among the Greens (see Table C.5).

The candidate scores for the AfD are the second lowest, both among all candidates and among elected candidates. Only the Left Party has candidates who are viewed more negatively than AfD candidates, arguably because of their high proportion of pensioners. Thus, it appears that the success of AfD candidates is not due to their observable characteristics but due to the AfD party brand.

Elections	902	902	902
Municipalities	406	406	406
N	34557	34557	34557

^a This table collects OLS regressions where the dependent variable is the log of the vote share of candidate i in municipality / electoral district m (defined as total votes received by candidate i relative to the number of eligible voters times maximum votes per voter) divided by the vote share of the outside option in municipality / electoral district m (100%-turnout). This specification corresponds to a logit model where voters have preferences over candidate characteristics. Since we do not observe individual voter choices, we use aggregate (“market-level”) vote data to infer voter preferences and apply the inversion for the logit model derived in Berry (1994b).

^b Stars indicate significance levels at 10%(*), 5%(**) and 1%(***). Heteroscedasticity and cluster-robust standard errors in parentheses. Standard-errors are clustered at the level of elections (municipality / electoral district \times year).

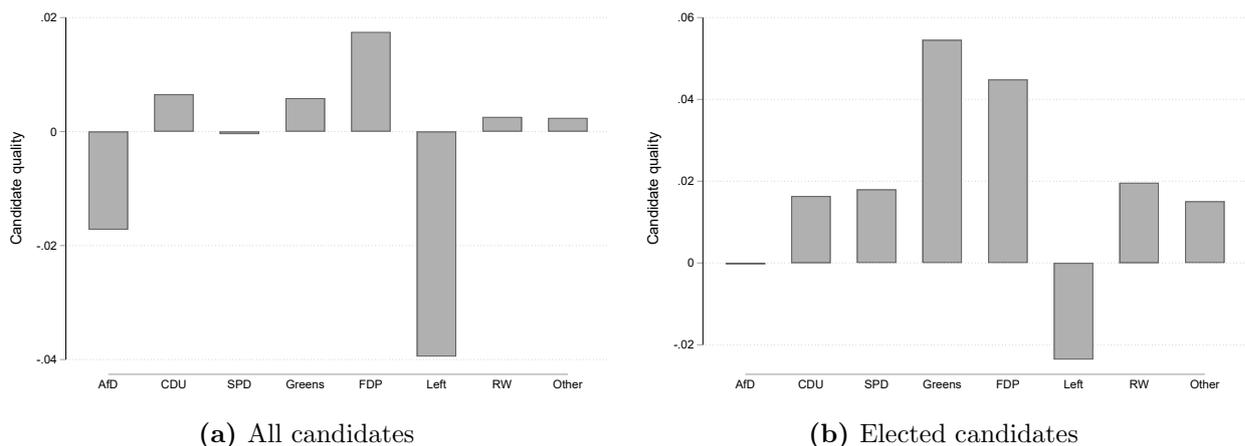

Figure 2: Estimated candidate quality per party. This figure shows the mean candidate score (the aggregate of the estimated “value” of candidate i ’s personal characteristics) of each party / voter initiative across the local elections in 2014, 2019, and 2024. We normalize candidate scores by subtraction with the overall mean candidate score (across all candidates). Subfigure (a) reports the mean normalized per party scores for all candidates. Subfigure (b) reports the mean normalized per party scores for elected candidates.

5.3 Robustness

5.3.1 Identification

Identification with turncoats The core identification assumption in our context is, as discussed in Section 5.1, that ζ_j is uncorrelated with the party dummies. One way to mitigate concerns regarding this assumption is to include candidate fixed effects, thereby relying on turncoats to identify the effect of party brands.

Thus, we expand Model (4) in Table 1 with candidate fixed effects and report the results in Model (1) of Table 2. The identifying assumption is that unobserved traits of candidates are time-constant. We obtain a coefficient estimate that, while in the same ballpark, is even higher than in the baseline. Note that in this specification, we retain observed candidate traits as covariates since candidates can change their stated occupation on the ballot or acquire (or decide to omit) an academic title between two elections. However, there are no changes in gender in our sample, and thus this variable is omitted.¹⁵

¹⁵More specifically, since we identify turncoats by names, we will not be able to identify changes in gender.

IV estimates Another strategy to mitigate concerns about unobserved candidate characteristics driving the positive party brand effect is to instrument the AfD party dummy. A reasonably plausible instrument can be constructed based on whether or not a candidate is a recontesting candidate. More specifically, in line with the results in Figure C.4, a “new” candidate can be expected to be more likely to run on an AfD list. Thus, a dummy indicating whether or not a candidate is a recontesting candidate can predict AfD list affiliation. The exclusion restriction is that conditional on incumbency (i. e., among non-incumbent candidates), whether or not a candidate is new or recontesting has no direct effect on her vote share. This is plausible as elections are five years apart, and voters should have no memories or distinct views about candidates who ran for but failed to win a council seat in the last election compared to candidates who are new. We report the results from this IV strategy in Model (2) of Table 2 and find that the AfD party brand estimate is of a similar magnitude as in the baseline.

5.3.2 Random coefficients

Nested logit estimations As discussed in Section 4, one concern with the logit specification in Equation (7) is that it imposes possibly implausible substitution patterns on voter preferences. Notably, voters are assumed to have uncorrelated preferences across party brands. In reality, it might be the case that a voter who views the AfD party brand positively also views the CDU party brand positively, or at least more positively than the party brands of left-wing parties. Not allowing for such correlations might lead to over- or underestimation of party brand effects.

One solution to address this concern is to group parties into “nests” that reflect political camps and to estimate the “nested logit” specification derived in Equation (10). The idea is that if voters primarily value that a candidate belongs to a particular political bloc, while the specific party is only of secondary importance, we should estimate a large nest-specific parameter.

Table 2: PARTY BRAND VS. CANDIDATE CHARACTERISTICS: CANDIDATE FIXED EFFECTS AND IV ESTIMATES

Election FE	Yes	Yes
Elections	792	902
Municipalities	306	406
N	15148	34514

^a This table collects OLS regressions where the dependent variable is the log of the vote share of candidate i in municipality / electoral district m (defined as total votes received by candidate i relative to the number of eligible voters times maximum votes per voter) divided by the vote share of the outside option in municipality / electoral district m (100%-turnout). This specification corresponds to a logit model where voters have preferences over candidate characteristics. Since we do not observe individual voter choices, we use aggregate ("market-level") vote data to infer voter preferences and apply the inversion for the logit model derived in Berry (1994b).

^b Model (1) reports results from a replication of model (4) in Table 1 where we additionally include candidate fixed effects. Identification of party and candidate characteristics thus comes from within-candidate variation. Specifically, identification of party effects is based on turncoats. Model (2) reports results from a replication of the baseline model where the AfD dummy is instrumented by a dummy for whether a candidate i is a recontesting candidate. Since AfD candidates are new entrants into local politics, this instrument (negatively) predicts AfD membership, see the Kleibergen - Paap weak identification test statistic reported at the bottom of the table. The validity of the instrument rests on the assumption that conditional of incumbency (for which we control), recontesting candidates are not more likely to receive more votes than new candidates.

^c Stars indicate significance levels at 10%(*), 5%(**) and 1%(***). Heteroscedasticity and cluster-robust standard errors in parentheses. Standard-errors are clustered at the level of elections (municipality / electoral district \times year).

One obvious complication to the nested logit approach is that it is ex-ante not clear how to group parties. Voters might view the AfD as a “conservative” party, implying that we should group the AfD together with the parties that are traditionally considered to be part of the “right-wing” camp: the CDU and FDP. On the other hand, one might emphasize that the AfD is a “new” party not affiliated with any of the traditional parties and thus group it with independents. One might even group the AfD with left-wing parties (particularly SPD and the Left Party) given recent electoral inroads the AfD has made into traditional left-wing milieus.¹⁶ Finally, the AfD could also be grouped together with the fringe right-wing parties, as some of its core positions, notably regarding immigration, overlaps with the traditional fringe right-wing bloc.

We thus report in Table 3 four specifications with the AfD grouped in four different nests. In Model (1), we group AfD candidates with right-wing candidates (CDU, FDP). In Model (2), we group AfD candidates with candidates of left-wing parties (SPD, Left Party, Greens). In Model (3), we group AfD candidates with candidates of the fringe right-wing parties. In Model (4), we group AfD candidates with independent candidates. In each specification, $\log(S_j/S_g)$ is endogenous. We use the number of candidates in each nest into which the AfD is grouped as instrument.

The results in Table 3 suggest that voter preferences are generally not strongly correlated within nests. In turn, the adjusted brand effect estimated for the AfD (which accounts for nest-level preferences), reported at the bottom of the table, is in the same ballpark as in the baseline for all four nests defined above. A substantive conclusion that follows from this finding is that the AfD as a party represents a unique political phenomenon, drawing equal amounts of votes from all parts of the political spectrum, rather than merely being a slightly more popular version of an established party.

BLP estimations While the nested logit is a straightforward extension of the plain logit, Berry et al. (1995) introduce a more flexible random coefficients approach, typically

¹⁶See <https://www.deutschlandfunknova.de/beitrag/bundestagswahl-ist-die-afd-die-neue-arbeiterpartei>.

^a This table collects OLS regressions where the dependent variable is the log of the vote share of candidate i in municipality / electoral district m (defined as total votes received by candidate i relative to the number of eligible voters times maximum votes per voter) divided by the vote share of the outside option in municipality / electoral district m (100%-turnout). We additionally control in each model for a term (ρ_g) that reflect the correlation between individual vote shares and the aggregated vote share of different political camps (left, conservative, fringe right-wing, independent). This specification corresponds to a nested logit model where voters have preferences for political camps ("nests") and candidate characteristics. Since we do not observe individual voter choices, we use aggregate ("market-level") vote data to infer voter preferences and apply the inversion for nested logit derived in Berry (1994b).

^b The row entitled AfD adjusted collects the AfD party brand coefficient after adjusting for nest-level preferences.

^c Stars indicate significance levels at 10%(*), 5%** and 1%***). Heteroscedasticity and cluster-robust standard errors in parentheses. Standard-errors are clustered at the level of elections (municipality / electoral district \times year).

referred to as BLP, to account for preference heterogeneity among consumers. We adapt the BLP approach to our context and estimate, besides α, β , also Σ , as introduced in Equation (7). However, it is reasonable to impose restrictions on Σ as it has up to $(P \times (P + 1))/2$ unique elements (recall that Σ is symmetric), and we require at least as many external instruments in the GMM estimation.¹⁷

We first estimate a model where we only allow for heteroscedastic preferences for all party dummies and the outside option (abstention). That is, the diagonal elements of Σ (the variances of the party dummies) are allowed to be positive, while the off-diagonal elements are all set to zero. Second, we estimate models that allow for arbitrary correlations in preferences between the AfD party dummy and the other party dummies as well as the outside option. That is, all non-diagonal elements are set to zero except for the elements indicating covariances between the AfD party dummy and the other party dummies and the intercept. Finally, for completeness, we also estimate a specification that allows for a fully unrestricted variance-covariance matrix with arbitrary correlations in preferences across all party brands.

We “instrument” $P_{j,p}$ and $X_{j,k}$ with themselves (i. e., party brands and candidate traits are treated as exogenous). We construct external instruments that “target” the elements of Σ using interactions of non-political candidate traits with the sum of other candidates with the same traits in her own and in other parties. The idea is that higher dispersion in non-political traits of candidates within and across parties in a given election reflects heterogeneity in underlying voter preferences faced by a particular candidate j . At the same time, traits of other candidates are plausibly orthogonal to ζ_j .

The BLP results are collected in Table 4. Model (1) collects the results for the specification where we only allow for random variances. The estimate for the AfD party brand is 0.79 and significant, and thus similar to the baseline estimates reported in Table 1. Model (2) collects the results from the specification where we additionally allow for ar-

¹⁷In fact, as voters might have heterogeneous preferences for non-political traits, too, Σ has potentially even more elements.

bitrary covariances between the AfD and other party dummies (as well as the intercept). The estimate for the AfD dummy is 1.20 and thus remains to be similar to the baseline. However, estimates are noisy, and thus the AfD dummy is statistically insignificant. In Model (3), we allow for non-zero covariances between all other party brands as well. The coefficients are estimated with even more noise (as indicated by the large standard errors). As such, while the AfD coefficient is larger than in the previous estimations, i. e., 1.51, it remains insignificant.

5.3.3 Further robustness tests

In Appendix B.2, we study whether the results are driven by municipalities where no or only few AfD candidates compete in local elections. In Appendix B.3, we complement our regular-expression based classification of occupations with classifications by a large language model (LLM). The core results, and notably the estimate for the AfD’s party brand, remain robust.

6 Counterfactuals

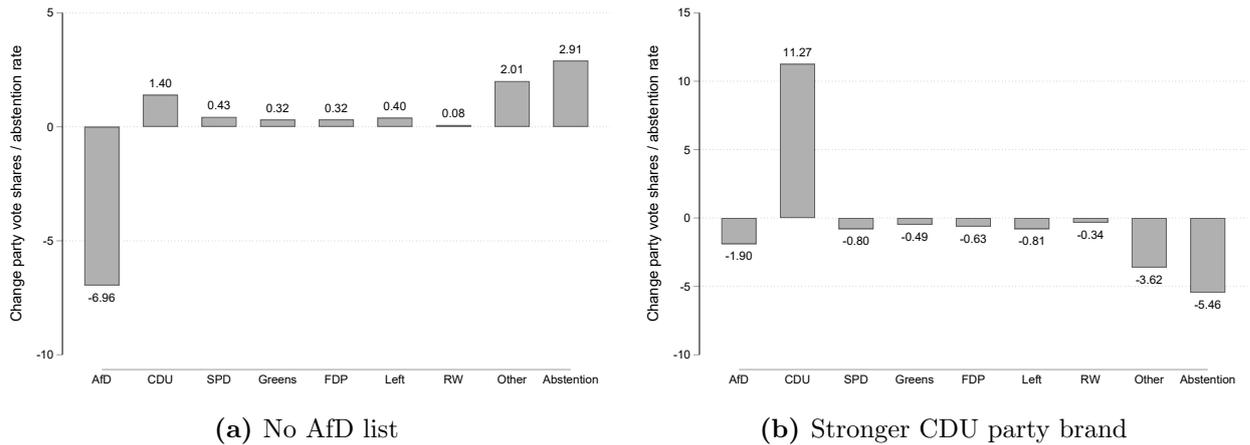

Figure 3: Counterfactual simulations of brand effects. This figure shows how party level vote shares change if no AfD party lists were available and thus AfD candidates would run as independents (subfigure a) and if the CDU brand would be as strong as the AfD brand (subfigure b).

Table 4: PARTY BRAND VS. CANDIDATE CHARACTERISTICS: BLP ESTIMATIONS

Elections	902	902	902
Municipalities	406	406	406
N	34557	34557	34557

^a This table collects estimations where the vote share of candidate i in municipality / electoral district m (defined as total votes received by candidate i relative to the number of eligible voters times maximum votes per voter) is related to party brands and non-political candidate characteristics using the approach proposed by Berry et al. (1995).

^b Model (1) allows for heteroscedastic preferences (non-zero variances) regarding party brands and the outside option (random intercept). Model (2) additionally allows for arbitrary covariances in preferences regarding the AfD's party brand and the party brand of party $P_{\neq AfD}$ as well as the outside option. Model (3) additionally allows for non-zero covariances between voter preferences for the party brands of the other parties.

^c Estimates are produced with the Python package PyBLP (Conlon and Gortmaker, 2020). We simulate 500 individuals for each election using Halton draws. In both models, we instrument all observable variables by themselves and use interactions between each personal (non-political) characteristic of candidate j with the number of other candidates with the same characteristics (separately in her own and in other parties) to target the non-linear parameters (i.e., the non-zero elements in Σ).

^d Stars indicate significance levels at 10%(*), 5%(**) and 1%(***). Standard errors are clustered at the level of elections (municipality / electoral district \times year).

Using the preference parameters estimated in Table 1, we construct two counterfactuals. First, we study how party-level aggregate vote shares would change if AfD candidates had run as independents rather than on AfD lists, i. e., how vote shares would evolve if no AfD party brand were available (e. g., due to a prohibition of the party). Second, we study how party-level vote shares would change if the CDU party brand – the largest party in Saxony – had a party brand that is as strong as the party brand of the AfD.

6.1 No AfD party list available

How would vote shares change if the AfD as a party were unavailable and its candidates were forced to run without its strong brand? We simulate this counterfactual by setting the brand value for AfD candidates to zero, essentially treating them as independents, and recalculating predicted candidate-level vote shares.

More formally, we define for each candidate j participating in a given election the predicted counterfactual mean utility as follows:

$$\hat{\Gamma}_{j,c} = -\hat{\alpha}_{AfD}P_{j,AfD} + \sum_p \hat{\alpha}_p P_{j,p} + \sum_k \hat{\beta}_k X_{j,k} + \hat{\zeta}_j. \quad (11)$$

The predicted choice probability of candidate j is then simply:

$$\widehat{Prob}_{j,c}^i = \frac{\exp(\hat{\Gamma}_{j,c})}{1 + \sum_j \exp(\hat{\Gamma}_{j,c})}. \quad (12)$$

The aggregated party vote share for party p in a given election is:

$$\widehat{Prob}_p^i = \sum_j P_{j,p} \widehat{Prob}_{j,c}^i, \quad (13)$$

while the abstention rate is:

$$\widehat{Prob}_o^i = 1 - \sum_p \widehat{Prob}_p^i. \quad (14)$$

Based on these expressions, we calculate the mean counterfactual change in party-level vote shares and abstention rates across elections where the AfD fielded candidates. Subfigure (a) of Figure 3 shows the changes in party vote shares. AfD candidates collectively lose on average 7 percentage points. To evaluate the size of this change, consider Appendix Figure C.8, which shows the predicted mean party-level vote shares in the elections where the AfD fielded candidates. The mean vote share of the AfD is 14 percentage points. As such, AfD candidates would collectively lose about 50% of their votes if forced to run as independents (this is in line with the marginal effects reported in Section B.1).

To whom do the AfD candidates lose? We observe the largest gain for the outside option, i. e., if no AfD lists were available, turnout would decline by about 3 percentage points. In addition, the independents (2 ppts) as well as the CDU (1.4 ppts) would gain noticeably. The other parties would observe no major gains.

6.2 CDU party brand equal to AfD party brand

The change in vote shares if other parties were to improve their brand values is another important counterfactual. While all parties could in principle improve their brand value, the most relevant case is an improvement in the brand value of the CDU, the largest and arguably the most well established party in Saxony.

To construct this counterfactual, we replace the brand estimate for the CDU candidates with the estimate of the AfD (while retaining the same value for the AfD candidates). More formally, we calculate mean utility for candidate j as follows:

$$\hat{\Gamma}_{j,c} = P_{j,CDU}(\hat{\alpha}_{AfD} - \hat{\alpha}_{CDU}) + \sum_p \hat{\alpha}_p P_{j,p} + \sum_k \hat{\beta}_k X_{j,k} + \hat{\zeta}_j. \quad (15)$$

The choice probabilities, party-level vote shares, and abstention rates are calculated as in Equations 11 - 14.

Subfigure (b) of Figure 3 visualizes the predicted changes in vote shares. On average, the aggregate vote share of CDU candidates increases by about 11 ppts. The predicted

vote share for the CDU using the estimates in Table 1 is 17% (see Figure C.8). Thus, the CDU vote share would increase by about 65% if it could improve its brand value to be at the same level of the AfD. However, this gain does not come at the expense of the AfD. It loses only 2ppts in this counterfactual, arguably because it continues to retain a strong brand value. The CDU gains come at the expense of the independents and are due to an increase in the turnout rate.

7 Decomposing the AfD’s party brand

What is conveyed to voters by the AfD party brand? A natural assumption is that the AfD party brand estimate reflects to a large degree the popularity of the AfD’s broad policy proposals. However, parties hold positions along different salient dimensions. The AfD is commonly perceived to be nationalist and anti-immigration. The party has also adopted “anti-progressive” positions, notably with respect to marginalized groups or womens’ rights; it brands itself as a “masculine” party. It opposes (fiscal) integration in the European Union and sometimes even advocates a “Dexit”. It voices skepticism about anthropogenic climate change and opposes mitigation measures. During the Covid 19-pandemic, it voiced among the major parties the strongest opposition against mobility and contact restrictions. It is the only major party that is at least partially in favor of rapprochement with the Russian Federation after its invasion of Ukraine in 2022.¹⁸ The AfD also serves as a generic protest and anti-establishment party. In the following, we assess the contribution of some of these unique policy positions to the value of the party brand.

¹⁸Another prominent party, *BSW*, also effectively proposes a more lenient approach towards the Russian Federation. However, the *BSW* was less relevant in the local election in Saxony in 2024 (it received 4.4% of the votes) and did not exist in 2019.

7.1 Party brands over time

The salience of the topics mentioned above changed over time due to outside events. For example, the Covid-19 pandemic and the war in Ukraine were not relevant during the 2019 election. Alternatively, the AfD might have served as a venue for protest votes against the parties forming the federal government in 2024 (SPD, Greens, FDP) given the its unpopularity at the time.

We can assess to what extent the AfD brand reflects these dimensions by exploring whether its brand value is higher in 2024 than in 2019. That is, have the value of the party brands (and other characteristics of candidates) changed over time?

We estimate the following model to asses over-time developments:

$$\log(S_j) - \log(S_0) = \sum_p \alpha_p P_{j,p} \times I(Year) + \sum_k \beta_k X_{j,k} \times I(Year) + \zeta_j. \quad (16)$$

That is, we interact the party dummies and the dummies indicating personal traits with dummies for the three election years in our sample, i. e., $t = 2014, 2019, 2024$.

Appendix Figure C.9 shows party brand estimates with year-specific subsamples. We find that the AfD brand value, relative to the independents, has increased from 2014 to 2019, but remained constant thereafter.¹⁹ Based on these findings, we conclude that the AfD's high brand value in Saxony is not due to its specific positions regarding the war in Ukraine, nor the Covid-19 pandemic, nor the unpopularity of the federal government in 2024. This is a surprising conclusion as a naive comparison of the party vote shares over time, where the AfD improved from 2019 to 2024 (see Figures 1 and C.1), would suggest the opposite. The rise in the AfD's vote shares between 2019 to 2024 is driven by other factors.²⁰

¹⁹For completeness, we also explore whether voters' perception of candidates' personal traits have changed over time. For example, voters might have come to prefer women more in more recent elections. However, as per Appendix Figure C.10, voter preferences for the personal traits of candidates have not changed meaningfully over time.

²⁰One important factor is that the AfD fielded more candidates in 2024 than in 2019. These new candidates could each attract additional votes for their observed and unobserved personal traits while

7.2 Spatial variation in the value of the AfD’s brand

To further understand what is conveyed by the AfD party brand to voters, we explore, in addition to temporal variation, the spatial variation in AfD brand values. For this, we first estimate the following model:

$$\log(S_j) - \log(S_0) = \alpha_{AfD} P_{j,AfD} \times I(Municipality) \times I(Year) + \sum_k \beta_k X_{j,k} + \zeta_j. \quad (17)$$

This model includes an interaction between dummies indicating a given municipality and election year and a dummy for the AfD party brand. We omit all other party brands, thereby estimating the value of the AfD party brand relative to all other party brands available in municipality m and election year t . This allows for a straightforward interpretation of the AfD’s party brand estimate as its value relative to the value of all other parties (in the baseline, the party brand effects were defined relative to the independents) in the election held in municipality m in year t .

We visualize the spatial and temporal variation of the party brand estimates based on Equation (17) estimate in Appendix Figure C.12. In line with the baseline results, we find that the AfD party brand generally has a positive value. However, there is heterogeneity across Saxony, and in some elections, the AfD brand has even a negative value.²¹

In the following, we exploit the observed spatial-temporal variation in the value of the AfD brand to further infer what is reflected by the AfD’s brand.²² The local strength of the AfD’s brand might be determined by “supply”, i. e., variation in the local AfD

simultaneously benefiting from the AfD brand, thus leading to an increase in the aggregate vote share of the AfD.

²¹Appendix Figure C.11 shows the distribution of estimates of the AfD’s brand value.

²²One may believe that the election-specific party brand estimates can be proxied by the aggregate vote shares of the AfD in higher-level elections across municipalities, and that therefore obtaining election-specific party brand estimates is unnecessary. That is, since elections at the state, federal, and European levels are centered around parties, one might attempt to simply use the AfD vote shares across these elections to capture voter preferences for the AfD. However, as we show in Appendix Section B.4, party-brand estimates do not correlate with vote shares in higher-level elections.

chapters policy positions (and other local determinants of the brand), or by “demand”, i. e., variation in how receptive voters are towards the AfD’s party brand.

We collected election manifestos of several local AfD chapters and find that the variation in local policy stances is limited. Local election manifestos essentially reiterate the national policy stances of the party, e. g., traditional families, low or no immigration, etc. Thus, we focus in the following on the extent to which voters are receptive to the AfD’s brand.

We correlate the local strength of the AfD’s brand with characteristics of municipalities, focusing on four particularly salient characteristics related to refugee inflows, population trends, unemployment rates, and local gender balances. The models we estimate are of the following form:

$$\text{AfD brand}_{m,t} = \alpha_m + \gamma_t + \beta M_{i,t} + \mu_{m,t}, \quad (18)$$

with α_m and γ_t indicating municipality- and year fixed effects, and $M_{i,t}$ a given municipality-specific characteristic observed in the election year $t = 2014, 2019, 2024$ (or shortly before). As municipality-specific AfD party brand values are obtained from the estimation of Equation (17), we weight observations by the inverse of the variance of the brand estimate.

Table 5 collects the results. In Panel A, we relate the (log of) total number of refugees (Model 1), the number of refugees per capita (Model 2), and the change in the number of refugees per capita between two elections (2014 to 2019 and 2019 to 2024) to the estimated value of the AfD’s brand. Ostensibly, a higher stock of refugees and higher refugee inflows are positively related to the value of the AfD brand: the AfD’s anti-refugee stance appears to be an important draw for voters.

In Panel B, we relate population trends to the AfD’s brand value. One reason why population is a salient characteristic of municipalities is that it reflects their viability and attractiveness. In general, declining municipalities will see outmigration. It has

been argued that economic decline might be one of the main drivers for populist voting (Rodriguez-Pose et al., 2023). However, we find that none of the population-related variables we explore are significantly correlated with the AfD’s brand value.

In Panel C, we explore a more specific measure for a municipalities’ economic conditions, notably unemployment. We consider the change in the total number of unemployed (in logs), the number of unemployed divided by the number of inhabitants, and the change in unemployed to inhabitants ratio between the last two elections. However, we observe, as for population trends, no significant correlations.

In Panel D, we relate gender-imbalances to the AfD’s brand value. In East-Germany, gender balances have shifted significantly after reunification due to the selective outmigration of (young) women (Stawarz et al., 2024). There are two channels through which gender balances might influence the AfD’s brand value. First, support for the AfD tends to be higher among men than women (Hansen and Olsen, 2024), implying that its brand might directly hold more value in male dominated municipalities due to the composition of the electorate. Second, the relative lack of (young) women appears to radicalizes men politically, particularly in East Germany (Dancygier et al., 2022). We find that there is indeed a positive and (in Models 2 and 3) significant effect of a higher gender imbalances on the AfD’s brand value. As such, we might conclude that the AfD’s image of a “masculine” party is another determinant of its brand value.

8 Conclusions

Far-right populists are increasingly successful across the globe. We disentangle whether their success is due to party brands or personal traits. Focusing on AfD political candidates in local elections across Saxony, we establish that AfD candidates’ success is primarily due to the value of their party brand, which is substantially higher than the brand value of all other major parties.

^a This table collects weighted least square regressions where the dependent variable is the estimated party brand in municipality m in year t (i.e., in a particular election) and the independent variables are municipality-specific characteristics. Observations are weighted by the inverse of the variance of the brand estimate.

^b We relate AfD brand estimates to indicators for the refugee population in municipality m (Panel A), aggregate population developments (Panel B), unemployment (Panel C), and gender imbalances (Panel D).

^c Stars indicate significance levels at 10%(*), 5%(**) and 1%(***). Heteroscedasticity and cluster-robust standard errors in parentheses. Standard-errors are clustered at the level of municipalities.

What are the policy implications? One important implication is that if non-populist parties (and by extension the governments formed by these parties) aim to diminish the popularity of populists, fielding candidates that are more similar to those of populist parties does not appear to be a promising strategy. While candidates with traits valued by voters naturally draw votes, AfD candidates do not have particularly popular traits. In fact, voters appear to prefer “traditional elites”, such as candidates with academic titles.

Instead, the goal of non-populist parties should be to reduce the distance between the value of their party brand and those of populists. In the German context, we find that the value of the AfD party brand appears to be primarily related to refugee inflows and local gender imbalances. Based on these observations, one might consider it as a promising strategy for non-populist parties to make their party messaging more similar to that of the AfD particularly along these dimensions. However, counterfactual simulations indicate that while this strategy might carry benefits for those parties that are able to close the distance of their party brand value to that of the AfD, it does not diminish AfD vote shares, as it would continue to retain a strong party brand.

Mainstream parties might thus have to develop other strategies eventually, not least because it is unclear whether all dimensions of populists’ brands can and should be replicated. One alternative strategy would be to directly target the value of populists’ party brand and the salience of issues from which they draw their strength. It is, however, unclear how this can be achieved. Future research on populist politics should thus explore in more detail how the value of populist party brands is determined in the political arena.

A Details on data collection and cleaning

A.1 Data collection

Data on the party affiliations and electoral performance of candidates was mainly collected by research assistants from the official websites of all Saxonian municipalities and / or online versions of local newspapers. Municipalities often post this information on their website or announce them in local newspapers. Municipal websites and newspapers also often report other information for all candidates when they are officially announced (notably their occupations). These announcements include the names and occupations of candidates as well as their initial rank on the party list. Our research assistants downloaded the information and copy-pasted or entered the data by hand into Excel files. During this process, they coded the gender of candidates based on their names.

We merged all of these Excel files (by municipal codes and election years) into one datafile. We also invested a significant amount of time to check for and correct any errors. We corrected errors whenever feasible, and if not, set the data point to missing.

Table C.3 compares the characteristics of the municipalities included in our hand-collected sample in each wave of elections (2014, 2019, 2024) with the remaining municipalities in Saxony. Table C.4 compares characteristics of the smaller sample of municipalities for which we have candidate-level votes data for all candidates with the remaining municipalities for each wave of elections.

A.2 Manual classifications

We clean this initial dataset further as follows. First, party names are not standardized across municipalities. For example, the Greens are referred to as “Grüne” in some municipalities and in other municipalities as “Die Grünen”, etc. We thus identify and match party names by hand.

Second, there is no standardized list of occupations. As such, we use regular expressions to classify occupations into categories. For example, we classify all candidates with

occupations that contain the strings “rentn”, “pensi”, “ruhe”, “i.R.”, “Rentn”, “Pensi”, “Ruhe” as pensioners. We confirm that these all candidates identified as pensioners in this way are indeed pensioners using random samples. We use a similar procedure to extract information on the other occupational characteristics of candidates reported in Table C.5. For academic titles, we focus on names and search for strings containing “Prof”, “prof”, “Dr.”, “DR.”, “Doctor”, “promov”, “dr.”, “professor”, or “Professor”.

A.3 Large Language Model (LLM) classifications

For the LLM classifications, the following prompt was given to Gemini (Model 2.5 FLASH) after a CSV file with candidate id’s and their stated occupations was uploaded (no further candidate-level information was given):

The uploaded CSV file contains a column named “occup_classification” with a list of occupations (in German) and two empty columns named “necessary_education” and “pr_social_status”.

Your task is to classify the occupations / employment statuses in the column “occup_classification” according to their characteristics and populate the two empty columns.

First, you should enter your estimate of the minimum level of education that is usually required in Germany to pursue each occupation listed under “occup_classification”. Use one of the following categories to classify the minimum educational requirements:

- “No formal education necessary”
- “Hauptschule completed”
- “Realschule completed”
- “Abitur (Gymnasium / Oberschule) completed”
- “Hochschule completed”

Enter your estimate for each occupation in the respective row in the column named “necessary_education”.

Do not classify generic employment statuses such as “Selbständig”, ”Rentner”, “in Rente” etc. In such cases, enter “unclear educational requirements”. If a column contains both a concrete occupation and a generic employment status (e.g. “Maurermeister in Rente”), you may use the occupation for classification. If an entry only contains an academic degree (e.g., Diplom-Ing.), you may use this degree to infer educational attainment even if no specific occupation is mentioned.

If you are unable to classify the educational requirements for an occupation with a reasonable degree of certainty, enter “unable to classify”.

Second, classify each occupation / employment status according to its “societal status” in Germany. With societal status, we mean how much ”respect” an occupation carries in German society. Note that societal status should not simply capture the likely salary associated with a profession. For example, police officers or primary school teachers might only earn an average salary, but might nonetheless be perceived as highly valuable for society. In other words, your entry should reflect the overall perception of the status of an occupation, both in monetary and non-monetary terms. In cases where only generic employment statuses such as “Selbständig”, “Rentner”, “in Rente” etc. are mentioned (without a specific occupation), you may classify according to the degree of “respect” these generic employment statuses receive within German society.

Populate the column named “pr_social_status” with your estimate. Use the following three categories:

- “High status”
- “Average status”
- “Low status”

If you cannot determine the societal status with a reasonable degree of certainty, enter “Status unclear”.

Each row (observation) should be evaluated independently and with contextual attention to linguistic variation, spelling inconsistencies, and semantic nuance.

A.4 Identification of candidates contesting in several elections

A.4.1 Recontesting and incumbent candidates

We identify recontesting and incumbent candidates in a given municipality based on their names. However, since there are sometimes minor variations in how names are listed in our original sources (e. g., whether a candidate lists a Ph.D title) as well as typos, we use a fuzzy match to match candidates across elections.

There are a few cases where the same given and surname appear more than once in a given election. As we cannot unambiguously match candidates across elections in such cases, we treat these candidates as non-recontesting and non-incumbents, respectively.

A.4.2 Turncoats

To identify turncoats, we first rely, as for recontesting and incumbent candidates above, on a fuzzy match of names across elections. In Table C.1, we define a candidate as a turncoat if her name appears on different party lists in the elections in $t - 1$ and t . For the turncoat regressions reported in Table 2, we include candidate fixed effects based on the fuzzy match. In these regressions, we drop candidates that we cannot unambiguously identify due their name appearing more than once in a given election.

B Further results

B.1 Marginal effect of AfD brand on candidate vote shares

Based on the estimated parameters for voter preferences as reported in Table 1, we construct the value of gaining or losing the AfD brand, respectively, for each candidate. While marginal effects are usually calculated by keeping all other covariates constant, political candidates can only belong to one party. To calculate the marginal effect of AfD membership for a non-AfD candidate, it is thus necessary to set her current party dummy to zero. Similarly, the marginal effect of AfD membership for AfD candidates can be calculated relative to different parties. We calculate the marginal effect relative to independents (i. e., we assume that AfD members become independents if they lose the AfD affiliation).

More formally, we construct the counterfactual choice probability for candidate c by expressing the predicted mean utility as follows:

$$\hat{\Gamma}_c = \hat{\alpha}_{AfD}(1 - P_c) + P_{c,AfD} \sum_p \hat{\alpha}_p P_{c,p} + \sum_k \hat{\beta}_k X_{c,k} + \hat{\zeta}_c. \quad (\text{B.1})$$

The counterfactual choice probability for each candidate c is then given as:

$$\widehat{Prob}_c^{i'} = \frac{\exp(\hat{\Gamma}_c)}{1 + \exp(\hat{\Gamma}_c) + \sum_{j \neq c} \exp(\hat{\Gamma}_j)}, \quad (\text{B.2})$$

with $\hat{\Gamma}_j$ indicating the predicted mean utility following Equation (5).

This formulation takes into account the indirect effect of the different party brand effect for candidate c on the choice probability of all other candidates $j \neq c$ (via the denominator).

The marginal effect of AfD membership for candidate c is then:

$$\Delta \widehat{Prob}_c^i = \widehat{Prob}_c^{i'} - \widehat{Prob}_c^i, \quad (\text{B.3})$$

with \widehat{Prob}_c^i the original predicted choice probability for candidate c following Equation (4).

Subfigure (a) of Figure B.1 shows the distribution of marginal effects among all non-AfD candidates, while Subfigure (b) shows the marginal effects for AfD candidates. Subfigure (a) suggests that the marginal effect of AfD membership on the expected vote share of non-AfD members can be as high as 24 percentage points. To put this number into perspective, note that the average vote share of candidates is 1.5% (recall that the vote shares are calculated with the abstention rate (the “outside option”) included in the denominator). The average marginal effect of AfD membership is 1.7 percentage points, which implies that an average non-AfD candidates could more than double her vote share if she switched to the AfD.¹

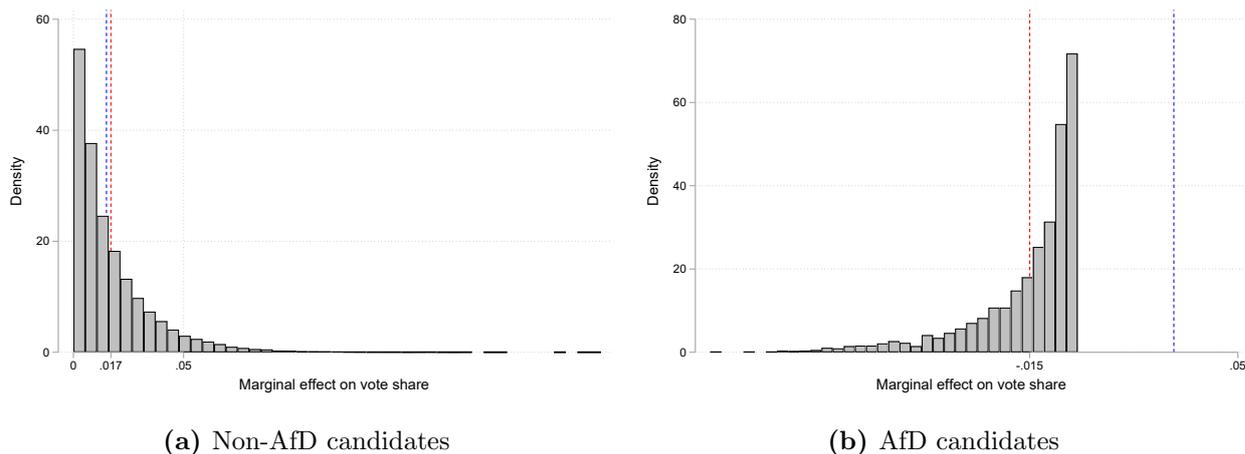

Figure B.1: Marginal effect of AfD membership on vote shares of candidates. This figure shows the distribution of marginal effects of gaining AfD membership among non-AfD and losing the AfD membership among AfD candidates. The red vertical line indicates the average marginal effect. The blue vertical line indicates the average vote share of non-AfD and AfD candidates, respectively.

Subfigure (b) indicates that the average vote share of AfD candidates is 2.95%. The average marginal effect of AfD membership for AfD candidates is 1.5 percentage points. Thus, switching away from the AfD and becoming an independent candidate is associated with an expected loss in vote shares by about 50%. However, the effect of losing the AfD affiliation can be as large as 11 percentage points.

¹In Appendix Figure C.7, we plot the marginal effects for all parties other than the AfD individually.

B.2 Number of AfD candidates

We explore how the estimate for the AfD party coefficient is influenced by municipalities with no or few AfD candidates. This is a relevant concern as even in 2024, the AfD did not participate in all municipalities across Saxony, and in several elections, there were only one or two AfD candidates.

We estimate the baseline model in Equation (7) using samples in which we omit elections with no or few AfD candidates. The results are collected in Table B.1. Omitting elections with no (Model 1), only one (Model 2), less than three (Model 3), less than four (Model 4), and no more than five (Model 5) AfD candidates produces essentially the same value for the AfD party brand as in the baseline.

For completeness, we also report a specification where we only include elections with up to four AfD candidates (Model 6). The party brand coefficient for the AfD is 1.201 and thus slightly larger than in the baseline, but overall in the same ballpark.

The estimates of the brand effects for the other parties are not affected by omitting municipalities with few or no AfD candidates. Similarly, the estimates for the effect of personal traits remain in the same ballpark as in the baseline.

B.3 Occupation coded by large language models

In the baseline regressions, we rely on regular expressions to match occupations to employment characteristics, i. e., whether a candidate mentions that she is a pensioner, whether she is employed in the public sector, and other characteristics. A complementary approach is to rely on classifications by a LLM.

LLMs can classify occupations into relevant groups that are difficult to identify with regular expressions. We prompt an LLM to classify stated occupations into three distinct groups based on societal status – an assessment of how much “respect” an occupation evokes within German society (low, average, high)– and five educational attainment categories (no formal education required, Lower School (*Hauptschule*), Middle-School (*Re-*

^a This table collects OLS regressions where the dependent variable is the log of the vote share of candidate i in municipality / electoral district m (defined as total votes received by candidate i relative to the number of eligible voters times maximum votes per voter) divided by the vote share of the outside option in municipality / electoral district m (100%-turnout). This specification corresponds to a logit model where voters have preferences over candidate characteristics. Since we do not observe individual voter choices, we use aggregate (“market-level”) vote data to infer voter preferences and apply the inversion for the logit model derived in Berry (1994).

^c This table collects robustness tests where certain elections are dropped: elections with no AfD candidate (Model 1), with only one or no AfD candidates (Model 2), with no more than two AfD candidates (Model 3), with no more than three AfD candidates (Model 4), and elections with no more than five AfD candidates (Model 5). For completeness, we also collect results from regressions where only elections with less than five AfD candidates included (Model 6).

^c Stars indicate significance levels at 10%(*), 5%** and 1%(***). Heteroscedasticity and cluster-robust standard errors in parentheses. Standard-errors are clustered at the level of elections (municipality / electoral district \times year).

alschule), High-School (*Gymnasium / Oberschule*), and University (*Universität*). See Appendix Section A.3 for the prompt we supply to the LLM.

We use the LLM classifications in addition to our regular-expression based classifications in Table 1 to reduce the influence of unobserved traits. The results are collected in Table B.2. We observe that the AfD party brand effect remains high and in the same ballpark as in the baseline. The brand estimates for other parties are also similar to the baseline. The effects of the observable personal traits already included in the baseline specification hardly change either.

With respect to the LLM classified variables, we observe in the most complete specification (Model 4) that voters prefer candidates with occupations associated with at least an average level of educational requirements compared to the base category (no or low formal education, or candidates with unclear educational attainment). Conditional on list placements and incumbency status, the societal status of an occupation carries no premium. This indicates, in particular, that parties place candidates with more respected professions further up on their lists. However, in Model (3), where we do not control for list placements and incumbency status, we observe that voters dislike candidates with medium or low status professions compared to the base category (occupations that cannot be unambiguously classified).

In Figure B.2, we recalculate the aggregated candidate quality per party with the LLM classifications included. Overall, the LLM classifications paint the same picture as our original regular-expression based classifications. AfD candidates have quality scores that are lower than those of most other parties. One difference is that, once societal status and educational attainment are included, elected FDP candidates have almost the same perceived quality as elected Green candidates.

^a This table collects OLS regressions where the dependent variable is the log of the vote share of candidate i in municipality / electoral district m (defined as total votes received by candidate i relative to the number of eligible voters times maximum votes per voter) divided by the vote share of the outside option in municipality / electoral district m (100%-turnout). This specification corresponds to a logit model where voters have preferences over candidate characteristics. Since we do not observe individual voter choices, we use aggregate (“market-level”) vote data to infer voter preferences and apply the inversion for the logit model derived in Berry (1994).

^b Unlike in the baseline reported in Table 1, we account for individual occupational characteristics by having a LLM classify individual occupations according to their minimal necessary level of education (middle school, high school, university) and the “social status” associated with the occupation (low, medium, high).

^c Stars indicate significance levels at 10%(*), 5%(**) and 1%(***). Heteroscedasticity and cluster-robust standard errors in parentheses. Standard-errors are clustered at the level of elections (municipality / electoral district \times year).

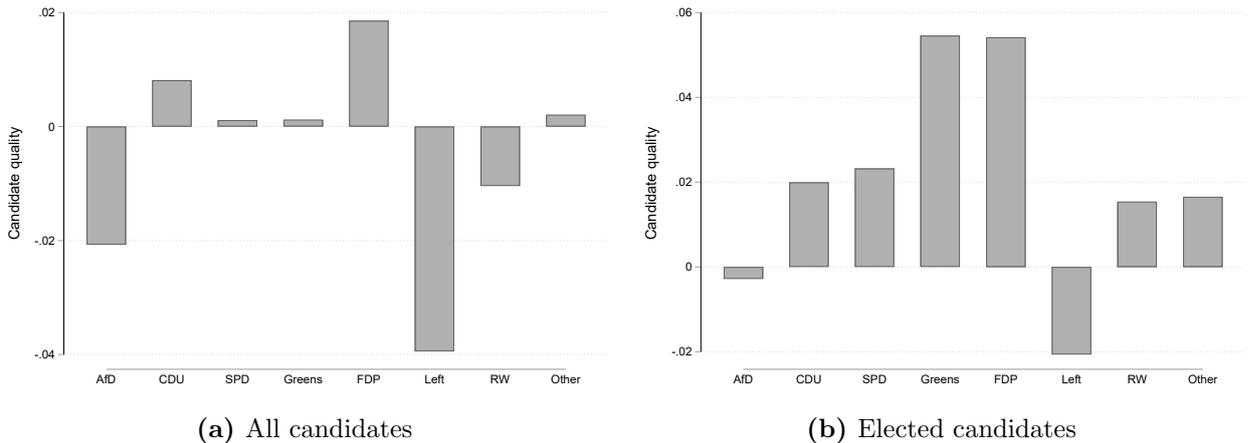

Figure B.2: Estimated candidate quality per party with LLM-based classification of occupations. This figure shows the mean candidate score (the aggregate of the estimated “value” of candidate i personal characteristics) of each party / voter initiative across the local elections in 2014, 2019, and 2024. We complement the candidate characteristics used for Figure 2 with LLM based classification of observations according to the “social status” and educational requirements. We normalize candidate scores by subtracting the overall mean candidate score (across all candidates). Subfigure (a) reports the mean normalized per party scores for all candidates. Subfigure (b) reports the mean normalized scores for elected candidates.

B.4 AfD party brand and vote shares in higher-level elections

The party brand effect as specified in Equation (3) reflects how much a candidate benefits from running on a particular list relative to running as an independent. We interpret this as the preference of voters for a particular party. Do higher values of the AfD party brand correlate with aggregate vote shares of the AfD in higher-level elections, i. e., in state, federal, or European elections?

Voters directly vote for party lists in these higher-level elections.² As such, the local party brand value should be correlated with vote shares. On the other hand, considerations beyond how much she prefers a particular party matter for how a voter casts her vote in higher-level elections. For example, vote choices might also be determined

²State and federal elections are held according to a mixed-member system, i. e., voters cast one vote for a particular candidate and one vote for a party list. However, the relative strength of parties in state and federal parliaments is almost exclusively determined by the list vote. European elections are held according to a pure proportional rule with only party lists.

by preferences regarding the “leading” candidates³ on party lists (Shikano and Herron, 2024), tactical voting (Cox and Shugart, 1996; Irwin and Van Holsteyn, 2012), and in anticipation (or in response) to state or federal level policies (Cox, 2009; Brollo and Nannicini, 2012). As such, the estimated party brand values arguably reflect a deeper, more accurate reflection of voter preferences for a party than the party’s final vote share.

It is thus worthwhile to study the relationship of the AfD party brand value in a particular municipality and AfD vote shares in higher-level elections within the same municipality. For this, we relate the election-specific AfD brand estimates to variation in AfD list vote shares in state, federal, and European Parliament elections in Figure B.3.

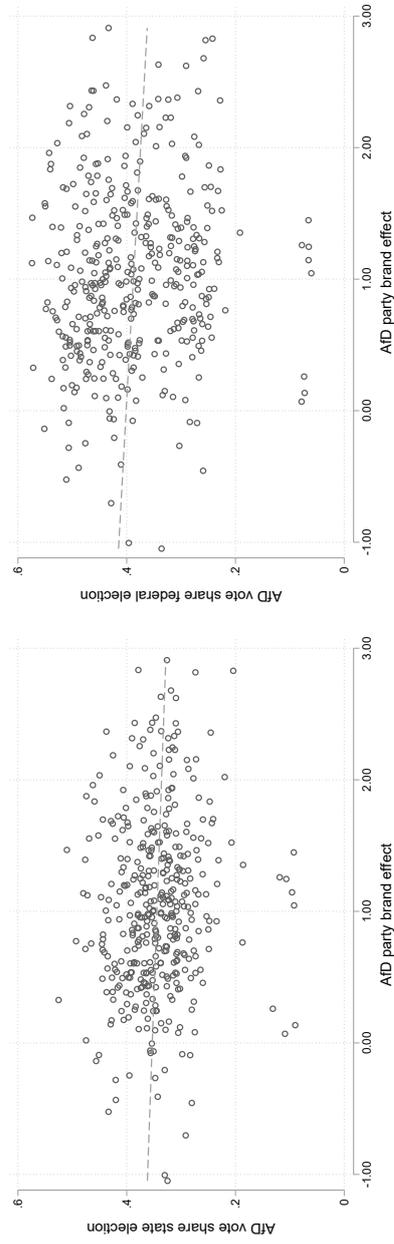

Local and European parliament elections are held on the same day in Saxony, and thus we match the brand estimates for the local election in $t = 2014, 2019, 2024$ to the European election vote shares on the same date. The state elections are held in the same year as the local elections, but several months apart. Nevertheless, we match each local election with the state election held in the same year. Federal elections are held in different years than the local elections. We thus match the local election results to the “closest” federal election, i. e., the local election in 2014 to the federal election in 2013, the local election in 2019 to the federal election of 2017, and the local election in 2024 to the federal election in 2025.

We find no strong correlation between the brand estimates and AfD’s vote shares in state, federal, and European elections. As such, the party brand estimates do not merely reflect the vote shares gained by the AfD as a party across higher-level elections. In fact, vote shares in higher-level elections might provide a misleading impression of the true popularity of the AfD as a party across space. As party-level vote shares are endogenous, other parties and higher-level governments might strategically react to how popular the AfD is in a given municipality, thereby trying to affect electoral outcomes.

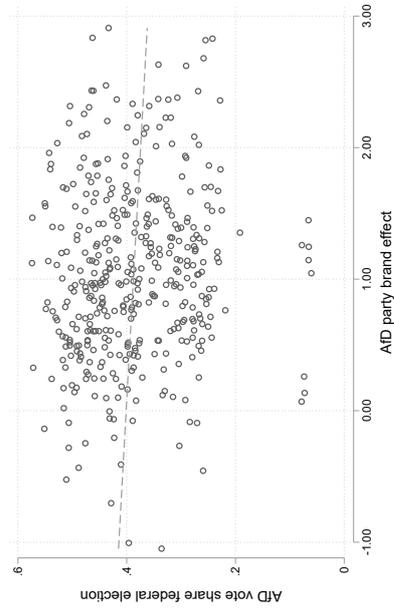

³The leading candidate of the larger parties is often the respective party’s candidate for the state governorship.

This finding might have methodological implications for studies that relate outside developments such as globalization or immigration to populist vote shares. If voters respond, e. g., to strategically allocated pork in conjunction to these developments⁴ by shifting their voting behavior, the vote share of populist parties will not accurately reflect voters' underlying pro-populist party preferences. Party brand estimates using local government election data arguably give a more accurate picture regarding how macroeconomic developments and shocks affect support for populist parties.

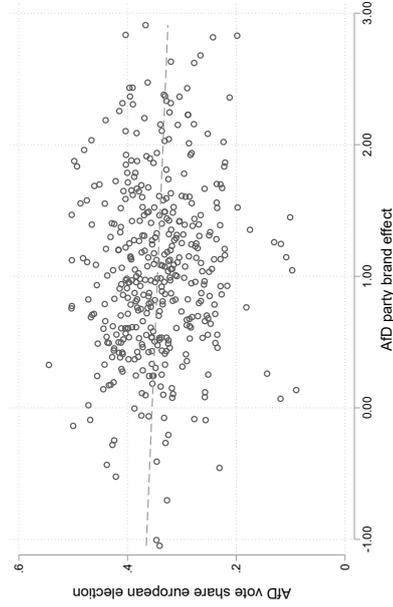

⁴For example, the federal and state governments allocate more resources to municipalities that host many refugees, see, e.g., <https://www.baden-wuerttemberg.de/de/service/presse/pressemitteilung/pid/land-gibt-bundeshilfen-fuer-gefluechtete-an-kommunen-weiter>.

(a) State election

(b) Federal election

(c) European election

Figure B.3: AfD party brand effects and vote shares in different elections. These figures plot the estimated AfD brand effect in municipality m to vote shares in different elections. In subfigure (a), we relate the AfD brand estimates to the vote shares in the state elections held later in the same year. In subfigure (b), we relate the brand estimates to the vote shares in the previous federal election (in 2013, 2017, and 2021). In subfigure (c), we relate the brand estimates to the European elections that are held at the same date as the local elections.

C Additional Figures and Tables

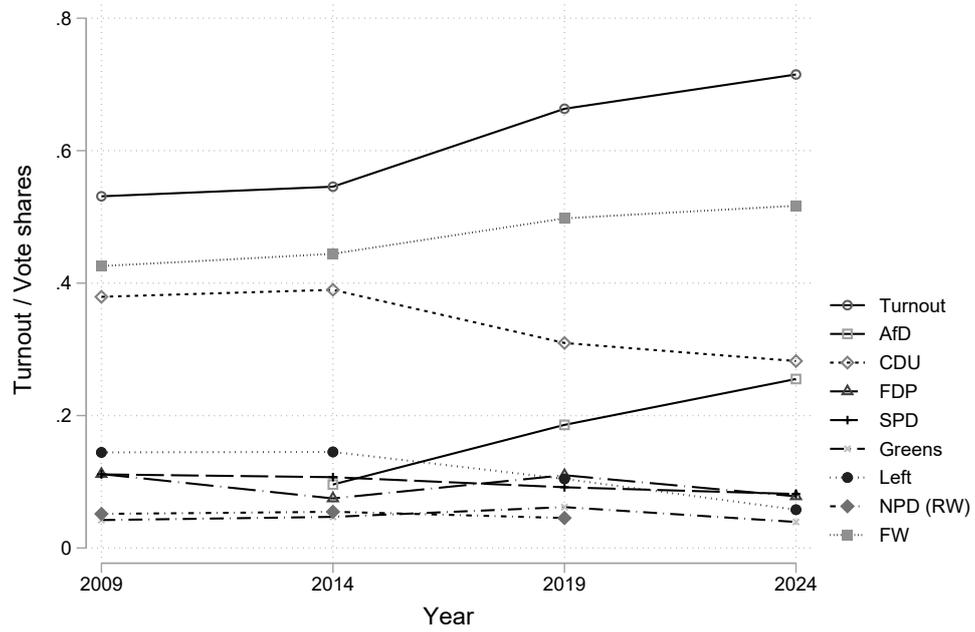

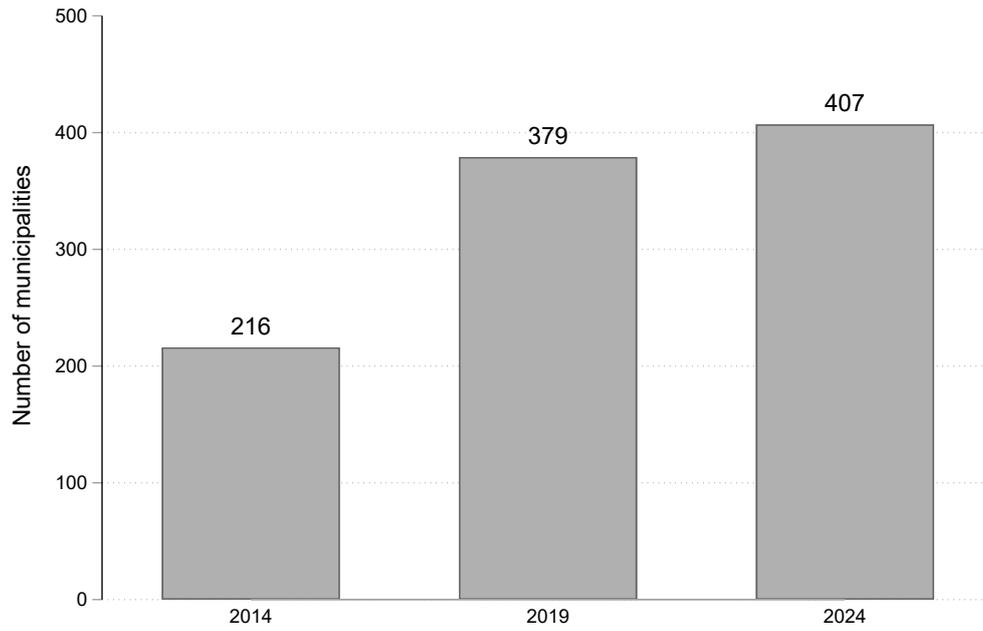

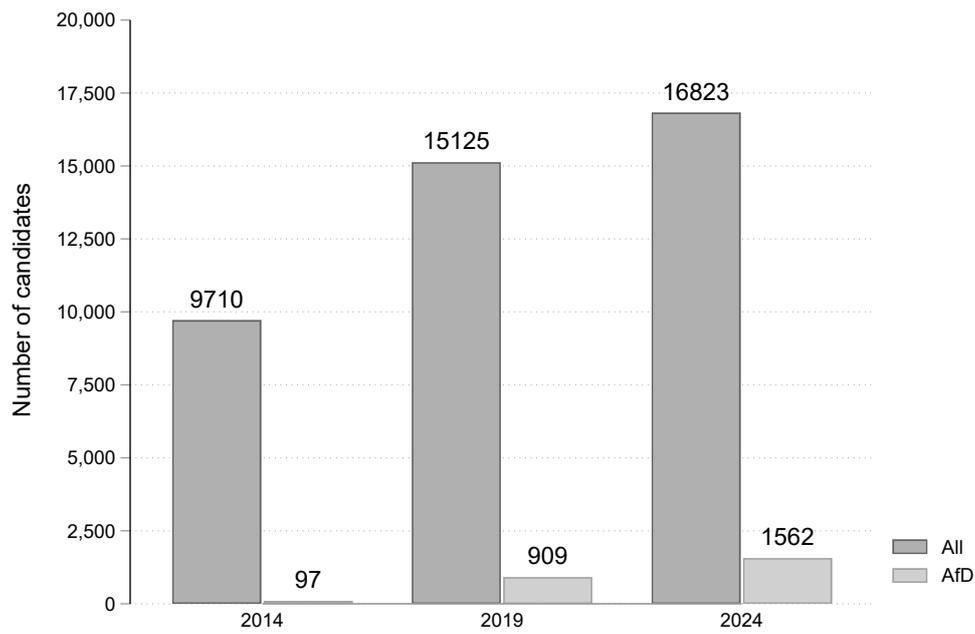

Figure C.1: Development of turnout and party vote shares in Saxonian local elections within municipalities. This figure shows the average development of vote shares and turnout within each municipality in Saxony.

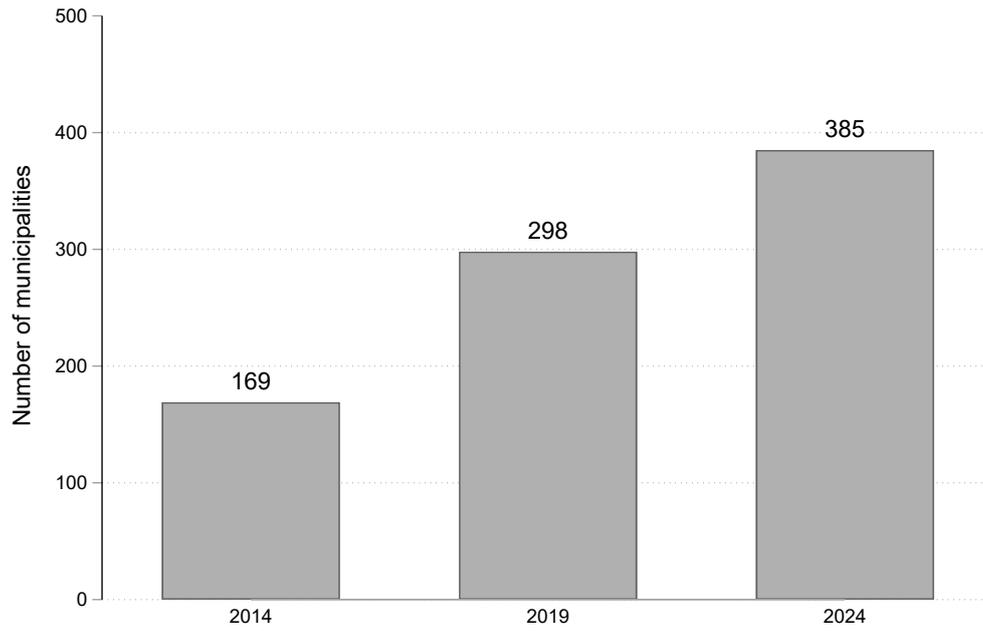

(a) Municipalities

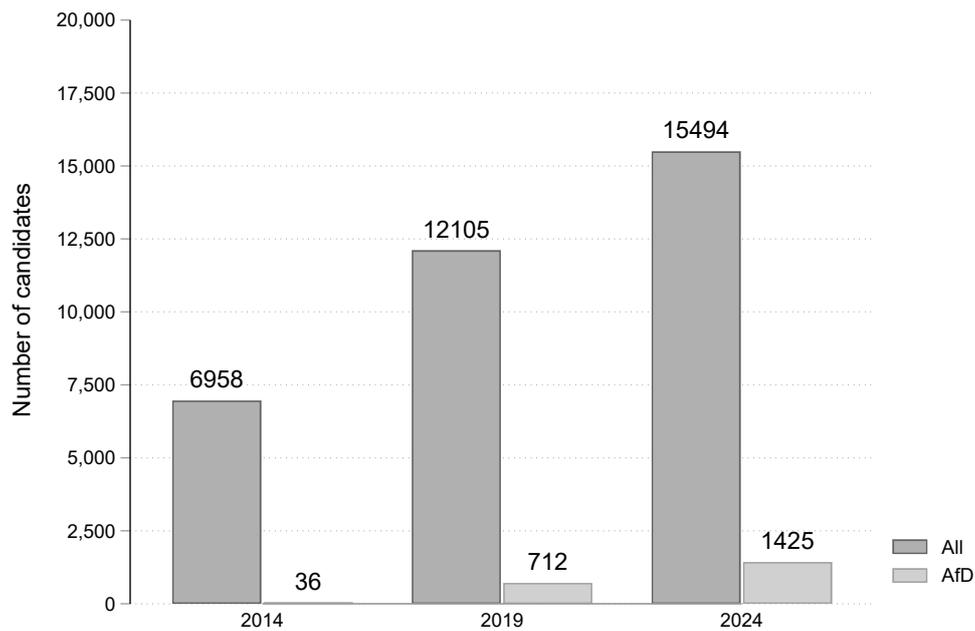

(b) Candidates

Figure C.2: Data coverage. The bar charts show the coverage of our dataset in terms of municipalities and candidates. Subfigure (a) shows the number of municipalities included in our sample in each legislative term (which corresponds with the number of elections for which we have data). Subfigure (b) shows the total number of (AfD) candidates included in our sample per legislative period.

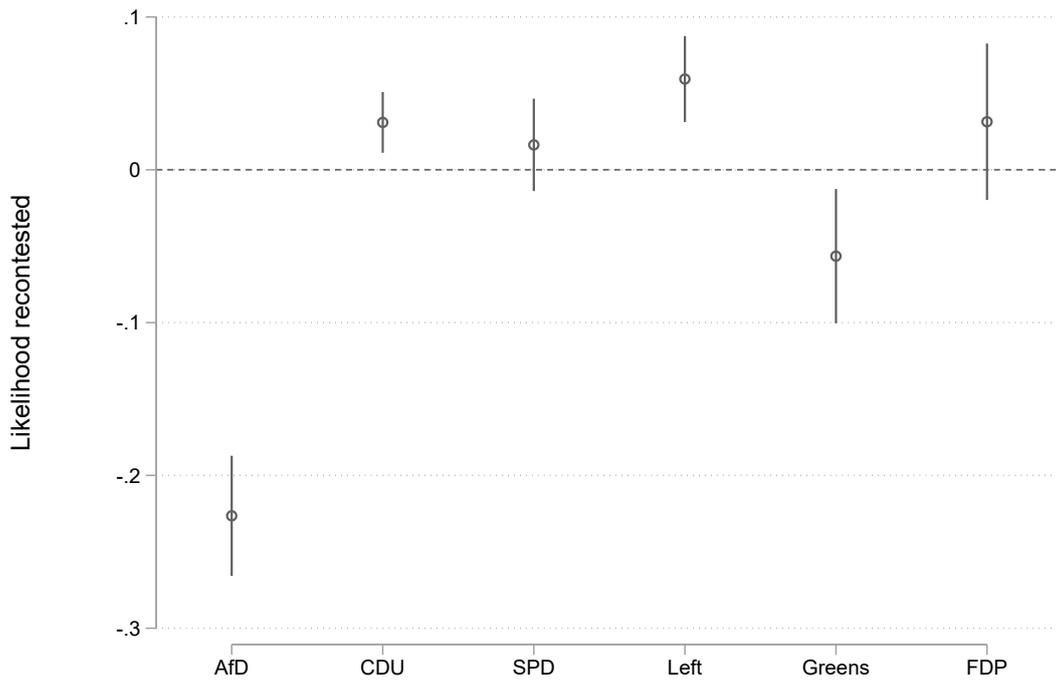

(a) Municipalities

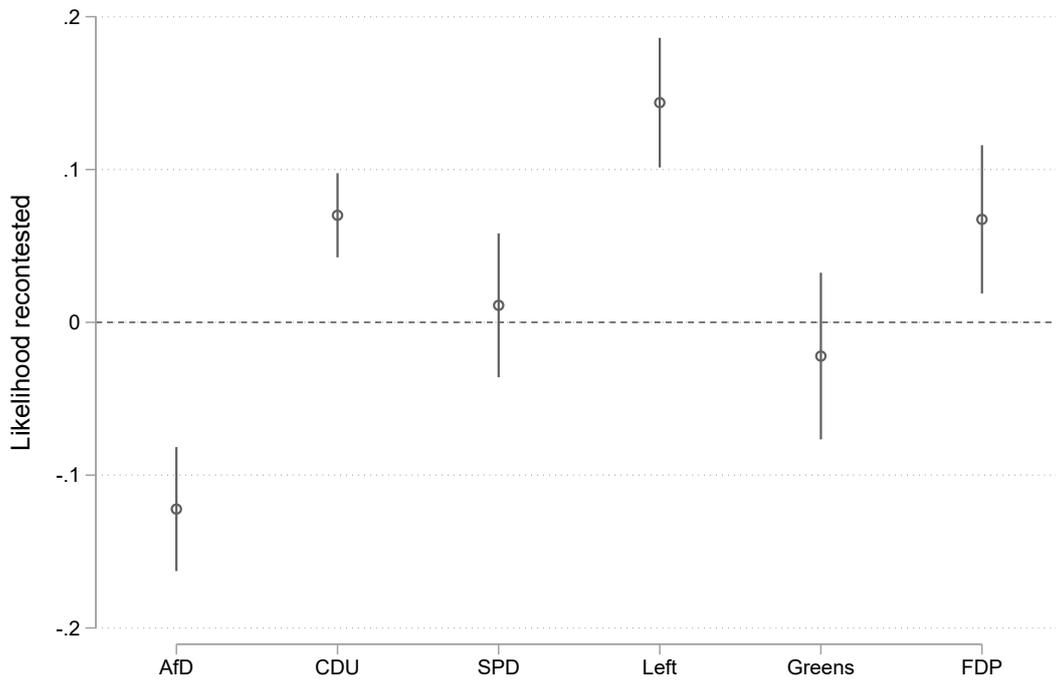

(b) Candidates

Figure C.3: Coverage of elections with complete information on candidate-level. The bar charts show the coverage of our dataset in terms of municipalities and candidates for elections where we were able to obtain the votes received by all candidates. Subfigure (a) shows the number of municipalities included in this sample in each legislative term (which corresponds with the number of elections for which we have data). Subfigure (b) shows the total number of (AfD) candidates included in this sample per legislative period.

(a) 2019 election

(b) 2024 election

Figure C.4: Likelihood of recontesting candidate. This figure estimates the likelihood whether a candidate is a recontesting candidate using a linear probability model with a dummy indicating whether a candidate is recontesting as dependent variable and party dummies as independent variables. See Equation 1.

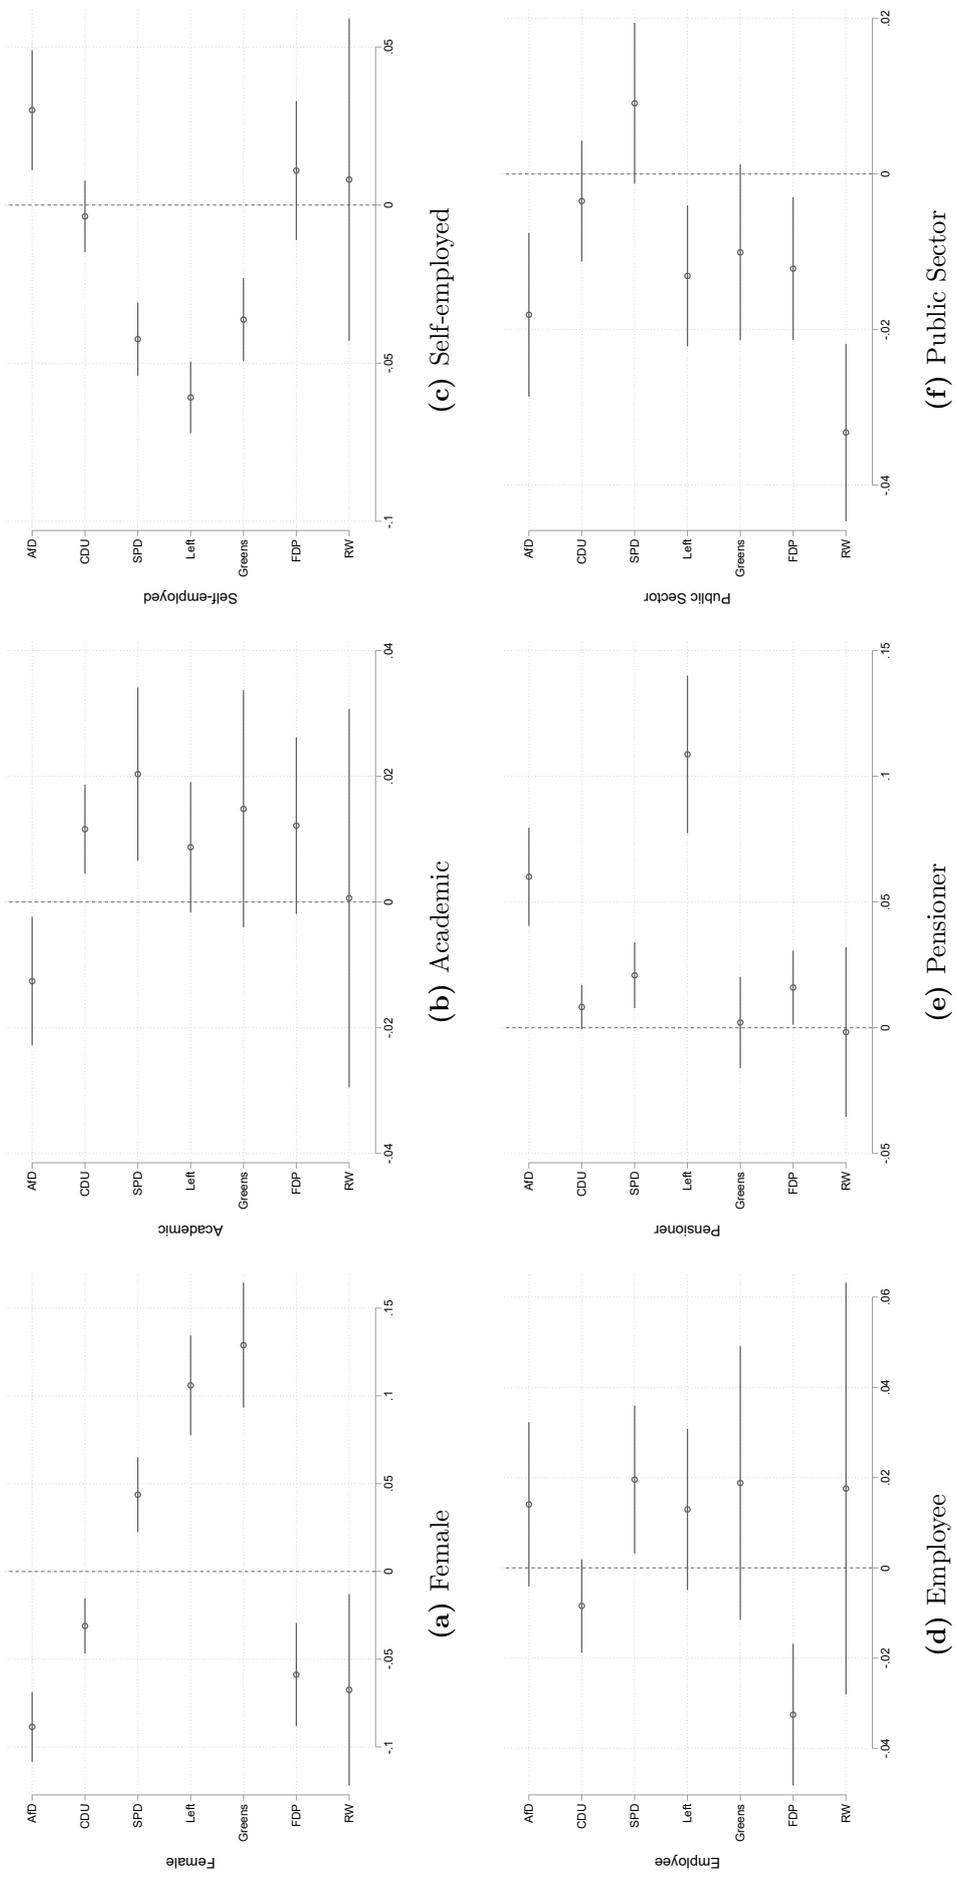

Figure C.5: Average candidate characteristics across parties, conditional on election fixed effects. This figure shows coefficient estimates of a regression with dummies for selected traits as dependent variable and party dummies as well as election fixed effects (see Equation (2)).

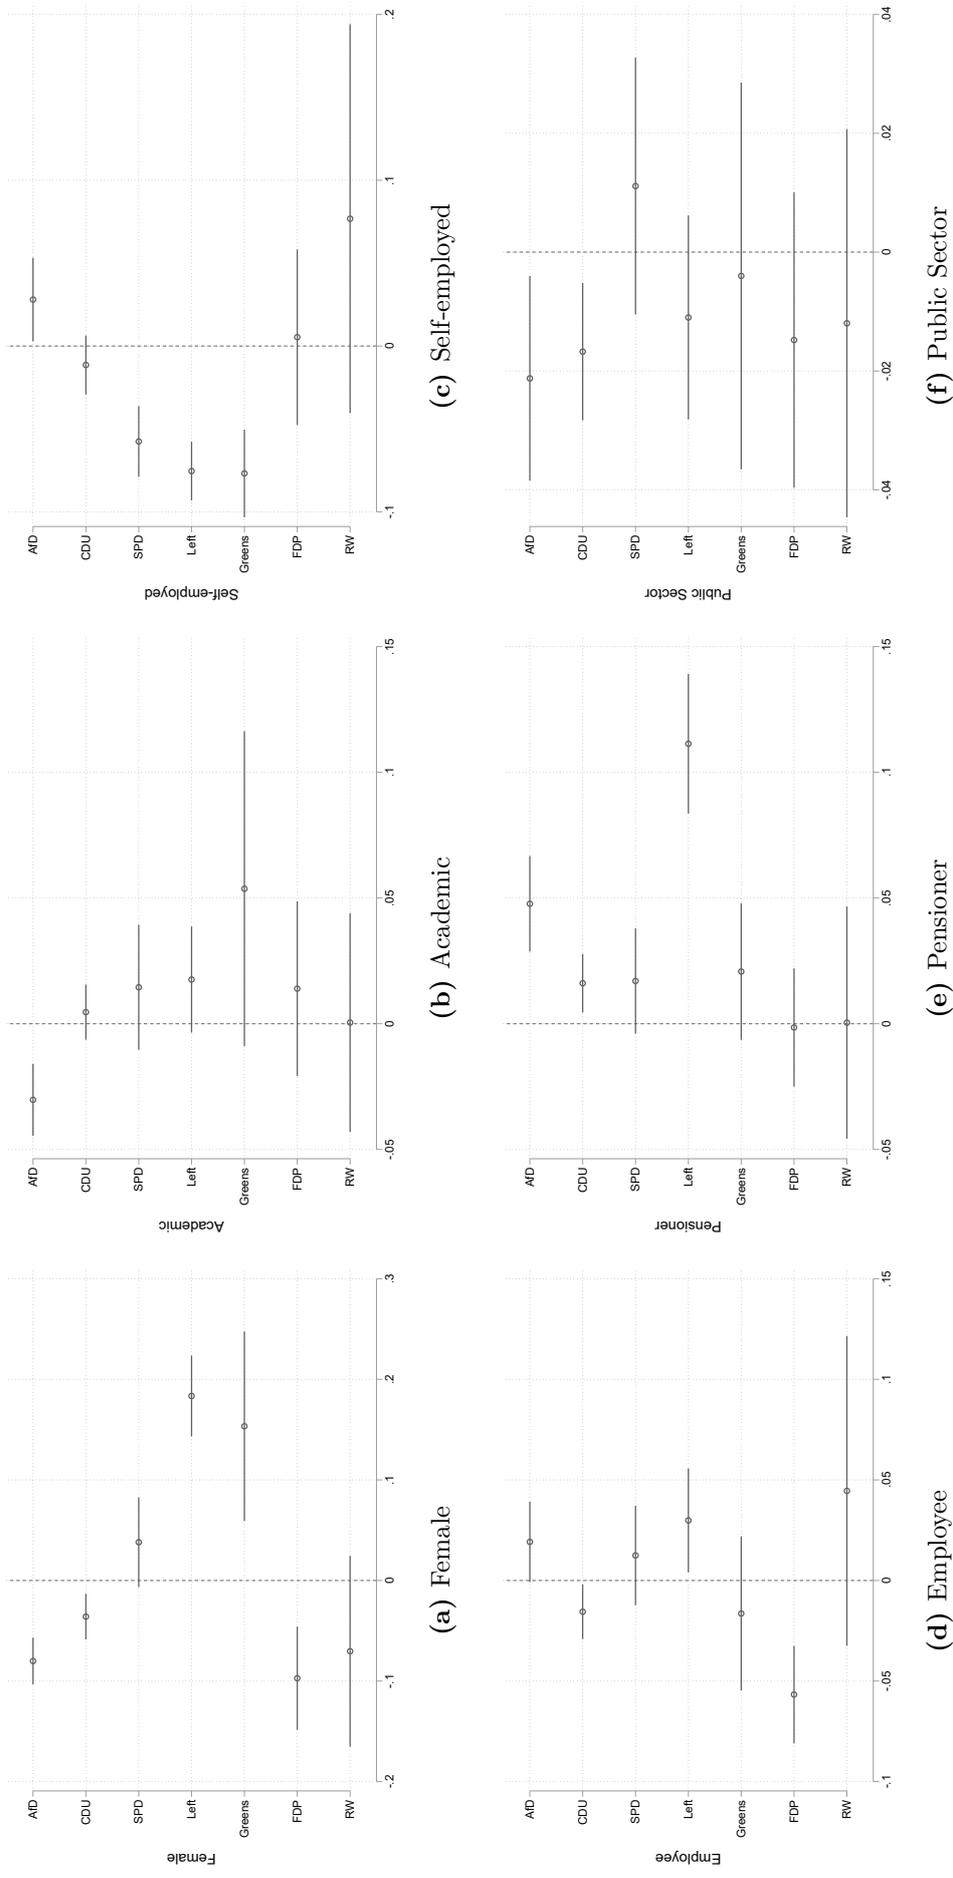

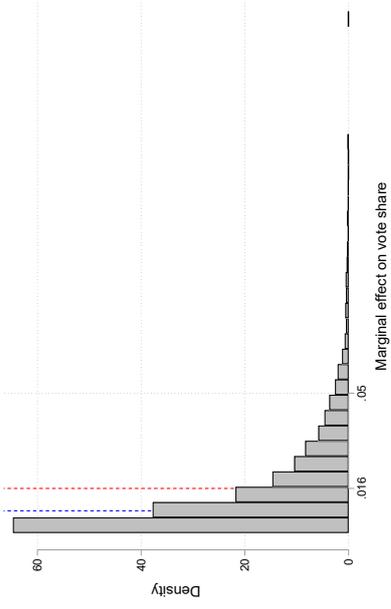

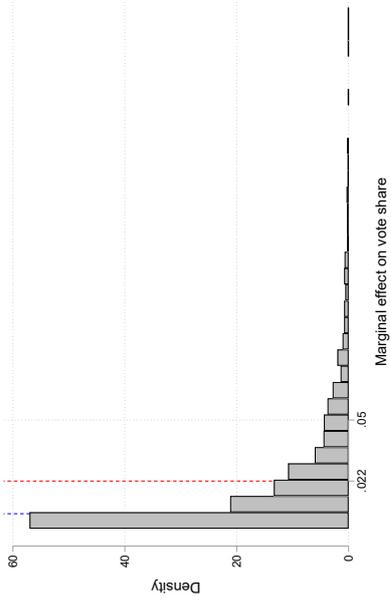

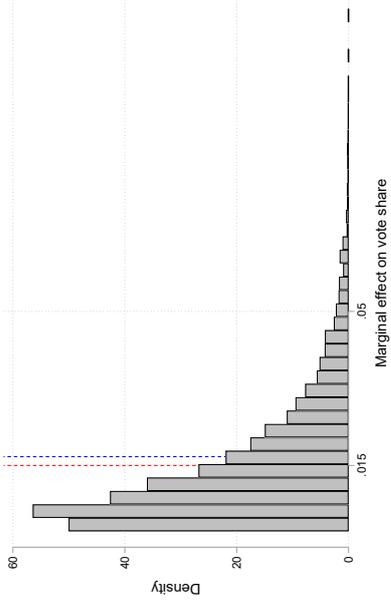

Figure C.6: Average elected candidate (councilor) characteristics across parties, conditional on election fixed effects. This figure shows coefficient estimates of a regression with dummies for selected traits as dependent variable and party dummies as covariates as well as election fixed effects (see Equation (2)). The sample is limited to elected candidates.

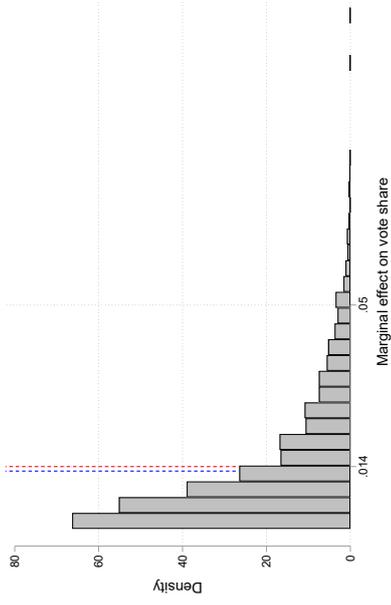

(a) CDU candidates

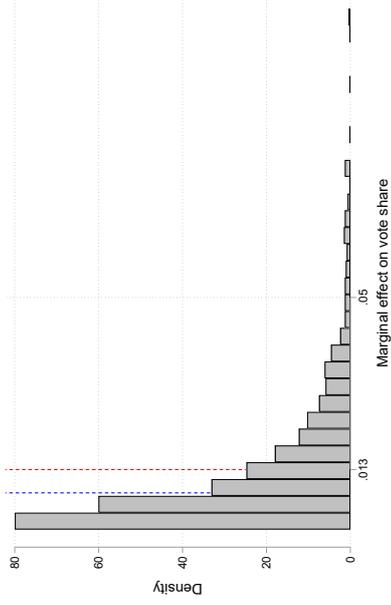

(b) FDP candidates

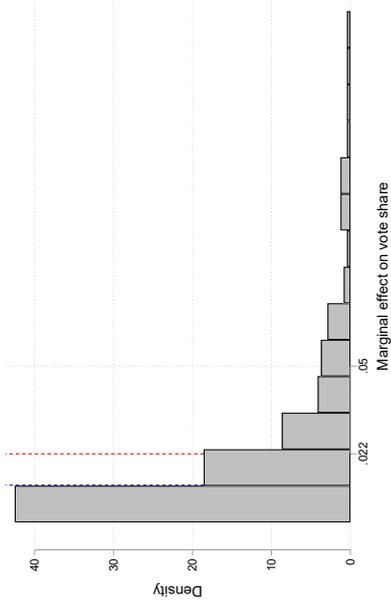

(c) SPD candidates

(d) Green candidates

(e) Left Party candidates

(f) RW candidates

Figure C.7: Marginal effect of AfD membership on vote shares of non-AfD candidates. This figure shows the distribution of marginal effects of AfD membership on non-AfD candidates by party. The red vertical line indicates the average marginal effect. The blue vertical line indicates the average vote share of AfD candidates.

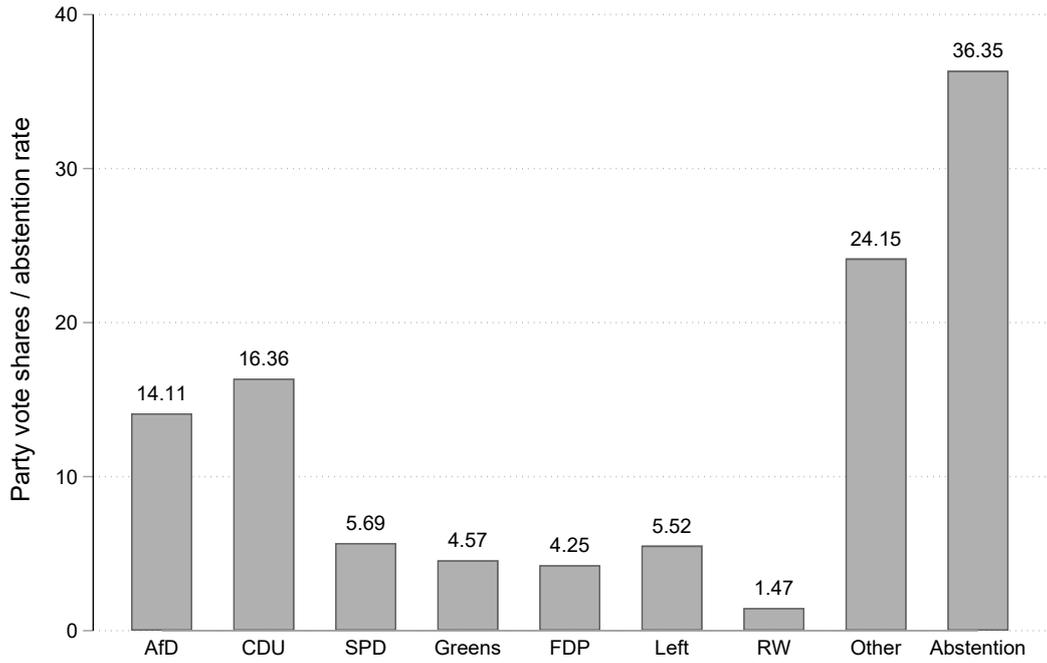

Figure C.8: Predicted party-level vote shares / abstention rates. This figure shows the predicted average party level vote shares using the estimates in Table 1.

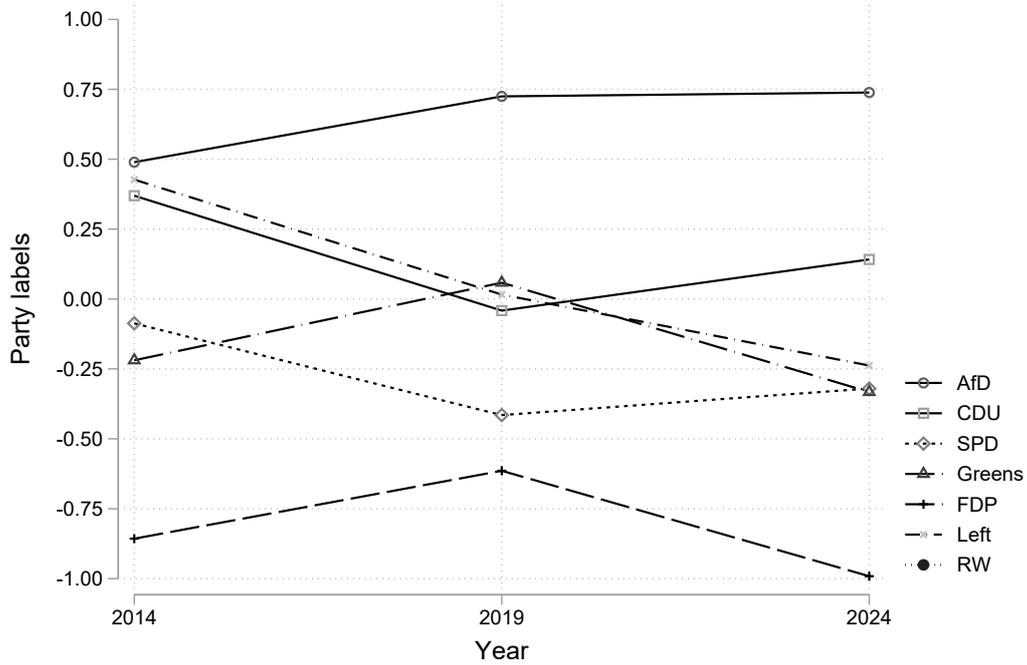

Figure C.9: Voter preferences for party brands over time. This figure reports the estimates for the party brand dummies as per Equation 16.

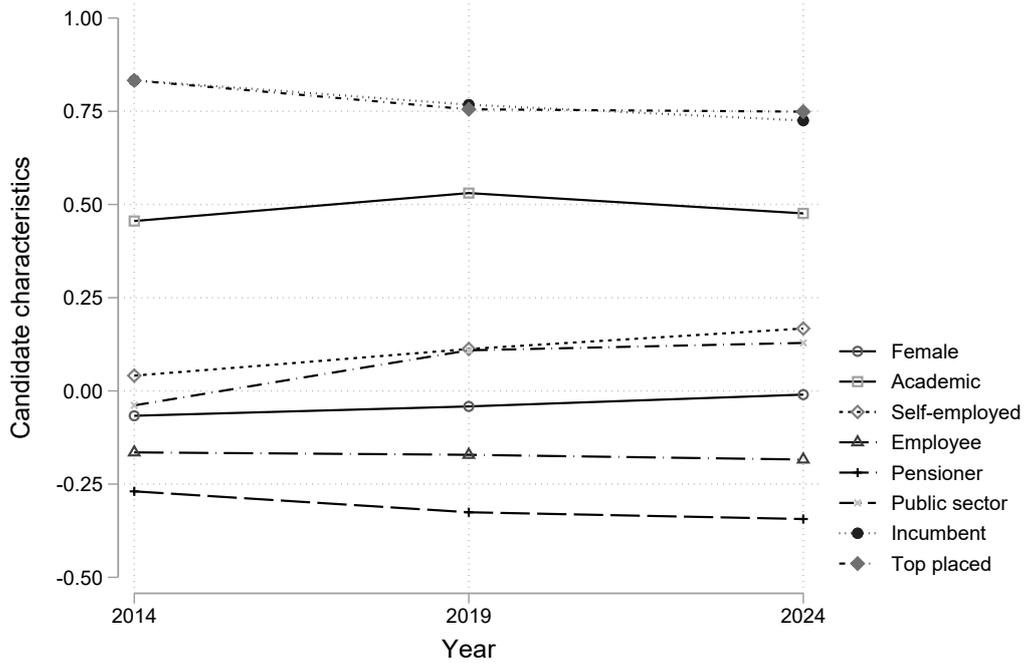

Figure C.10: Voter preferences for candidate characteristics over time. This figure reports results for personal candidate characteristics from estimating Model (3) in Table 1 with election-year specific samples.

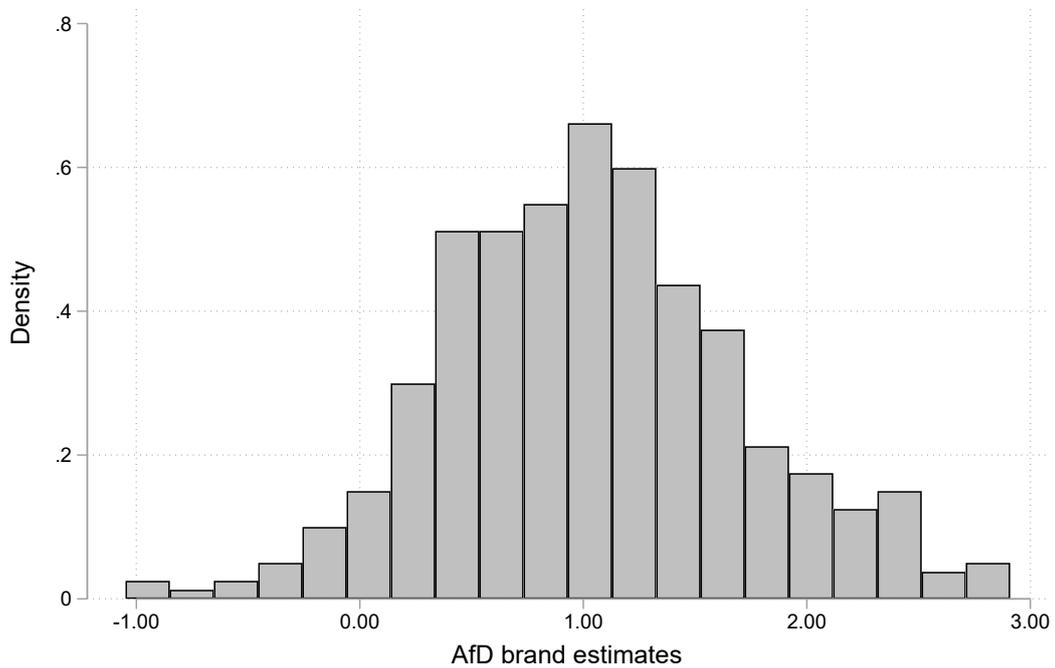

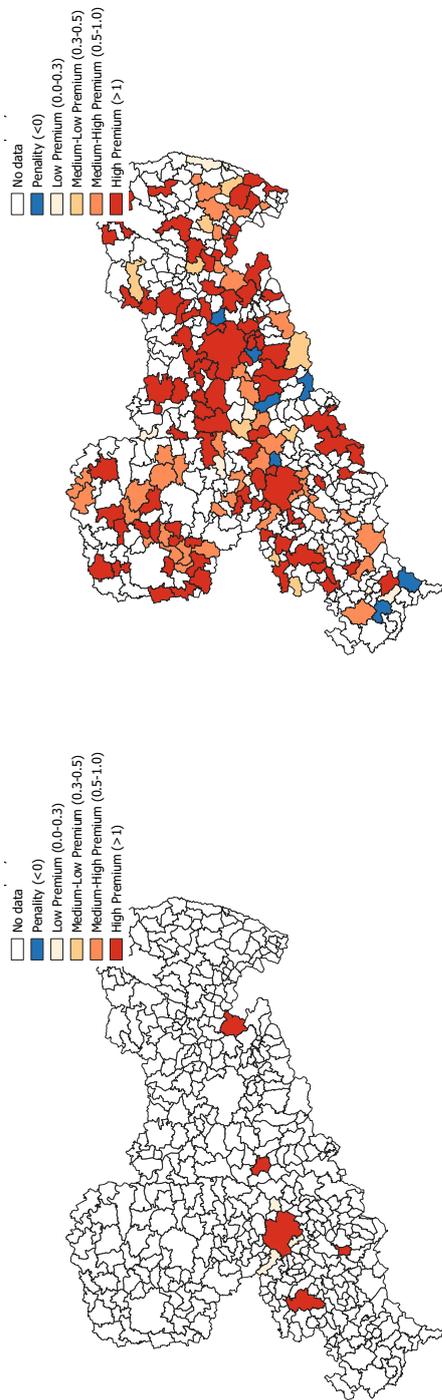

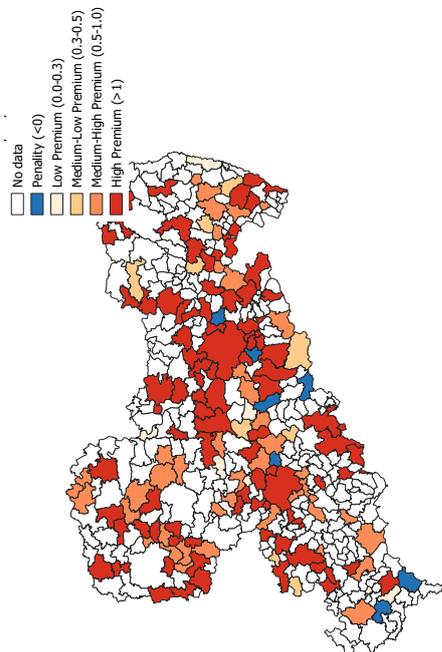

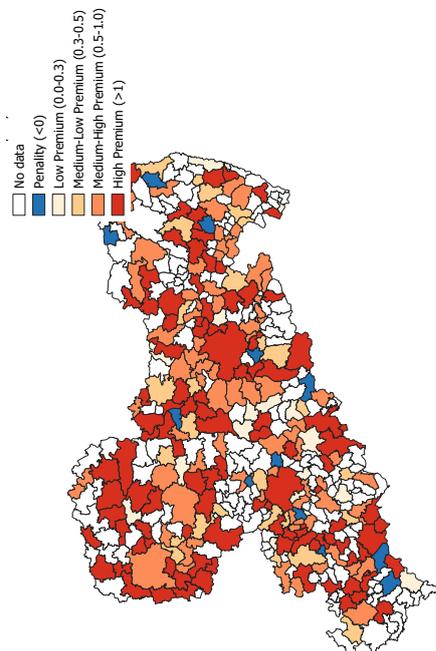

Figure C.11: Distribution of AfD party brand effects across “markets” (municipalities and over-time). This figure reports the distribution of the estimates of Equation (17) with municipality- and election-year specific samples.

(a) 2014

(b) 2019

(c) 2024

Figure C.12: AfD party brand effects across “markets” (municipalities and over-time). This figure reports results from estimating Equation (17) with municipality- and election-year specific samples. Subfigure (a) shows a map of the AfD party brand effects across municipalities in the local election of 2014. Subfigure (b) shows a map of the AfD party brand effects in the election of 2019. Subfigure (c) shows a map of the AfD party brand effects in the election of 2024. Municipalities where the AfD did not field candidates are colored white.

Table C.1: PARTIES TO WHICH TURNCOATS SWITCHED TO/FROM IN 2019 AND 2024

To \ From	AfD	CDU	SPD	FDP	Greens	Left	RW	Other	Total
Panel A: Turncoats from 2014 to 2019									
AfD	-	13	4	3	1	4	0	15	40

Mean vote share	0.026	0.026	0.026
Election FE	Yes	Yes	Yes
Elections	959	959	902
Municipalities	408	408	406
N	37137	37137	34518

^a This table collects OLS regressions where the dependent variable is the vote share of candidate i in municipality / electoral district m (defined as total votes received by candidate i relative to the total number of votes cast).

^b Model (1) only includes a dummy for whether or not candidate i is a turncoat. Model (2) controls additionally for the AfD party dummy and an interaction between the turncoat and the AfD party dummy. We explore whether turncoats who switched to the AfD perform better than turncoats who switched to other parties. In Model (3), we control for additional characteristics of candidates.

^c Stars indicate significance levels at 10%(*), 5%(**) and 1%(***). Heteroscedasticity and cluster-robust standard errors in parentheses. Standard-errors are clustered at the level of elections (municipality / electoral district × year).

Table C.3: ELECTION-LEVEL CHARACTERISTICS OF FULL AND HAND-COLLECTED SAMPLE
