The Employment Consequences of Anti-Dumping Tariffs: Lessons from Brazil*

Gustavo de Souza[†] and Haishi Li[‡]

January 14, 2026

Abstract

How do import tariffs affect employment? We develop an empirical strategy to identify the effects of tariffs using a difference-in-differences strategy, comparing anti-dumping (AD) investigations resulting in AD tariffs to those not resulting in AD tariffs. We find that an AD tariff decreases imports and increases employment in the protected sector. Moreover, employment in downstream firms decreases, while upstream firms are unaffected because the protected sector sources inputs abroad. Using a model to quantify the aggregate effects, we find that the Brazilian AD policy increased employment by 0.06% at a welfare loss of 2.4%.

Keywords: employment, tariffs, anti-dumping, international trade

JEL Codes: F13, F16

* We are grateful to the editor, Daniel Yi Xu, and two anonymous referees for their thoughtful comments and constructive suggestions, which have greatly improved the paper. We thank participants at numerous seminars and conferences for their very helpful comments. 1 Introduction

With the promise to “bring jobs back,” tariffs are usually advocated as a tool to increase domestic employment. Yet, their actual employment effects remain a source of debate among economists, as tariffs create complex and often offsetting effects across protected, upstream, and downstream sectors along the supply chain. Despite their policy relevance, comprehensive empirical estimates of sectoral employment effects and quantitative assessments of aggregate outcomes remain limited. For instance, Flaaen and Pierce (2024) document employment gains in protected sectors alongside losses in downstream sectors but do not examine upstream effects, while Huang et al. (2019), Handley et al. (2020), Bown et al. (2021) focus on the decline in downstream firm performance.

Theoretically, tariffs reallocate domestic demand toward domestically-produced products, possibly raising employment in protected sectors and their upstream suppliers; at the same time, they may increase input costs for downstream sectors, which could reduce downstream employment. The aggregate employment effect therefore depends on the relative elasticities of employment in protected, upstream, and downstream sectors.

In this paper, we ask the following: What is the employment effect of tariffs and how does it propagate through the value chain? We develop a new empirical strategy based on difference-in-differences that exploits World Trade Organization (WTO) anti-dumping (AD) regulations. The strategy enables us to systematically estimate tariff effects on trade and employment across the supply chain, and use a model to aggregate these effects. The identification strategy is to compare the employment growth between sectors with AD investigations resulting in AD tariffs to those with AD investigations not resulting in duties. We find that tariffs increase employment in the protected sector and negatively affect downstream firms, but do not significantly affect upstream employment. Using a model to aggregate these elasticities, we find that the Brazilian AD policy increased employment by 0.06%.

Identifying the effects of tariffs is challenging because they are usually correlated with other policies, aggregate shocks, or retaliation from other countries. In many countries, tariffs and other favorable policies target politically relevant sectors, making it difficult to disentangle the effects of these other policies from the effect of tariffs. Moreover, protection

from international competition usually targets sectors in decline (Staiger and Wolak 1994, Prusa 1997, Steinbach and Khederlarian 2022) or is followed by retaliation from the foreign country (Flaaten and Pierce 2024), once again creating a confounding effect.

We isolate the effect of tariffs by comparing sectors and products with AD investigations resulting in AD tariffs to those with investigations not resulting in AD tariffs in Brazil, which is a small open economy. According to WTO regulations, firms harmed by foreign competition can apply to the federal government for protection by AD tariffs. If the application satisfies certain conditions, the government opens an investigation. Subsequently, an AD tariff is triggered if and only if the price of the investigated product was greater in its home market than in the foreign market *before the beginning of the investigation*. Therefore, conditional on a product being investigated, the decision to impose a tariff and its size is made based on pre-determined variables in foreign countries, which can be teased out with fixed effects because, empirically, we find that foreign prices affect the level of trade and employment but not their trends. Importantly, conditional on an investigation, AD tariffs should not depend on domestic labor market trends, other policies, or political connections. Moreover, because Brazil is a small open economy, foreign prices are not affected by labor market shocks in the country.¹

To implement our identification strategy, we collect information on all AD investigations initiated by Brazil.² Next, we link each investigation to firms in the protected sector, upstream sectors, and downstream sectors. This information is then matched to an employer–employee dataset that contains details on wages and employment at the firm level.

We implement a difference-in-differences strategy comparing the growth rates of trade and employment of firms when investigations resulted in AD tariffs to those when investigations did not result in AD tariffs. The treatment group is the set of products whose AD investigations led to the imposition of a tariff. The control group is the set of products whose AD investigations did not result in a tariff change. The identifying assumption is that the treatment and control groups follow parallel trends.

¹In practice, we also exploit variation in the size of the tariff within the treatment group. This approach is valid because the level of AD tariffs—not only the decision to implement them—are based on fixed pre-determined characteristics in foreign countries that can be teased out with fixed effects.

²Among global economies, Brazil ranks sixth in terms of the number of AD investigations launched, after the United States, India, European Union, Canada, and Argentina (Bown 2005). See also Soto (2016).

To validate our identification strategy, we implement a battery of exercises and robustness checks. First, we show that pre-period parallel trends hold for all the variables considered. Second, we show that our results cannot be explained by other major shocks hitting the Brazilian economy, such as the Brazilian trade liberalization or fluctuations in the exchange rate. Third, we implement placebo tests to show that our results are not driven by sectoral or labor market trends. Fourth, we find that adding or removing controls from our main specification does not change the results. Fifth, we show that running our main regressions at the region level, instead of the firm level, delivers similar results. Finally, we also find the same results using an instrumented difference-in-differences strategy with pre-period international prices as the instrument.

To further validate the identifying assumption, we show that political connections cannot predict AD tariffs, but international prices can, as stipulated by WTO regulations. Treatment and control groups are equally likely to make campaign contributions or to receive procurement contracts, subsidies, tax breaks, or subsidized loans from the government; this shows that AD tariffs are not imposed to protect politically connected sectors. We also show that AD tariffs are not correlated with preferential trade agreements or Most Favored Nation (MFN) tariffs. Moreover, using only international prices, we can predict Brazilian AD tariffs with an R-squared above 0.95, which shows that the Brazilian government follows the WTO regulations closely.

We find that AD tariffs decrease imports and increase employment in the protected sector. A 100% ad valorem AD tariff decreases imports by 25% without a significant effect on the imports' price, which supports the idea that Brazil is a small open economy. In contrast to Flaaen et al. (2019), we find no corresponding increase in imports from other locations.

Tariffs increase the employment, exports, and imports of protected firms. A 100% ad valorem tariff generates a 1.8% employment increase among firms shielded from international competition. Despite the growth of protected firms, firms upstream from them are not significantly affected, as protected firms substitute domestic inputs with imported ones. Finally, employment in downstream firms decreases significantly, whereby a 100% ad valorem tariff on all inputs of a firm reduces employment by 3.8%.

The empirical results are informative about firm-level responses to AD tariffs but are

silent on the aggregate effects. To make aggregate quantitative predictions, we build a small open economy model with international trade, input-output linkages, and labor force participation. We show that the model’s key parameters can be identified from the estimated reduced-form elasticities. In the model, workers choose to work in different sectors or stay outside the labor force. To produce, firms use labor and input from all sectors. The sectoral input is supplied by imperfectly substitutable domestic and foreign producers. We calibrate the model to reproduce the effect of AD tariffs on employment and international trade.

From the quantitative model, we conclude that the Brazilian AD policy increased employment and GDP, but the effects of tariffs on employment depend on the position of the tariffed product along the value chain. We find that the Brazilian AD policy increased employment and GDP by 0.06% and 0.05%, respectively, and decreased consumption-equivalent welfare by 2.43%. Moreover, the aggregate effect of a tariff depends on the position of the product in the value chain. Imposing tariffs that protect the computer, electrical, and machinery sectors (which are further down the value chain) increases aggregate employment. However, imposing tariffs that protect the agriculture and mining sectors (which are relatively upstream in the value chain) decreases aggregate employment. These results indicate that, if the goal of tariffs is to increase employment, they should protect sectors at the end of the value chain that use inputs from a wide range of sectors.

Our main contribution is twofold: First, we show that the effect of tariffs on employment along the supply chain can be identified by leveraging WTO regulations, and second, we quantify their aggregate impacts with a quantitative model. As such, this paper contributes to the emerging body of literature investigating the supply chain effects of trade protections. Predominantly empirical in nature, this body of research has based its identification strategies on the trade policy institutions of specific countries, economic shocks occurring during distinct episodes, and tariff changes within particular sectors. Studies have examined the China shock (Acemoglu et al. 2014, Pierce and Schott 2016), the 2018–19 U.S. tariffs on China (Flaaen and Pierce 2024, Huang et al. 2019, Handley et al. 2020, Trimarchi 2020), the Trump administration’s tariff on washing machines (Flaaen et al. 2019), the Bush administration’s steel tariffs (Cox 2021), industrial subsidies in the steel sector (Blonigen 2016), voting patterns of U.S. members of congress (Bown et al. 2021), rules of origin requirements

in free trade agreements (Conconi et al. 2018), and monthly variation in temporary trade barriers (Barattieri and Cacciatore 2023).

We contribute to this body of literature by showing that the effect of tariffs on employment can be identified by leveraging WTO regulations. Because our strategy relies on the design of the WTO AD regulations, it is applicable to virtually all WTO members who have implemented AD investigations.³

This paper also contributes to the literature studying AD tariffs.⁴ The literature has shown that AD tariffs reduce imports, leading to trade depression.⁵ However, the evidence on trade diversion—the impact of tariffs on imports of other products and countries—is mixed. Prusa (1997), Baylis and Perloff (2010), Flaaen et al. (2019), and De Souza et al. (2024) find that AD tariffs increase imports from non-targeted countries, while Konings et al. (2001), Crowley (2006) and Durling and Prusa (2006) find no significant third-country effect. This literature also reveals that AD tariffs influence firm performance in the protected sector (Konings and Vandenbussche 2008, Pierce 2011, Jabbour et al. 2019), as well as employment (Trimarchi 2020, Barattieri and Cacciatore 2023, Bown et al. 2021).

Closest to us, Bown et al. (2021) and Barattieri and Cacciatore (2023) also examine the impact of AD tariffs on the supply chain. Bown et al. (2021) employ a shift-share instrument based on political changes in swing states to show that politically motivated AD trade protection significantly reduces employment in downstream industries. Similarly, Barattieri and Cacciatore (2023), leveraging variation in the timing of AD tariffs, find that these tariffs offer minimal employment benefits in protected industries while causing persistent job losses in downstream industries due to higher input costs and reduced competitiveness.

Most studies in this literature compare products investigated for dumping and subject to AD tariffs to those that have never been investigated. However, this method introduces biases in estimating the effects of tariffs for two reasons. First, sectors investigated for dumping often experience different employment and trade trends compared to non-investigated sectors. According to WTO regulations, an AD investigation can only be initiated if a

³For instance, building on the methods developed in this paper, De Souza et al. (2024) investigate how AD tariffs impact Russia’s total exports, identifying trade elasticities in the short, medium, and long term.

⁴For a more comprehensive review of the literature, see Blonigen and Prusa (2016).

⁵See Staiger and Wolak (1994), Lloyd et al. (1998), Prusa (1997), Vandenbussche and Zanardi (2010), Irwin (2014), Besedeš and Prusa (2017), and Sandkamp (2020).

sector is experiencing declining revenue or employment alongside increasing imports. As a result, these sectors are unlikely to follow similar trends or face comparable shocks. Second, the investigation process itself can influence trade and employment by creating trade policy uncertainty, which further complicates the comparison.

We contribute to this literature in three ways. First, we show that we can leverage the WTO’s AD regulations to identify the effect of tariffs on employment and trade.⁶ Second, unlike Bown et al. (2021) and Barattieri and Cacciatore (2023), we find that tariffs significantly increased employment in the protected sector. This finding is consistent with Flaaen and Pierce (2024), who studied the effects of U.S.-China trade war tariffs. Finally, to our knowledge, we are the first to provide a general equilibrium analysis of the aggregate employment effects of AD tariffs, accounting for midstream, upstream, and downstream impacts as well as flexible labor supply decisions.⁷

Our paper contributes to the extensive literature examining the labor market consequences of international trade. While empirical studies largely agree that import competition leads to decreased employment and wages in affected sectors (Trefler 2004, Autor et al. 2013, Dix-Carneiro and Kovak 2015, Dix-Carneiro and Kovak 2017, and Devlin et al. 2021, among others) and that tariffs result in employment declines in downstream sectors (Handley et al. 2020, Bown et al. 2021, Flaaen and Pierce 2024, among others), there is disagreement regarding the impacts of tariffs on protected sectors and their propagation upstream, which results in uncertainty around the aggregate effect of tariffs.⁸ Quantitative works, including Caliendo et al. (2019) and Rodríguez-Clare et al. (2020), predict that trade protection can

⁶A similar identification strategy was also used by Pierce (2011) and Konings and Vandenbussche (2008). However, we are the first to show that this strategy satisfies several exogeneity requirements. We demonstrate that pre-period parallel trends hold for all our variables of interest, that the institutional setting supports our identification strategy, that international prices can predict AD tariffs, that AD tariffs are uncorrelated with other policies, and that they are not correlated with other shocks hitting the Brazilian economy or the business cycle.

⁷For example, Gallaway et al. (1999) evaluate U.S. real income loss from AD tariffs using a computable general equilibrium model, but do not consider labor supply decisions. Egger and Nelson (2011) study the real income loss from AD tariffs using a regression approach, and therefore do not account for input-output linkages or labor supply decisions. Ruhl (2014) uses a small open economy model with firm dynamics to identify significant U.S. real income losses from AD tariffs. However, Ruhl’s model does not account for input-output linkages. Most of these works primarily focus on real income rather than on employment or welfare.

⁸Flaaen and Pierce (2024) and Trimarchi (2020) find that U.S.-China trade war tariffs weakly increased employment in the protected sectors, but Barattieri and Cacciatore (2023) and Bown et al. (2021) find that AD tariffs had a negligible employment effect in the protected sectors.

increase total employment, whereas Barattieri et al. (2021) predict otherwise.

We contribute to this literature by presenting new evidence on tariff effects on employment in protected and upstream sectors. Our empirical estimates show moderate aggregate employment gains from AD tariffs and highlight the significance of input-output linkages in determining the aggregate employment effect.

The rest of the paper proceeds as follows. In Section 2, we review the WTO AD rules, the practice of AD investigations in Brazil, and the data used in this study. In Section 3, we explain our empirical strategy. In Section 4, we present the main empirical results. In Section 5, we introduce the model. In Section 6, we describe the procedure to estimate the model. In Section 7, we show the quantitative results. Finally, in Section 8, we conclude.

2 Institutions and Data

2.1 Anti-Dumping Investigations

The identification strategy exploits the design of the WTO AD regulations to isolate the effect of tariffs from other confounders. In this section, we describe these regulations to argue that, conditional on an AD investigation being opened, the AD tariff is triggered by pre-determined variables outside of Brazil. Because these variables affect the level of trade and employment but not their trends, we can compare the growth rates of employment and imports when AD investigations resulted in AD tariffs to those when AD investigations did not result in AD tariffs..

Dumping is defined as international price discrimination whereby the exporter charges a lower price in the destination market than in their home market. According to WTO regulations, the destination market harmed by dumping is allowed to set an AD tariff to exactly offset this price difference. The WTO AD regulations, which Brazil follows, define three steps for the creation of an AD tariff: (1) firms harmed by dumping file a complaint to the Ministry of Economy, (2) the government opens an investigation into whether the foreign competitor has engaged in dumping, and (3) an AD tariff is imposed to exactly offset the

estimated price difference based on pre-investigation prices.⁹

The process starts with a domestic firm or a group of domestic firms filing a complaint with the Ministry of Economy. The complaint must show that the sector has been harmed by foreign dumping practices. Firms must present evidence that they have experienced a decrease in profits, sales, or wages, and link this to increased import competition from an international competitor. This suggests that the sales and prices of investigated and non-investigated products may follow different trends.¹⁰

The government, upon receiving the complaint, determines whether it should open an investigation or dismiss the case. This decision is made based on whether there is enough proof linking the national supplier's decreased economic performance to increased imports from the international competitor. In the empirical analysis below, we only consider the cases in which an investigation was opened.

After the government opens an investigation, it calculates the price of the imported product in its home market before the investigation, adjusted for currency difference and transport cost (the "normal value"), and compares it with its price in Brazil. If the imported product comes from a non-market economy, the normal value is calculated using the pre-investigation price in a third market.¹¹

If the government finds that the foreign competitor is charging a lower price in Brazil than its normal value, the government will create an AD tariff to make the Brazilian post-tariff price equal to the normal value. Therefore, the AD tariff is set based on pre-determined price differences charged by the foreign exporter in Brazil and in its home market. The AD tariff, once imposed, lasts for five years and is then reevaluated. Most AD tariffs are reinstated after five years because the price differences remain.

⁹See the Agreement on Implementation of Article VI of the GATT 1994 (World Trade Organization (1994a)).

¹⁰We discuss this further in Section A.3.

¹¹The Brazilian government considers only China and Vietnam to be non-market economies. In those cases, the third country chosen as a reference for the normal value will depend on data availability. In general, the normal value in a non-market economy can also be estimated using estimates of the production

2.2 Data

To understand the effect of tariffs on employment exploiting WTO regulations, we merge four datasets. They contain information on AD tariffs, product-level imports, firm-level employment, and firm-level imports. For information on AD tariffs and investigations, we use the Global Antidumping Database (Bown 2005). For each AD investigation in Brazil, the Global Antidumping Database contains the investigated product’s name and classification, the country of origin, the start and conclusion dates of each investigation, and the measures taken. Section A.1 presents a set of summary statistics of AD investigations in Brazil.

Data on imports come from the Secretary of International Trade of the Ministry of Economy in Brazil, which provides monthly statistics on imports and exports for Brazil at the product level. These data are used to understand the effect of tariffs on trade. The third database, RAIS, covers employment information on Brazilian firms. This database provides a yearly employer–employee matched dataset containing information on workers’ wages, hours, occupations, and demographics. It also contains data on the sector and location of the firm. Using a concordance table provided by the Brazilian Secretary of International Trade, we link each AD investigation to its sector. This enables us to study how tariffs affect employment.

Throughout the paper, we focus the analysis on firms with more than one worker that have been active for more than 10 years. The goal is to prevent changes in the composition of firms from driving the results.¹² Our analysis spans from 1995 to 2016. We also drop the service sector and government sector from the empirical analysis.

3 Empirical Strategy

We use a difference-in-differences strategy to identify the effect of AD tariffs on trade and employment, comparing products, sectors, and firms that faced AD investigations resulting in tariffs to those with investigations not resulting in tariffs. The key identifying assumption is that prior to the imposition of anti-dumping duties, employment and wage growth is on the same trajectory for sectors that ultimately receive AD protection and sectors that

cost, but this method is not used in Brazil. See WTO’s Technical Information on Anti-dumping (World Trade Organization 1994b).

¹²One could worry that this choice could lead to sample selection. Indeed, that would be the case if AD

are investigated but do not receive protection. In this section, we first discuss how the institutional setting of AD tariffs supports the identifying assumption. Then, we lay out the empirical model. In the final part, we discuss a battery of tests supporting the identifying assumption.

3.1 Identification

Identification Challenge. To identify the effect of tariffs, one cannot simply compare products with AD investigations to products with no AD investigations. As discussed in Section 2, AD investigations are typically initiated in sectors experiencing increased imports and decreasing employment. Section A.3 shows that investigated products have a lower price and higher volume than non-investigated ones. They are also in a decreasing price and increasing volume trend at the time of the investigation.

Products with and without AD investigations are also not comparable due to trade policy uncertainty. An AD investigation itself might affect trade and employment by creating uncertainty around future trade policy.¹³ Therefore, one cannot tease out the effect of trade policy uncertainty by comparing investigated and non-investigated products.

Identification. According to WTO regulations, after an investigation is completed, the decision to impose an AD tariff is a function of the pre-determined characteristics of the product. Conditional on being investigated, a product on which a tariff is imposed only differs from a product on which a tariff is not imposed in the level of international prices.

If the only difference is the international price level—and not their trends—comparing the growth rate of imports of these two sectors identifies the effect of the AD tariff. Moreover, the effect of trade uncertainty is teased out because the treatment and control groups are both exposed to AD investigations.

To illustrate, suppose Brazil has two industries—automobiles and steel—both declining due to low-priced imports. Foreign automobiles are cheaper due to higher productivity

tariffs led firms to enter or exit the market. In Section A.5.4, we show that our results are the same if we keep all the firms in the sample. We also show that AD tariffs did not lead to firm entry or exit.

¹³As highlighted by Staiger and Wolak (1994), Prusa (2001), Lu et al. (2013), Besedeš and Prusa (2017), among others.

abroad, whereas foreign steel is cheaper due to foreign dumping; consequently, an AD tariff is imposed only on steel. The effect of the tariff is identified by the mitigation of the decline in the protected sector (steel) relative to the likely continued decline of the non-protected sector (automobile). This identification holds if, prior to the AD investigation, both industries followed parallel downward employment trends.

Applicability to other countries. While this study focuses on Brazil, the identification strategy is applicable to other WTO members. WTO rules require that member states align their domestic AD regulations with the WTO Anti-Dumping Agreement. To impose an AD duty, authorities must conduct an investigation following the standardized procedures described above, and the duty magnitude must be based on the difference between the normal value and the export price prior to the investigation.¹⁴ Consequently, the identification strategy developed in this study can be applied to virtually all WTO members.

3.2 Empirical Model

3.2.1 Imports

Main Empirical Model. We use the following empirical model to identify the effect of imposing an AD tariff $\tau_{p,c,q}$ on imports of product p from country c in quarter q :¹⁵

$$y_{p,c,q} = \theta^{imp} \tau_{p,c,q} + \beta \mathbb{I}_{p,c,q} \{\text{After AD}\} + \eta_{p,c} + \eta_{q,c} + \epsilon_{p,c,q}, \quad (1)$$

where $y_{p,c,q}$ is the log of total imports of product p from country c in quarter q . $\mathbb{I}_{p,c,q} \{\text{After AD}\}$ is a dummy taking a value of 1 after the beginning of the first investigation; it captures the effect of tariff uncertainty. $\tau_{p,c,q}$ is the ad valorem AD tariff imposed; for the control group, it takes a value of 0. If the AD tariff is later removed, $\tau_{p,c,q}$ takes a value of 0. $\eta_{p,c}$ is a product–country fixed effect removing any level differences between treatment and control. It also captures the effect of differences in international prices that ultimately led to the

¹⁴We acknowledge that the exact formula used to compute duty margins may vary across countries. However, this affects only the magnitude of the imposed duty, not the validity of the identification strategy.

¹⁵In our analysis, each product refers to an 8-digit Nomenclatura Comum do Mercosul (NCM) code. The first six digits of the NCM code are the same as those of a Harmonized System (HS) code. The Brazilian government adds two additional digits to improve granularity.

tariff. $\eta_{q,c}$ is a quarter–country fixed effect.¹⁶

Identifying Variation. The parameter of interest, θ^{imp} , captures the effect of AD tariffs on imports. Figure 1 illustrates the main identifying variation. The y-axis plots the growth rate in the outcome of interest, such as imports, and the x-axis the distance to the beginning of the investigation. The main source of variation informing θ^{imp} is the difference between investigated products without an AD tariff (the control group) and investigated ones with an AD tariff (the treatment group) in terms of their growth rate after the investigation. If the assumption of parallel trends is valid, the control and treatment groups should have similar growth rates before the tariff was imposed.¹⁷

Figure 1: Illustration of the Identifying Variation in the Effect of AD Tariffs

Description: This figure provides an illustration of the identifying variation used to estimate the effect of tariffs. The blue line represents the stylized trajectory for products subject to an AD tariff (treated), while the black line represents products subject to an investigation but received no tariff (control). The treatment effect is captured by the difference between the two lines after the beginning of the investigation. Under the parallel trends assumption, the outcomes for both groups should evolve identically prior to the onset of the investigation.

Treating Investigation Beginning as “Time 0.” Our preferred specification treats the investigation beginning—rather than the conclusion—as “time 0.” Because WTO rules re-

¹⁶There are few cases of AD investigations against the same 8-digit product. Consequently, there is not enough power to identify θ^{imp} including product–time fixed effects. However, in the robustness section, we add sector–year and sector–country–year fixed effects, and obtain similar estimates.

¹⁷ θ^{imp} is also informed by the differences in the AD tariff among the treated product–country pairs.

quire the investigating authority to conduct consultations and collect public feedback before reaching a final decision, domestic firms may anticipate likely outcomes and adjust their behavior during the investigation process.¹⁸ Since this anticipatory effect is specific to the treatment group, centering the analysis on the investigation initiation allows us to correctly capture the full tariff effect, whereas treating the tariff imposition date as “time 0” would leave this anticipatory effect to the pre-period, likely violating the parallel trends assumption. Although Section 4.5 shows that our findings are robust to using the conclusion date (as AD investigations in Brazil typically last less than a year), we believe the initiation date offers a cleaner identification strategy with fewer confounding factors in the pre-period.

Pre-Period Parallel Trends Test. To test for parallel trends in the pre-period, we use the following specification:¹⁹

$$y_{p,c,q} = \sum_j \theta_j \tau_{p,c,\text{first}} \mathbb{I}_{p,c,q} \{j \text{ Qrt. to AD}\} + \sum_j \beta_j \mathbb{I}_{p,c,q} \{j \text{ Qrt. to AD}\} + \eta_{p,c} + \eta_{q,c} + \epsilon_{p,c,q}, \quad (2)$$

where $\mathbb{I}_{p,c,q} \{j \text{ Qrt. to AD}\}$ is a dummy that takes a value of 1 if quarter q is j quarters to the beginning of the first AD investigation; $\tau_{p,c,\text{first}}$ is the first AD tariff imposed on product p from country c ; and θ_j captures the dynamic effects of the first AD tariff. Parallel trends in the pre-period imply that $\theta_j \approx 0$ for all $j < 0$.²⁰

3.3 Midstream, Protected Sector Firms

We use difference-in-differences to identify the effect of AD tariffs on protected sector employment. The treatment group is the set of firms whose products faced AD investigations that led to an AD tariff. The control group is the set of firms whose products were not subject to an AD tariff despite being investigated.

However, most of the variation is coming from the comparison between treatment and control. To keep the graph intuitive, we remove the within-treatment variation.

¹⁸See, for example, page 15 of https://www.gov.br/mdic/pt-br/assuntos/comercio-exterior/defesa-comercial-e-interesse-publico/arquivos/legislacao-roiteiros-e-questionarios/decreto_8058_eng.pdf.

¹⁹In these tests, we consider only the first AD investigation, as is standard in the literature, to ensure that there is no confounding investigation in the pre-period.

²⁰We calculate event-studies relative to the beginning of the investigation. We chose this approach because

Main Empirical Model. The main specification is:

$$y_{i,s,t} = \theta^{mid} \tau_{s,t}^{mid} + \beta \mathbb{I}_{s,t} \{\text{After AD}\} + X'_{i,s,t} \kappa + \eta_i + \eta_t + \epsilon_{i,t}, \quad (3)$$

where $y_{i,s,t}$ is a labor outcome of firm i in sector s in year t , and $\tau_{s,t}^{mid}$ is the average of ad valorem AD tariffs imposed on products produced by sector s in year t .²¹ Firms in the control group have zero tariffs, but for the treatment group, the variable $\tau_{s,t}^{mid}$ increases from zero after the decision of the first investigation and keeps changing as AD tariffs are imposed or removed. The variable $\mathbb{I}_{s,t} \{\text{After AD}\}$ is a dummy that takes a value of 1 after the first AD investigation; it captures the effect of being exposed to an AD investigation. Finally, η_i is a firm fixed effect, capturing level differences between firms, including the factors that led to the AD tariff. η_t is a year fixed effect accounting for aggregate shocks, such as the business cycle.²²

Identifying Variation. The parameter of interest, θ^{mid} , captures the effect of AD tariffs on outcome $y_{i,s,t}$ in the protected sector. It is identified from the difference in the growth rate of variable $y_{i,s,t}$ between firms in sectors with an AD investigation that led to an AD tariff (the treatment group) and firms in sectors with an AD investigation without an AD tariff (the control group). Because we are using tariffs on the right-hand side, the parameter of interest is also informed by variations in the size of the tariff within the treatment group. Once again, if the assumption of parallel trends is valid, firms with different exposure to tariffs should be growing at the same rate before the beginning of the investigation. The identifying variation is similar to the one plotted in Figure 1.

the AD investigation itself may affect trade and the labor market. Once an investigation begins, firms familiar with WTO rules could infer the outcome of the investigation from international prices. Consequently, the effects of the investigation could appear before the AD tariff is officially imposed, shortly after the investigation starts.

²¹Sectors are defined according to the 4-digit National Classification of Economic Activities (CNAE) codes.

²²The controls are a set of fixed effects for the number of products investigated in the previous five years.

Pre-Period Parallel Trends Test. To test for pre-period parallel trends, we use the following model:

$$y_{i,s,t} = \sum_j \theta_j \tau_{s,first}^{mid} \times \mathbb{I}_{s,t} \{j \text{ Yrs. to AD}\} + \sum_j \beta_j \mathbb{I}_{s,t} \{j \text{ Yrs. to AD}\} + \eta_i + \eta_t + \epsilon_{i,t}, \quad (4)$$

where $\tau_{s,first}^{mid}$ is the first AD tariff imposed on products of sector s and where $\mathbb{I}_{s,t} \{j \text{ Yrs. to AD}\}$ is a dummy that takes a value of 1 if year t is j years before the beginning of the investigation that results in the first AD tariff. Parallel trends in the pre-period imply that $\theta_j \approx 0$ for all $j < 0$.

3.3.1 Downstream Firms

Empirical Specification. The effect of an AD tariff on downstream firms depends on the factor share on the tariffed product. Firms with a larger input share of the tariffed input should be more affected by an AD tariff than those with a lower factor share. Exploiting that, we define the increase in input costs due to tariff $\tau_{s,t}$ on downstream sector d as follows:

$$\tilde{\tau}_{d,t}^{down} = \sum_s \frac{\text{Sales from Sector } s \text{ to Sector } d}{\text{Cost Expenditure of Sector } d} \times \tau_{s,t}^{mid},$$

where $\frac{\text{Sales from Sector } s \text{ to Sector } d}{\text{Cost Expenditure of Sector } d}$ is sector d 's factor share on inputs from sector s and $\tau_{s,t}$ is the average AD tariff on products of sector s in year t .²³ The downstream specification is:

$$y_{i,d,t} = \theta^{down} \tilde{\tau}_{d,t}^{down} + \beta \mathbb{I}_{d,t} \{\text{After AD}\} + X'_{i,d,t} \kappa + \eta_i + \eta_t + \epsilon_{i,t}, \quad (5)$$

where $y_{i,d,t}$ is a labor outcome of firm i in sector d , $\tilde{\tau}_{d,t}$ is the change in input cost to a firm in sector d caused by AD tariffs in other sectors, $X'_{i,d,t}$ is a set of controls, η_i is a firm fixed effect, and η_t is a year fixed effect.²⁴

Identifying Variation. The parameter of interest is θ^{down} , which captures the effect of increasing the cost of importing inputs. θ^{down} is identified from the difference in growth rates

²³Section A.2 describes how we construct the input-output table at 4-digit sector level for Brazil.

²⁴The controls are a set of fixed effects for the number of inputs with AD investigation in the past five

between sectors with a large increase in their input cost compared to sectors with a lower increase. Because, according to our input-output table, almost all sectors buy inputs from all other sectors, all firms are at least weakly exposed to AD tariffs in their inputs.

To have a comparable and cleaner identification, we also run Equation (5) limiting the sample to firms in the main downstream sector of each investigated midstream sector.²⁵ In this specification, the treatment group consists of the firms in the sector whose main supplier had an AD investigation that led to a tariff increase, while the control group consists of the firms in the sector whose main supplier never received protection with an AD tariff despite being investigated.²⁶

Parallel Trends Test. We test parallel trends on the specification limited to the main downstream firms, which provides a clearer definition of the treatment and control groups:

$$y_{i,d(s),t} = \sum_j \theta_j \tilde{\tau}_{d(s)}^{down} \times \mathbb{I}_{d(s),t} \{j \text{ Yrs. to AD}\} + \sum_j \beta_j \mathbb{I}_{d(s),t} \{j \text{ Yrs. to AD}\} + \eta_i + \eta_t + \epsilon_{i,t}, \quad (6)$$

where $\tilde{\tau}_{d(s)}^{down}$ is the increase in input cost in main downstream sector $d(s)$ caused by the first AD tariff imposed on a product produced by sector s , and where $\mathbb{I}_{d(s),t} \{j \text{ Yrs. to AD}\}$ is a dummy that takes a value of 1 if year t is j years to the beginning of the investigation that results in the first AD tariff.²⁷

years. In the robustness section, we also add as controls a 2-digit sector-year fixed effect, and AD tariffs on the suppliers and on their own products.

²⁵The main downstream sector is the one that buys the largest share of the reference sector's production. Section A.2 formally defines the main downstream (and upstream) sectors. A similar empirical strategy is also employed by Feng et al. (2023), who examine how the impact of climate disasters propagates to main upstream and main downstream countries.

²⁶It is important to note that, as is usual in difference-in-differences approaches, we are recovering the relative effect of the tariff. All firms are affected through the input-output connections and other general equilibrium effects. Still, firms that are the main consumers of a product with a tariff hike, should be relatively more affected than others. In the sections below, we use a model to match these estimated relative effects by running the same regressions in the model. In this way, we recover the aggregate effect of tariffs common to all firms. In Section A.5.3, we consider a regression that includes all midstream, weighted average upstream, and weighted average downstream tariffs.

²⁷Formally, $\tilde{\tau}_{d(s)}^{down} = \frac{\text{Sales from Sector } s \text{ to Main Downstream Sector } d(s)}{\text{Cost Expenditure of Sector } d(s)} \times \tau_{s,t}^{mid}$.

3.3.2 Upstream Firms

We calculate the exposure of upstream firms to tariffs on their consumers as:

$$\tilde{\tau}_{u,t}^{up} = \sum_s \frac{\text{Sales from Sector } u \text{ to Sector } s}{\text{Production of Sector } u} \times \tau_{s,t}^{mid},$$

where $\tau_{s,t}$ is the average AD tariff on sector s in year t . The main model is:

$$y_{i,u,t} = \theta^{up} \tilde{\tau}_{u,t}^{up} + \beta \mathbb{I}_{u,t} \{\text{After AD}\} + X'_{i,u,t} \kappa + \eta_i + \eta_t + \epsilon_{i,t}, \quad (7)$$

where $y_{i,u,t}$ is a labor outcome of firm i in sector u and year t . $\tilde{\tau}_{u,t}^{up}$ is the average AD tariff on customers of sector u . The other variables are as described earlier. The identifying variation and the parallel trends test are similar to the specification with downstream firms.

3.4 Validation

The identifying assumption is that, conditional on being investigated, sectors with an AD tariff and sectors with no AD tariff follow parallel trends because the decision to impose a tariff is based on pre-determined level characteristics of each sector, and not their trends. In this section, we show that parallel trends are supported by institutional facts and exogeneity tests. Moreover, AD tariffs are not correlate with other policies implemented in the period, political connections, sectoral shocks, or the business cycle.

AD Tariffs Can Be Predicted with International Prices. In Section A.4.1, in line with the WTO regulations, we show that prices outside of Brazil can predict AD tariffs with an R-squared above 0.95.²⁸ These results suggest that it is very unlikely that labor trends are affecting the Brazilian government's AD policy, which supports our assumption of parallel trends.

Placebo Tests. To further guarantee that the treatment and control groups do not differ in underlying shocks or trends, we implement two placebo tests, as shown in Section A.4.2.

²⁸As discussed in Section A.4.1, AD tariffs should be a function of the import's price in Brazil and in the home country during the pre-period. However, because the price in the home country is not observed,

First, we demonstrate that tariffs are not correlated with employment changes in sectors that are not subject to AD tariffs but have similar employment trends. This placebo test indicates that the results are not driven by sectoral shocks to sectors following a certain employment trend. In our second placebo test, we show that there is no correlation between AD tariffs and employment changes five years before the AD tariff’s implementation, supporting the notion that the identifying effect is not coming from labor market trends.

Other Policies and Political Connection. In Section A.4.3, we show that, conditional on AD investigations, AD tariffs are not correlated with political connections, government subsidies, tax breaks, or other tariffs. Although the correlation between AD tariffs and public procurement is statistically significant at the 10% level, it is not economically meaningful: A 100 percentage point increase in AD tariffs increases the probability of a government contract by just 0.09 percentage points. This correlation is likely spurious, as adding controls or changing the functional form leads to statistically non-significant coefficients.

Business Cycle. If the government is more likely to impose an AD tariff during downturns, the estimates of interest could be contaminated. In Section A.4.4, we show that the AD policy is not correlated with the business cycle.

International Competition and Parallel Trends. AD tariffs are determined by international price levels, and imports subject to these tariffs typically had lower prices. Why, then, are firms facing greater import competition exhibiting parallel trends with those experiencing less competition? As shown in Figure A.5, despite facing lower international prices, firms in the treatment group follow the same trend in international prices as those in the control group. This indicates that, while the levels of international competition differ, the trends in international competition remain consistent between the two groups. Because these firms share the same trend in international prices, we can isolate the effect of tariffs using fixed effects.

we proxy this price using the AD tariff of other countries and the distribution of prices of the investigated product. The details of our test can be found in Section A.4.1.

4 Results

4.1 Effect of AD Tariffs on Imports

AD Tariffs Affect Quantity Imported but Not Prices. Figure 2 shows the dynamic effects of the AD tariff on log imports. Note that, in the quarters before the announcement of the tariff increase, the control and treatment groups follow similar trends, which validates our identifying assumption. This changes abruptly when the investigation begins; 10 quarters later, a 100% marginal tariff leads to an approximately 50% decrease in imports.

Tariffs cause a drop in the quantity imported but do not affect prices, according to Table 1, which is consistent with the idea that Brazil is a small open economy. Using variation from all AD tariffs, column 1 of Table 1 shows that a 100% increase in tariffs leads to a 25% drop in imports. Moving AD tariffs from the 25th percentile to the 75th percentile would reduce imports by 11%. According to columns 2 and 3, which show the effects of tariffs on the quantity imported and the price of imported goods, the drop can be explained by the decrease in the quantity imported. The lack of a price effect, displayed in column 3 of Table 1, indicates that Brazilian demand for international goods is too small to have a significant effect on international prices.^{29,30}

No Trade Diversion. There is no significant evidence of trade diversion: firms neither shift imports of tariffed goods to another country nor increase imports of similar untariffed products. We run a regression of imports of the tariffed products from countries not facing Brazilian AD investigations on product-level AD tariffs. Table 2 shows that AD tariffs do not affect imports of tariffed products from other countries.³¹

We also investigate whether firms shift from importing the tariffed products to importing other products similar to the tariffed ones. We run a regression of imports of the products

²⁹This indicates that we find a complete pass-through of AD tariffs in Brazil. This finding is consistent with Blonigen and Haynes (2002), Sandkamp (2020), and the recent works studying 2018–19 U.S. tariffs (Amiti et al. 2019, Amiti et al. 2020, Fajgelbaum et al. 2020, and Cavallo et al. 2021).

³⁰Figure A.5 shows the dynamic effects of AD tariffs on import prices. Consistent with our identification strategy, the figure demonstrates that the treatment and control groups follow parallel trends in the pre-period, despite the treatment group facing lower average international prices.

³¹In other words, we run Equation (1) with $y_{p,c,q}$ standing for imports of product p in quarter q by all countries except c .

Figure 2: **Effect of AD Tariffs on Imports**

Description: This figure contains the coefficients of the effect of AD tariffs on imports using the dynamic model 2 plotted against quarters relative to the beginning of the investigation on the x-axis. Imports are measured in freight on board (FOB) current dollars at the NCM product code level. Import data are from the Secretary of International Trade of the Ministry of Economy, and AD data are from the Global Antidumping Database. The sample is composed of product–origin combinations that had at least one AD investigation. The shaded area indicates the 95% confidence interval. Standard errors are clustered at the product–origin level.

that do not face AD investigations but fall within the same 4-digit HS code impacted by the product-level AD tariff.³² Table 2 shows that imports of similar products from the tariffed country are not significantly affected by AD tariffs.

The non-significant trade diversion resulted from two offsetting effects: (1) downstream firms shift away from tariffed imports toward untargeted countries and products, whereas (2) the decline in downstream firm performance (documented in the next section) reduces overall import demand. Table A.10 confirms such substitution, showing that imports of targeted products from untargeted countries and imports of similar but untargeted products from the targeted country both rise significantly *relative to targeted imports*. Tables A.11 and A.12 further show significant trade diversion among products that are easier to reallocate: those less reliant on contracts (Nunn 2007), with easier access to trade finance (Manova et al. 2015), and with low inventory requirements (Manova et al. 2015).

³²In other words, we run Equation (1) with $y_{p,c,q}$ standing for imports from country c , in quarter q , of all products within the same 4-digit HS code of product p except product p .

Description: This table presents the estimated parameters of model 1. The sample is composed of product–origin combinations that had at least one AD investigation. $\log(\text{Value Imports})$ is the log of FOB current dollar imports at the NCM level. $\log(\text{Quantity Imports})$ is the log of quantity imported, and $\log(\text{Price})$ is the log of price per unit. Import data are from the Secretary of International Trade of the Ministry of Economy, and AD data are from the Global Antidumping Database. The sample runs from 1995 to 2016. Standard errors are clustered at the product–origin level.

4.2 Midstream Firms

Protected Sector Expands. This section shows that an AD tariff increases the wage bill, employment, exports, and imports of protected sector firms. The effect of AD tariffs on the wage bill is presented in Figure 3. Before the introduction of the tariff, the treatment and control groups follow similar trends, once again validating our identification strategy. The introduction of the tariff leads to a relative increase in the wage bill of firms protected by the AD tariff. Five years after its introduction, a 100% AD tariff increases the wage bill of protected sector firms by about 3%.

According to the results in Table 3, AD tariffs increase the employment, wage bill, exports, and imports of protected sector firms. Columns 1 and 2 of Table 3 show the effect of tariffs on employment and on the wage bill. A 100% AD tariff increases employment by 1.8% and the wage bill by 1.9%. In terms of interquantile shift, moving AD tariffs from the 25th percentile to the 75th percentile increases employment and the wage bill by 3.5% and 3.6%, respectively. Columns 3 and 4 show how the probability of becoming an exporter or importer is affected by tariffs.³³ Column 3 shows that a 100% AD tariff would increase the probability of a protected sector firm becoming an exporter by 0.4%, while column 4 shows

³³These findings do not contradict our previous result that AD duties reduce protected product imports,

Description: This table shows the effect of AD tariffs on imports from other countries and other products. In columns 1 and 2, we show the coefficient of a regression of average AD tariffs at the product level on imports of countries not exposed to AD investigations. In columns 3 and 4, we show the coefficient of a regression of AD tariffs on the imports of other products with the same 4-digit HS code from the same country. Import data are from the Secretary of International Trade of the Ministry of Economy, and AD data are from the Global Antidumping Database. Standard errors are clustered at the product–origin level.

Figure 3: Midstream Wage Bill

Description: This figure contains the coefficients of the effect of AD tariffs on the log wage bill using the dynamic model 4. The x-axis contains the number of years relative the first AD investigation. Wage bill data are from RAIS, and AD data are from the Global Antidumping Database. The sample is composed of firms in sectors producing the product under AD investigation. We constrain the sample to the set of firms observed for five years before and after the AD investigation. These sample restrictions are made to avoid compositional changes. The shaded area indicates the 95% confidence interval. Standard errors are clustered at the firm level.

since those protected products are imported by *downstream* firms, whose performance declines—as we document next. By contrast, midstream firms expand and increase both imports and exports; the products they import are what we refer to in this paper as *upstream* products.

that the same tariff would increase the probability of the same protected firm becoming an importer by 0.3%. Columns 5 and 6 show the effects of AD tariffs on the intensive margin of exporting and importing.

We find a larger effect of tariffs on midstream firms than Bown et al. (2021), who find an elasticity close to zero. Our estimate is comparable to that of Flaaen and Pierce (2024), after adjusting for different regressors.³⁴

Description: This table presents the estimated parameters of model 3. The sample is composed of firms in sectors that produce the product under an AD investigation. We limit the sample to the set of firms observed for five years before and after the AD investigation. $\log(\# \text{ Workers})$ is the log of the total number of workers in the firm. $\log(\text{Wage Bill})$ is the log of the firm’s total labor expenditure. $\mathbb{I}(\text{Exporter})$ is a dummy that takes a value of 1 if the protected firm exports any product that year. $\mathbb{I}(\text{Importer})$ is a dummy that takes a value of 1 if the protected firm imports any product that year. $\log(\text{Exports})$ is the log of expected exports of the firm. $\log(\text{Imports})$ is the log of expected imports of the firm. Expected exports and imports are calculated following de Souza (2021), who describes how expected exports and imports are calculated at the firm level. $\tau_{s,t}^{mid}$ is the average AD tariff imposed on products produced by the sector of each firm. Standard errors are clustered at the firm level.

4.3 Downstream Firms

Downstream Firms Shrink. The effects of the tariffs propagate downstream, decreasing employment and the wage bill. Figure 4 traces the dynamic effects of AD tariffs on

³⁴Using the model presented in this paper, along with many other canonical trade models, the partial elasticity of employment with respect to tariffs can be expressed as follows: $\Delta \log(L^s) = \beta \frac{IM^s}{X^s - IM^s + EX^s} s_{IM}^s \Delta \log(t^s) |_{\{P^s\}, \{X^s\}}$, in which β is a structural parameter that summarizes the economy’s fundamentals. $\frac{IM^s}{X^s - IM^s + EX^s}$ denotes the ratio of sector s import to the sector’s output. s_{IM}^s denotes the share of import exposed to the tariff. Flaaen and Pierce (2024) estimate $\frac{\partial \log(L^s)}{\partial \frac{IM^s}{X^s - IM^s + EX^s}} = \beta \Delta \log(t^s) = 0.08$, which implies $\beta = 0.4$ if the average tariffs during the 2018 U.S.-China trade war were 20% (Bown 2021).

downstream firms. Once again, treatment and control firms show similar trends prior to the introduction of the AD tariff, diverging only after the beginning of the investigation, which supports our identification strategy. When tariffs are imposed on the inputs of these firms, employment decreases. A 100% AD tariff on all the inputs of a firm would lead to a 10% drop in the wage bill five years after the beginning of the investigation.

Figure 4: **Downstream Wage Bill**

Description: This figure contains the coefficients of the effect of AD tariffs on the log wage bill of firms downstream to the AD tariff using the dynamic model 6. The x-axis contains the number of years relative to the first AD investigation. Wage bill data are from RAIS, and AD data is from the Global Antidumping Database. The sample is composed of firms whose main input is under AD investigation. We constrain the sample to the set of firms observed for five years before and after the AD investigation. These sample restrictions are imposed to avoid compositional changes. The shaded area indicates the 95% confidence interval. Standard errors are clustered at the firm level.

Columns 1 and 2 of Table 4 show the average effect of AD tariffs on the main downstream firms.³⁵ A 100% AD tariff on all the inputs of these firms would lead to a 3.8% drop in employment and an 8.5% drop in the wage bill. For instance, moving input-weighted AD tariffs from the 25th percentile to the 75th percentile would decrease employment by 0.3% and the wage bill by 0.8%.

The downstream effects of AD tariffs are not limited to the main buyer of an input,

In contrast, we estimate $\frac{\partial \log(L^s)}{\partial \log(t^s)} = \beta \frac{IM^s}{X^s - IM^s + EX^s} s_{IM}^s = 0.0184$. Given an import-to-output ratio of 14.3% and a share of imports subject to AD of 18.44% in Brazil, we derive the structural parameter ($\beta = 0.7$). The partial elasticity requires us to hold aggregate prices and expenditures constant. Deriving this elasticity in general equilibrium requires a production network approach, which we will leave to future research.

³⁵As Figure 4 demonstrates, these firms follow the same trend prior to the introduction of the tariff.

according to the results in Table 4. Columns 3 and 4 show the effect of tariffs on firms in an average downstream sector. AD tariffs have no significant effect on employment at these firms, although they do have a negative impact on the wage bill.

We identify a smaller effect of tariffs on downstream firms than many other papers in the literature. The elasticity of employment downstream from tariffs estimated by the literature ranges from -0.08 to -0.3 .³⁶ There could be several reasons for this difference. Among them is our new identification strategy, which enables us to mitigate confounding effects, such as the policy uncertainty associated with investigations. Furthermore, our strategy addresses the differential trends between sectors—specifically investigated industries typically exhibiting steeper declines due to foreign import competition than non-investigated sectors.³⁷

Table 4: **Effect of AD Tariffs on Downstream Firms**

Mean Ind. Var	.07	.07	.05	.05

Description: This table presents the estimated parameters of model 5. The sample is composed of firms in sectors downstream to the product under AD investigation. We limit the sample to the set of firms observed for five years before and after the AD investigation. Columns 1 and 2 limit the sample to the main downstream firms. Columns 3 and 4 contain all downstream firms. $\log(\# \text{ Workers})$ is the log of the total number of workers in the firm. $\log(\text{Wage Bill})$ is the log of total labor expenditure of the firm. $\tilde{\tau}_{d,t}^{\text{down}}$ is the average AD tariff imposed on the inputs used by downstream firms. Standard errors are clustered at the firm level.

³⁶Bown et al. (2021) find a downstream employment elasticity of approximately -0.3 for all sectors and roughly -0.15 for manufacturing sectors with respect to average input tariffs. The findings in Cox (2021) imply a downstream employment elasticity of -0.08 due to average steel tariffs.

³⁷Our estimates are comparable to those of Flaaen and Pierce (2024) after a model-based calculation. In many trade models, the partial elasticity of downstream employment to midstream tariffs is shown by the following: $\Delta \log(L^s) = -\beta \Gamma^{ss'} \frac{IM^{s'}}{X^{s'}} s_{IM}^{s'} \Delta \log(t^{s'})|_{\{P^s\}, \{X^s\}}$. $\Gamma^{ss'}$ denotes the share of midstream sector s' in downstream sector s total cost. $\frac{IM^{s'}}{X^{s'}}$ denotes the share of imports in sector s' total expenditure and

4.4 Upstream Firms

Upstream Firms Are Not Significantly Affected. Despite increasing employment in the protected sector and decreasing it in the downstream sector, this section shows that AD tariffs do not affect firms upstream, i.e., firms that sell inputs to the midstream firms. A potential explanation is that, as shown in Table 3, midstream firms purchase their inputs internationally instead of buying locally.

Figure 5: Upstream Wage Bill

Description: This figure contains the coefficients of the effect of AD tariffs on the log wage bill of firms upstream to the AD tariff using the dynamic model. The x-axis contains the number of years relative to the first AD investigation. Wage bill data are from RAIS, and AD data are from the Global Antidumping Database. The sample is composed of firms whose main input is under AD investigation. We constrain the sample to the set of firms observed for five years before and after the AD investigation. These sample restrictions are made to avoid compositional changes. The shaded area contains the 95% confidence interval. Standard errors are clustered at the firm level.

Figure 5, which traces the dynamic effects of AD tariffs on the wage bill of the main input provider of the national supplier, indicates that there is no difference between the treatment and control groups before and after the AD tariff is implemented. Table 5 shows that even using variation from all the AD investigations, there is no significant effect of AD tariffs on

$s_{IM}^{s'}$ denotes the share of imports exposed to tariffs. β is a structural parameter summarizing the economic fundamentals. Flaaen and Pierce (2024) estimate $\frac{\partial \log(L^s)}{\partial [\Gamma^{ss'} \frac{IM^{s'}}{X^{s'}} s_{IM}^{s'}]} |_{\{P^s\}, \{X^s\}} = -\beta \Delta \log(t^{s'}) = -0.463$, which implies $\beta = 2.3$, if the average tariffs during the 2018 U.S.-China trade war were 20%. In contrast, we estimate $\frac{\partial \log(L^s)}{\partial [\Gamma^{ss'} \log(t^{s'})]} = -\beta \frac{IM^{s'}}{X^{s'}} s_{IM}^{s'} = -0.038$. Given an import-to-expenditure ratio of 12.5% and a share

employment or the wage bill. Columns 1 and 2 of Table 5 show the effect of AD tariffs on the numbers of workers and the wage bill in the main suppliers of sectors protected by the AD tariff. Columns 3 and 4 show the effect of AD tariffs on an average upstream sector. We find a small positive effect on upstream employment, but no significant effects in other specifications.

Table 5: **Effect of AD Tariffs on Upstream Firms**

	(1)	(2)	(3)	(4)

Mean Ind. Var	.29	.29	.05	.05

Description: This table presents the estimated parameters of model 7. The sample is composed of firms in sectors upstream to the product under AD investigation. We limit the sample to the set of firms observed for five years before and after the AD investigation. Columns 1 and 2 limit the sample to the main upstream firms. Columns 3 and 4 contain all upstream firms. *log(# Workers)* is the log of the total number of workers in the firm. *log(Wage Bill)* is the log of total labor expenditure of the firm. $\hat{\tau}_{u,t}^{up}$ is the average AD tariff imposed on the sectors that upstream firms sell to. Standard errors are clustered at the firm level.

4.5 Robustness

We find that AD tariffs increase employment at firms in the protected sector. The effects of these tariffs propagate to downstream firms, thereby lowering their employment, but do not significantly affect upstream firms. In this section, we show that these results are robust to the addition of controls, to different specifications, and to the use of alternative identification strategies exploiting the WTO regulations.

Controls. Tables A.13 through A.16 in Section A.5.2 show that the effects of AD tariffs on trade and on the wage bill are stable across specifications. Our main conclusion that AD

tariffs increase the wage bill midstream, decrease it downstream, and have no effect upstream remains unchanged when adding a 1-digit sector-year fixed effect, a 2-digit sector-year fixed effect, dummies for the number of products investigated, dummies for the number of products with AD tariffs as control, and controlling for AD tariffs upstream and downstream. While adding 2-digit sector-year fixed effects renders some coefficients non-significant, the point estimates remain consistent with our main narrative.³⁸

Treating Investigation Conclusion Date as Time 0. Our findings remain robust if we treat the investigation conclusion date as time 0. Brazilian law requires AD investigations to conclude within 10 months, so most investigations start and end either within the same calendar year or one year apart.³⁹ Consequently, our analysis of the employment effects of AD tariffs—focused on annual employment responses—remains largely unaffected by this timing adjustment.

Event study Figure A.6 shows the effect of tariffs on log imports; Figure A.7, on the log wage bill in the protected sector; Figure A.8, on the log wage bill in downstream sectors; and Figure A.9, on the log wage bill in upstream sectors. Tables A.17–A.20 report the corresponding difference-in-differences estimates of the average treatment effects.

Comparing Importers and Non-importers in Downstream Sectors. To further strengthen our finding that downstream firms are adversely affected by tariff protection, we compare downstream firms that imported in the previous year with those that did not. Importing firms should experience larger negative effects, as they rely more on tariffed intermediate inputs. However, downstream firms that relied only on domestic inputs may also be indirectly affected negatively: higher tariffs on foreign inputs enable domestic midstream, protected firms to raise their prices, increasing input costs even for non-importing downstream firms.

of imports subject to AD of 18.44%, we derive the structural parameter ($\beta = 1.67$).

³⁸It is worth noting that including a 2-digit sector-year fixed effect limits the identification of the parameter of interest to variation within 2-digit sectors. However, only 25% of 2-digit sectors contain both a treatment and a control sector, resulting in high variance and low variation in specifications that include a 2-digit sector-year fixed effect.

³⁹See, for example, page 25 of https://www.gov.br/mdic/pt-br/assuntos/comercio-exterior/defesa-comercial-e-interesse-publico/arquivos/legislacao-roteiros-e-questionarios/decreto_8058_eng.pdf.

Specifically, we extend Equation (5) by including an interaction between the downstream (sector d) AD tariff exposure and an indicator for whether downstream firm i imported in the previous year:⁴⁰

$$y_{i,d,t} = \theta^{down,0} \tilde{\tau}_{d,t}^{down} + \theta^{down,1} \mathbb{I}_{i,t} \{i \text{ Imported in Previous Year}\} \times \tilde{\tau}_{d,t}^{down} + \beta \mathbb{I}_{d,t} \{\text{After AD}\} + X'_{i,d,t} \kappa + \eta_i + \eta_t + \epsilon_{i,d,t}, \quad (8)$$

Table A.21 shows that downstream firms that imported lost significantly more wage bill than those that did not. Non-importing firms also reduced their wage bill. Similar to Table 4, the effects on employment are less significant, but largely point in the same direction. This suggests that trade protection reduces downstream firm performance through two channels: more expensive imported inputs and (weakly) the general equilibrium effect of more expensive domestic inputs.

All Sectors. Following Acemoglu et al. (2014) and Bown et al. (2021), in Section A.5.3, we run a specification with the exposure of each firm to midstream, downstream, and upstream tariffs. Under this specification, the results are still the same, i.e., AD tariffs increase employment midstream, their effects propagate downstream, and they do not affect upstream firms.

Sectoral Regressions. In Section A.5.4, we study the effect of AD tariffs on sectoral aggregates. We show that the results remain the same: AD tariffs boost employment midstream, decrease employment at downstream firms, and they do not significantly affect upstream firms.

Instrumental Variable. In Section A.4.1, we show that AD tariffs can be predicted with high accuracy using international prices and the AD policy of other countries. Exploiting this result, we use the AD policy of other countries as an instrument for AD tariffs in Brazil. In Section A.5.5, we show that tariffs increase employment midstream, decrease it downstream,

⁴⁰Ideally, we would interact downstream AD tariff exposure with whether a firm imported the specific product facing an AD investigation, or the value of those imports. However, we lack firm-product level import data for all years. Consequently, we have to rely on a firm's overall import status to create the necessary variation among firms in downstream sectors.

and have no significant effect upstream.

Regional Variation. In Section A.5.6, we also identify the effect of AD tariffs on local labor markets. Leveraging heterogeneous exposure to the tariffs’ effects owing to the heterogeneous sectoral composition of regional labor markets, we find that tariffs increase employment midstream, decrease employment downstream (in particular, by educational attainment group), and have no impact upstream.

Other Shocks. In Section A.5.7, we show that heterogeneous exposure to aggregate shocks cannot explain our results. We add as controls to our main specification terms capturing heterogeneous exposure to exchange rate fluctuation and the Brazilian trade liberalization. We still find that tariffs midstream increase employment, decrease employment downstream, and have no effect upstream.

5 Model

To study the aggregate employment consequence, we build a quantitative model of the Brazilian economy. The model translates the relative employment effects that we identify into aggregate effects, taking into account the general equilibrium forces.

5.1 Environment

The model is static. There are $i \in \{0, 1, \dots, N\}$ countries; $i = 0$ denotes Brazil. Brazil has S production sectors and a population with measure L . Households optimally choose to work in one of the S sectors and supply labor to the sector in which they work, or stay out of the labor force ($s = 0$). If they work, they earn a sector-specific wage, decide how much labor to supply, and receive a dis-utility from working.

If households do not work, they receive social insurance from the government. To finance the social insurance, the government generates revenue from three sources: It imposes an income tax on all households, borrows from the rest of the world, and collects tariff revenues.

The firm’s problem builds on Caliendo and Parro (2015): it produces tradable output

with labor and non-tradable input from all sectors according to a constant-return-to-scale technology. The output market is competitive.⁴¹ Each production sector has a representative firm. To make the non-tradable input, the firm sources tradable output from all sectors and countries. Brazilian tradable output is used domestically and exported.

We assume that Brazil is a small open economy in the sense that Brazilian AD tariffs do not affect the ex-tariff foreign prices faced by Brazilian importers, an assumption supported by the empirical results (see Table 1).

5.2 Workers

Brazil is endowed with a population of fixed measure L . A representative household ω chooses which sector to work in and the amount of labor to supply in this sector, receives income, and chooses their consumption bundle. The total population consists of the labor force in all sectors and those who do not work. Households differ in their dis-utility to work in each sector.

Consumption. Household ω in sector s chooses final goods consumption of sector r , $c_r^s(\omega)$. The preference of households across different sectoral goods is given by:

$$C^s(\omega) = \left(\sum_{r=1}^S (d_r)^{\frac{1}{\theta}} (c_r^s(\omega))^{\frac{\theta-1}{\theta}} \right)^{\frac{\theta}{\theta-1}}, \quad (9)$$

where d_r is a taste parameter and θ is the elasticity of substitution across sectors.

Income. Households working $l^s(\omega)$ in sector s receive wage w^s . If the household chooses to stay out of the labor force, ω receives income transfer b from the government. In any case,

⁴¹As long as mark-ups are not affected by tariffs, a model with monopolistic competition would deliver identical results.

households pay a fraction δ of their income in taxes.⁴² The budget constraint is:

$$\sum_{r=1}^s P^r c_r^s(\omega) = \begin{cases} (1 - \delta)w^s l^s(\omega) & , s > 0 \\ (1 - \delta)b & , s = 0 \end{cases}. \quad (10)$$

Labor Supply. Conditional on working in sector s , households decide how much labor to supply. The utility of worker ω , supplying $l^s(\omega)$ to sector s and consuming $C^s(\omega)$, is given by:

$$U^s(\omega) = \begin{cases} C^s(\omega) - \frac{\psi^s}{\psi^s + 1} l^s(\omega)^{\frac{\psi^s + 1}{\psi^s}} & , s > 0 \\ C^s(\omega) & , s = 0 \end{cases}, \quad (11)$$

where ψ^s , the Frisch labor supply elasticity within sector s , governs the elasticity of substitution between labor and leisure. In some sectors, ψ^s is low and it is costly for workers to adjust their labor supply. There is no dis-utility from working for those who do not work.⁴³

Households choose between the different sectors. They receive an idiosyncratic preference shock $z^s(\omega)$ for working in sector s . $z^s(\omega)$ follows a Fréchet distribution with shape parameter μ .⁴⁴ Households also have an exogenous taste for working in sector s given by a^s .

Households' Problem. Households maximize utility subject to the consumption bundle (9), the budget constraint (10), and the endogenous utility (11):

$$\begin{aligned} \max_{s, \{c_r^s(\omega)\}_{r=1}^s, \{l_s(\omega)\}_{s=1}^S} & U^s(\omega) a^s z^s(\omega) \\ \text{s.t.} & (9), (10), \text{ and } (11) \end{aligned} \quad (12)$$

⁴²This assumption ensures that fiscal policies do not distort the impact of trade shocks on a household's sector choice.

⁴³We assume that a household's labor supply problem is governed by the Greenwood et al. (1988) (GHH) preference for tractability. The GHH preference focuses on the substitution between leisure and consumption as it mutes the income effect. Cravino and Levchenko (2017) and Bonadio et al. (2021) also assume that a representative household supplies labor to each sector following the GHH preference. However, they abstract from the household's sector choice problem and their self-selection into the non-working sector.

⁴⁴ $z^s(\omega)$ has c.d.f.: $F(z^s(\omega)) = \exp(-(z^s(\omega))^{-\mu})$.

Heterogeneous Labor Supply Elasticity. The implied sectoral labor supply elasticity is heterogeneous across sectors. Note that the labor supplied to sector s is given as:⁴⁵

$$L^s = \begin{cases} \frac{\tilde{a}^s \left(\frac{w^s}{P}\right)^{\lambda^s}}{\sum_{s=1}^S \tilde{a}^s \left(\frac{w^s}{P}\right)^{\lambda^s} + \tilde{a}^0 \left(\frac{b}{P}\right)^\mu} L & , s > 0 \\ \frac{\tilde{a}^0 \left(\frac{b}{P}\right)^\mu}{\sum_{s=1}^S \tilde{a}^s \left(\frac{w^s}{P}\right)^{\lambda^s} + \tilde{a}^0 \left(\frac{b}{P}\right)^\mu} L & , s = 0 \end{cases}, \quad (13)$$

where $\lambda^s = \mu(1 + \psi^s) + \psi^s$ denotes the Frisch elasticity. An increase in a sector's wage causes an increase in its labor supply through two channels. First, more households choose this sector (governed by μ). Second, each household in this sector supplies more labor (governed by ψ^s). The second channel creates heterogeneous sectoral labor supply elasticities.⁴⁶

5.3 Government

The social insurance system is financed by three sources of government revenue. The first is the income tax, δ . The second is borrowing from the rest of the world through a trade deficit (TD).⁴⁷ The third is the tariff revenue (TR).⁴⁸ With the fiscal revenues, the government pays each non-working household a fixed social insurance income b :

$$bL^0 = \delta \left(\sum_{s=1}^S w^s L^s + bL^0 \right) + TD + TR. \quad (14)$$

⁴⁵See Section B.1 for the proof.

⁴⁶If $\psi^s = 0, \forall s$, the labor supply problem will be reduced to a discrete choice problem where households only choose sectors, and the labor supply elasticity will be the same (and equal to the Fréchet shape parameter μ) for all sectors.

⁴⁷This is a common property of static models of international trade: The value of foreign borrowing is equal to the trade deficit.

⁴⁸The tariff revenue is a function of import values and the tariffs imposed on these imports, which we specify below.

5.4 Firms

Intermediate Goods. Each sector s contains a representative competitive firm. Firms use labor and a composite bundle from each sector to produce:

$$Y^s = A^s \left((e^s)^{\frac{1}{\rho}} (L^s)^{\frac{\rho-1}{\rho}} + \sum_{s'=1}^S (f^{ss'})^{\frac{1}{\rho}} (M^{ss'})^{\frac{\rho-1}{\rho}} \right)^{\frac{\rho}{\rho-1}},$$

where A^s is the total factor productivity (TFP), L^s is the labor demand by sector s , and $M^{ss'}$ is the quantity of sector s' output used by sector s . ρ denotes the elasticity of substitution across inputs. e^s and $f^{ss'}$ are labor- and input-augmenting technology parameters.⁴⁹

A firm's profit maximization problem implies that Brazilian firms set prices, P_0^s , that are equal to the marginal cost.⁵⁰

Composite Intermediate Goods. Firms acquire inputs from different countries. Inputs are aggregated at the sector level using a CES production function:

$$Q^s = \left(\sum_{i=0}^N (g_i^s)^{\frac{1}{\sigma^s}} (Y_i^s)^{\frac{\sigma^s-1}{\sigma^s}} \right)^{\frac{\sigma^s}{\sigma^s-1}},$$

where Q^s denotes the quantity of the non-tradable input bundle, g_i^s is a preference shifter for inputs from sector s and country i , and σ^s is the trade elasticity (the elasticity of substitution across countries).⁵¹ Y_i^s denotes the quantity of sector s tradable goods imported from foreign country i . Y_0^s is the quantity of Brazilian tradable output used in Brazil.⁵²

Brazilian exporters face the same trade elasticity σ^s . Foreign demand for Brazilian sector s output can be written as:

$$Y_{F0}^s = (P_0^s)^{-\sigma^s} E_F^s,$$

⁴⁹These parameters enable us to match the factor shares observed in the data.

⁵⁰These prices are a CES-aggregate of sectoral wages and composite goods prices (see Equation (B.3)). Denote sector s producer's expenditure share on input from sector s' with $s_M^{ss'}$, whose formula is reported in Equation (B.4) in Section B.2.

⁵¹Like many works in the trade literature, including Broda and Weinstein (2006) and Caliendo and Parro (2015), we let the trade elasticity differ across sectors.

⁵²Therefore, the rest of Brazilian sector s output, $Y^s - Y_0^s$, is exported. Equation (B.5) presents Brazilian

where E_F^s is a function of foreign income and price. Because Brazil is a small open economy, E_F^s can be treated as being exogenous to Brazilian AD tariffs.

Products. Sector–origin–level import, Y_i^s , is produced by combining different products:⁵³

$$Y_i^s = \left(\sum_{l \in \Omega_i^s} (h_{il}^s)^{\frac{1}{\zeta^s}} (y_{il}^s)^{\frac{\zeta^s-1}{\zeta^s}} \right)^{\frac{\zeta^s}{\zeta^s-1}},$$

where Ω_i^s denotes the set of products that Brazil imports from country i in sector s , y_{il}^s denotes the quantity of imports in product l of sector s from country i , h_{il}^s is a preference parameter for products, and ζ^s is the elasticity of substitution across products. We allow the product-level elasticity of substitution to be heterogeneous across sectors and to differ from country-level substitution.

We present the market clearing conditions and equilibrium definition in Section B.2. To compute counterfactuals, we rewrite the model in changes, which we present in Section B.3.⁵⁴ We also present in Section B.3 the equilibrium definition for the model in changes.

Comparing the Model to Literature. Our model and estimation strategy differ from those of Caliendo and Parro (2015) and Caliendo et al. (2019) in three important ways. First, we account for the substitutability across final products and complementarity across inputs. Second, we introduce flexible labor supply decisions, which help us to understand aggregate employment consequences. Third, we estimate trade and labor supply elasticities credibly with the difference-in-differences method. We discuss these details in Section B.5.

6 Identification of Model Parameters

In this section, we summarize how we identify the model parameters. In Section C, we describe each of these steps in detail.

sector s expenditure on country i .

⁵³Fajgelbaum et al. (2020) uses a similar technology that aggregates products to sectors.

⁵⁴By doing so, we eliminate the economic fundamentals that are exogenous to tariff changes and are difficult to calibrate or estimate.

Calibration. We calibrate a set of parameters based on Brazilian economic statistics in 1995. They include input-output coefficients, sectoral exports, sector population shares, consumption expenditure shares, and the social insurance tax rate. Each model sector refers to a Classificação Nacional de Atividades Econômicas (CNAE) 2.0 4-digit sector.

Elasticity of Substitution across Product Lines. To estimate the elasticity of substitution across product lines, ζ^s , we study the effect of AD tariffs on the import of products from a particular destination. ζ^s captures how easily the importer can switch product lines within sector–origin-level imports, and it governs the impact of AD tariffs on sector–origin-level prices. In the section of calibration, we show that the elasticity of substitution across product lines, ζ^s , can be identified with a closed-form solution from the effect of AD tariffs on imports.

Elasticity of Substitution across Countries. The Armington trade elasticity, σ^s , which captures how easily sector-level imports can be substituted across different countries, is identified with a closed-form solution from the effect of AD tariffs on imports at the country level.

Labor Supply Elasticity. The labor supply elasticity, λ^s , governs the effects of tariffs on employment. In Section C, we show that λ^s can be identified with closed-form solution from the effects of AD tariffs on wages and employment.

Indirect Inference. We estimate ρ , the elasticity of substitution across labor and materials, and θ , the demand elasticity across sectoral products, by indirect inference. ρ governs how much demand for workers increases out of an increase in the demand for the final product. Because of that, we choose a value for ρ to approximate the effect of AD tariffs on midstream employment. θ governs how much the demand of the final consumer changes because of a change in prices. Accordingly, we choose a value for θ to approximate the effect of AD tariffs downstream.

We guess a set of parameters, $\{\rho, \theta\}$, and provide actual annual tariffs, $\{\tau_{i,t}^s\}$, to the model. For each year, we solve the counterfactual equilibrium with the model in changes

(see Section B.3). We then run the same panel regression in the model as in the data. We target the effects of AD tariffs on employment at midstream firms and at the main downstream firms. We present the detailed procedures in Section C.3.

Table 6 shows the estimated parameters and their confidence intervals. Labor and materials are complements, with an elasticity of substitution of 0.67. Final goods are substitutes, with an elasticity of substitution of 4.41. These values fall within the estimated range in Oberfield and Raval (2021), who find that across different specifications and industries, the elasticity of substitution across inputs falls between 0.6 and 1.0 and the final demand elasticity varies between 3.0 and 5.0.⁵⁵

Table 6: **Estimated Elasticities and Targeted Moments**

Parameters	Targeted Moments	Parameter Value
Elasticity of substitution	Elasticity of midstream employment	0.6694
across inputs ρ	with respect to midstream tariffs	(0.6594,0.6796)
Elasticity of	Elasticity of main downstream employment	4.4082
final demand θ	with respect to midstream tariffs	(4.3658,4.4506)

Description: This table presents the elasticities that are estimated in the model—i.e., the elasticity of substitution between labor and inputs ρ and the elasticity of final demand θ . The values presented in parentheses are the lower and upper bounds of the 95% confidence interval of the estimated parameters. Standard errors are calculated by bootstrapping.

Non-targeted Moments. The model matches both targeted and non-targeted moments. Table 7 shows a series of elasticities that we identified with data in Section 3 alongside their model-generated counterparts. The model exactly matches the targeted moments, i.e., the effects of tariffs on midstream employment and on downstream employment at main downstream firms. The second panel shows the model performance on a set of non-targeted moments.⁵⁶ In particular, we find no upstream effects in the model, just as we have not found them in the data. Protected firms substitute domestically produced upstream products with imports, an empirical pattern that the model is able to accurately replicate.

⁵⁵Additionally, Imbs and Mejean (2015) estimate an output elasticity of 4.1. Foster et al. (2008) estimate an input elasticity of 0.52. Su (2017) also finds that inputs are complements, while outputs are substitutes. All these papers use U.S. data.

⁵⁶The model predicts a small negative effect of tariffs on midstream exports, while the data in Table 3 show a positive effect; that said, the positive effect documented in the data is not significant.

Table 7: **Targeted and Non-Targeted Moments, Data and Model**

	Data	Model
<i>Targeted Moments</i>		
Midstream employment	0.0184	0.0184
Main downstream employment	-0.0383	-0.0383
<i>Non-targeted Moments</i>		
Main upstream employment	0.0032	0.0029
Midstream wage bill	0.0186	0.0218
Main downstream wage bill	-0.0857	-0.0769
Main upstream wage bill	-0.0003	0.0037
Exports by midstream firms	0.0133	-0.0061
Imports by midstream firms	0.0286	0.0224
<i>Employment Elasticity with Respect to Average Tariffs</i>		
Midstream tariffs	0.009	0.0117
Upstream tariffs	-0.0158	-0.0276
Downstream tariffs	-0.009	-0.0021

Description: This table presents the targeted and non-targeted moments in the data and in the model. Moments 1–8 refer to the elasticity of midstream, main downstream, and main upstream employment and the wage bill, as well as exports and imports with respect to midstream tariffs. Moments 9–11 refer to the joint impact of midstream, average downstream, and average upstream tariffs (see Section A.5.3). The data moments refer to the corresponding estimated coefficients that are presented in the empirical section. The model moments refer to those estimated with model-simulated data and Equations (C.1) and (C.2). The employment elasticity with respect to average tariffs refers to the joint impact of own sector, average upstream, and average downstream tariffs that we document in Table A.22.

7 Quantitative Results

7.1 Brazilian Anti-Dumping Policy

Table 8 shows the aggregate effects of Brazil’s AD policy.⁵⁷ The Brazilian AD policy increased employment by 0.06%. Tariffs shift the demand for protected goods from overseas to the national market, which increases employment in protected firms and decreases it in downstream firms. The downstream effect is almost large enough to offset the employment and output gains in the protected sectors.

⁵⁷We call the Brazilian AD policy the cumulative AD tariffs implemented by the Brazilian government. We present formulas used to compute these aggregate statistics in Section B.4. In Section C.6, instead of looking at the overall AD policy, we study the impact of AD tariffs that Brazil imposed each year.

The Brazilian AD policy decreased real income by 1.3%. Tariffs increase producers’ marginal cost and final prices to consumers. As a consequence, the real income of workers decreases, even though there are more workers.

Welfare decreased by 2.4%. Since the model considers the labor supply decision, we should measure welfare in consumption-equivalent terms; that is, we hold the labor–leisure choice fixed at the baseline level and determine the percentage change in consumption that makes households indifferent in the choice between a world with an AD policy and one without.⁵⁸ As AD policy increases employment, the combined effects of decreased consumption and increased labor supply lead to a greater reduction in welfare than in real income.

Table 8: **Aggregate Effect of Brazilian AD Policy**

Variable	Baseline Model	No Input-Output
Employment	0.06%	0.15%
GDP	0.05%	0.14%
Real income	-1.32%	-0.75%
Welfare	-2.43%	-1.53%

Description: This table shows the effect of Brazilian AD policy on aggregate employment, GDP, real income, and welfare. For each of the variables of interest, we calculate the percentage change between the equilibrium with the Brazilian AD policy and the benchmark equilibrium in which no AD tariff is imposed. These aggregate variables are defined in Section B.4. The Brazilian AD policy refers to each sector’s maximum AD tariff for all years. We show the effect predicted by the baseline model and a model that does not have input-output linkages.

It is important to consider the input-output relationship of firms. Table 8 shows that without this connection, the predicted effect on employment is almost twice as large, while the welfare cost is lower. The model without input-output connections fails to take into account the fact that AD tariffs decrease employment downstream; consequently, it overstates the positive impact of AD tariffs on overall employment.

Understanding the Greater Welfare Effects of AD Policy Compared to Previous Works. We find a greater welfare loss from AD policies compared to Egger and Nelson

⁵⁸Since Lucas (1987), consumption-equivalent terms have often been used to measure the welfare change. Our equation transforms non-consumption terms that enter the utility, e.g., leisure, into consumption, such that they can be compared to other real economic variables, e.g., GDP and employment (Jones and Klenow 2016).

(2011) because we measure welfare in consumption-equivalent terms and account for input-output linkages. We also find a greater real income loss from tariffs than Gallaway et al. (1999) and Fajgelbaum et al. (2020) because we account for the endogenous decrease in foreign transfers (trade deficit) due to tariffs.⁵⁹ We discuss these points in detail in Section C.6.1.

7.2 Propagation Through Input-Output Linkages

Figure 6 shows that the aggregate effect of AD tariffs depends on the protected sector's position in the value chain. On the y-axis, we plot the impact of a 200% AD tariff placed on each 4-digit CNAE 2.0 sector, averaged across all 4-digit sectors within each broad sector. The x-axis represents the average upstreamness of each broad sector, indicating the average number of sectors passed through by one dollar of output to reach the final demand (upstreamness definition in Section C.4).

Figure 6a shows that the employment impact of sector-level tariffs is negatively correlated with sector upstreamness.⁶⁰ There are two empirically relevant channels: the direct effect on the protected sector and downstream propagation.⁶¹ When a sector is downstream in the value chain, few sectors are further downstream of it. The negative employment effect in downstream sectors is smaller and the positive effect in the protected sector dominates.⁶²

Figure 6b shows that the impact of sector-level tariffs on welfare is not correlated with sector upstreamness and is negative for almost all sectors. The tariff affects economic welfare through two main channels: prices and wages. Taxing downstream sectors substitutes more imports with domestic labor, which increases domestic prices and decreases welfare. At the same time, taxing upstream sectors decreases employment in more downstream sectors by

⁵⁹Fajgelbaum et al. (2020) studies the 2018 U.S.-China trade war, but the scope and magnitude of the trade war tariffs are comparable to those imposed under the AD policy in Brazil. The trade war tariffs affected 13% of U.S. imports, leading to an average price increase of 14% among the targeted varieties, while the U.S. import-to-GDP ratio was 15%. Similarly, in 1995, the AD policy in Brazil affected 6% of imports, with an average tariff increase of 14.3%, and Brazil's import-to-GDP ratio was 10.2%.

⁶⁰This correlation persists even when controlling for sector characteristics, such as broad sector fixed effects, GDP value-added shares, employment shares, import shares, and trade elasticities (Table C.8).

⁶¹As discussed in the empirical section and supported by the model's predictions in Table C.5, tariffs have no significant propagation effect in upstream sectors.

⁶²In Section C.6.3, we show the aggregate consequences of imposing 200% sector-level tariffs on each 4-digit sector, without taking their means for broad sectors. The negative correlation between aggregate

Figure 6: Effect of a 200% Sectoral Import Tariff on Employment and Welfare

Description: These figures show the effect of a 200% sectoral AD tariff on aggregate employment and welfare. For each large sector, the x-axis plots the average upstreamness, which measures the average number of sectors that one dollar of a sector's output passes through to reach the final demand. In Section C.4, we present more details of how we measure sector upstreamness. The y-axis of Figure 6a plots the change in employment caused by a 200% AD tariff. The y-axis of Figure 6b plots the effect of a 200% tariff on welfare. To avoid cluttering the figure, we average the effects within large sectors.

cutting their wages, and this, too, leads to lower nominal income and welfare.⁶³

7.3 Optimal Import Tariff Policy

If the goal of the government is to maximize employment, how should it choose tariffs? We study the choice of tariffs that maximize employment while keeping the government's budget constant.⁶⁴ We present this optimal tariff problem in Section C.5.

Figure 7a shows that the input-output linkages are an important factor in the choice of employment-maximizing tariffs.⁶⁵ Figure 7a plots the upstreamness of each broad sector on the x-axis and the sectoral tariffs that maximize employment on the y-axis. If the government's goal is to maximize employment, tariffs should be large (an average of 373%) and strongly negatively correlated with sector upstreamness. The government should minimize the negative downstream employment effect by setting higher tariffs on sectors selling directly to the final consumer.

Figure 7b shows that the optimal tariffs that maximize welfare should be low (an aver-

employment effect and sector upstreamness persists.

⁶³Figure C.5 confirms this intuition, which shows that the impacts of sector-level tariffs on both the nominal income and consumer price are negatively correlated with sector upstreamness.

⁶⁴For tractability, we require tariffs to be below 1000%. We also experimented with setting the upper bound to 900%. Our findings are robust to these bounds.

⁶⁵In Section C.6.4, we show the optimal tariffs that maximize employment, GDP, real income, and welfare on each 4-digit sector, without taking their means for broad sectors.

age of 7.8%) and positively correlated with sector upstreamness. Imposing higher tariffs on downstream sectors reallocates more production from abroad to domestic labor than imposing higher tariffs on upstream sectors. This, in turn, contributes to higher consumer prices, which further reduces welfare.

“Bring jobs back” provides a new rationale for tariff escalation. Antràs et al. (2022), Caliendo et al. (2021), and Shapiro (2021) find that tariffs are larger in downstream sectors, a phenomenon that they call “tariff escalation.” Our findings suggest a new mechanism for tariff escalation. We show that a policymaker whose goal is to maximize employment will also increase tariffs less in upstream sectors because they negatively impact employment in other sectors.⁶⁶

According to Table 9, a government that uses tariffs can increase employment by at most 2.8%, but it causes a 15.9% decrease in welfare.⁶⁷ If, instead, the government chooses tariffs to maximize welfare, employment will increase by 0.01% but welfare should decrease by only 1.46%.⁶⁸ These findings highlight the trade-offs that policymakers face: the tariffs that increase employment are likely to harm consumer welfare.

Table 9: **Optimal Import Tariff Policy**

Effect on	Optimal tariffs that maximize				Effect of Brazilian AD policy
	Employment	GDP	Real Income	Welfare	
Employment	2.82%	2.46%	0.03%	0.01%	0.06%
GDP	2.32%	2.49%	0.07%	-0.10%	0.05%
Real income	-7.97%	-6.64%	-0.87%	-1.02%	-1.32%
Welfare	-15.85%	-14.63%	-1.77%	-1.46%	-2.43%

Description: This table shows the optimal tariff according to different objectives of the government and its effect on aggregate variables. The change in outcomes is made from the equilibrium without tariffs.

⁶⁶Antràs et al. (2022) and Caliendo et al. (2021) explain tariff escalation with a model in which a government chooses sectoral tariffs to maximize consumer welfare and firms freely enter and exit sectors. In these models, protecting downstream sectors leads to more entries in upstream sectors, thus alleviating the pressure of tariffs on downstream prices. Protecting upstream sectors, on the other hand, leads to more exit in downstream sectors, which further increases the consumer price and causes more welfare loss.

⁶⁷The real income loss from optimal tariffs that maximize employment is comparable to the real income loss from autarky for Brazil that is described in the literature. Using an input-output table that has 251 sectors, Ossa (2015) shows a 9.8% gain from trade for Brazil. This translates into a 8.9% real income loss from autarky.

⁶⁸Compared with the baseline equilibrium where no AD tariff is imposed, the optimal tariffs that maximize real income and welfare still reduce real income and welfare because of the fiscal constraint: The government

Figure 7: Tariffs to Maximize Employment and Welfare

Description: These figures show the sectoral optimal tariffs that maximize employment and welfare. The optimal tariffs solve a problem that maximizes the respective aggregate variable, subject to the equilibrium constraints and the additional constraint that the government collects the same tariff revenue as it collects from the benchmark tariffs (see Section 7.3). The Brazilian AD policy refers to each sector's maximum AD tariff in all years. The x-axis plots the average upstreamness of each broad sector, which measures the average number of sectors that one dollar of a sector's output passes through to reach final demand. In Section C.4, we present more details of how we measure sector upstreamness. The y-axis plots the tariff that maximizes employment (Figure 7a) and welfare (Figure 7b).

8 Conclusion

This paper examines how the impacts of tariffs propagate along the value chain and their aggregate consequences. The empirical method we develop to answer this question can be applied to investigate various economic outcomes resulting from tariffs across different countries, sectors, and time periods. We compile detailed data on AD investigations, trade, and the input-output table, matching them to firm-level administrative employment data in Brazil. Using a difference-in-differences strategy, we find that AD tariffs reduce imports but do not significantly divert trade to imports of similar products or from other foreign countries. AD tariffs significantly increase employment in the protected sector and strongly decrease employment in downstream sectors, but do not significantly increase employment in upstream sectors. We also demonstrate that Brazilian AD tariffs are indeed predominantly determined by past foreign prices, proving the validity of the empirical strategy.

To quantify the aggregate, general equilibrium effects of these tariffs, we build a small open economy model of Brazil that takes into account international trade, input-output linkages, and labor force participation. The model can reproduce the micro-elasticities, and it

is required to collect the same tariff revenue as it collects from the benchmark tariffs. If tariffs are set low for some sectors, they have to be high for other sectors to ensure that the fiscal constraint holds. These tariffs raise welfare relative to the incumbent Brazilian AD policy.

matches the aggregate moments of the Brazilian economy. We find that Brazilian AD policy weakly increases aggregate employment but decreases consumer welfare. On average, protecting downstream sectors increases aggregate employment more than it protects upstream sectors. A government whose objective is to maximize employment has strong incentives to increase tariffs, especially for downstream sectors. This moderately increases aggregate employment but substantially undermines consumer welfare.

Drawing on our findings, policymakers can learn that when setting tariffs, they face an important trade-off between employment and welfare. Strong WTO rules, trade agreements, and domestic political institutions could prevent policymakers from creating jobs by raising tariffs without limits—a policy that imposes excessive harm on consumer welfare.

A Empirical Evidence

A.1 Statistics of Anti-Dumping Investigation in Brazil

In this section, we discuss the AD measures and investigations undertaken by Brazil between 1989 and 2017. Table A.1 presents the number of investigations, affected products, and countries. Treated refers to the product–country pair that had an AD tariff applied or price adjustment.

Table A.1: **Statistics of Brazilian AD Investigations**

	Treated	Control	All
# Investigations	393	183	576
# Products	155	108	227
# Countries	50	45	65
Avg. Tariff	0.35	0	0.24

Description: This table presents the statistics of Brazilian AD investigations between 1989 and 2017. Each investigation is a product–country pair. The average tariff is calculated using the imposed ad valorem tariff. Where the tariff is per-unit, we calculate the corresponding ad valorem value using trade data of the preceding year.

Figure A.1a shows the AD investigations by year. In 1994, the Brazilian government filed a broad complaint that covered 124 types of artificial and synthetic fabric from South Korea. Because we count investigations at the product level and not at the complaint level, we observe a large spike in that year. The complaint was rejected for all products. With the exception of this spike, the treatment and control groups are evenly distributed over time.

Table A.2 shows the top five countries with the most investigations. China is the leader, and 80% of the investigations on China end with a tariff increase or price adjustment. Notably, there is a large variation in the tariffs imposed.

Figure A.1: Brazilian AD Policy Over Time

Description: Figure A.1a shows the average number of AD investigations per year at the product level. Figure A.1b shows the average AD tariff at the product level conditional on an AD being imposed.

Table A.2: Statistics of Brazilian AD Investigations by Country

Country	# Investigations	% Treated	Avg. Tariff
China	113	0.850	0.782
South Korea	63	0.317	0.336
United States	58	0.638	0.581
India	34	0.588	0.324
Taiwan	25	0.800	0.445
Germany	22	0.773	0.388

Description: This table presents the number of products investigated for dumping between 1989 and 2017 in Brazil by country. The data source is the Global Antidumping Database.

While AD tariffs target specific products and countries, they can lead to significant tariff variations at the sector level. Figure A.2 and Table A.3 show the average AD tariff faced by each CNAE 2.0 4-digit sector. Figure A.2a shows, for each CNAE 2.0 4-digit sector, the AD tariff faced by the average product–country pair that was subject to an AD tariff. Figure A.2b shows, for each CNAE 2.0 4-digit sector, the AD tariff faced by the average product–country pair, taking into account the product–country pairs that never faced AD tariffs.⁶⁹ Even if we include in the average the product–country pairs that never had AD

⁶⁹In Figure A.2, we only show the 4-digit sectors that were subject to AD tariffs. To compute the average AD tariff for each sector, first, we compute the imports in each product from each country in an average

tariff changes, for some sectors, the average AD tariff is as high as 30%. These figures show that AD tariffs can lead to substantial price variations across sectors, even if only a subset of products and countries in each sector are hit by AD tariffs.

Table A.3 shows the summary statistics of AD tariffs by broad sectors. In Section 6, we estimate the cross-product and cross-country elasticities of substitution for the same set of broad sectors. Within each broad sector, some 4-digit sectors were subject to an AD tariff. In the aggregate, about 20% of all 4-digit sectors (53 out of 297) were protected. Taking into account the 4-digit sectors that never received an AD tariff, the average AD tariff per 4-digit sector is 1.94%; the highest tariff is for the wood and paper sector (5.4%) and the lowest tariff is for the computer, electrical and machinery equipment sector (0.1%). Among the 4-digit sectors that were subject to AD tariffs, the average AD tariff per 4-digit sector is 10.5%, the highest is for the wood and paper sector (29.0%) and the lowest is for the computer, electrical and machinery equipment sector (0.77%). The percentiles of the tariffs also show that within each broad sector, some 4-digit sectors face large tariffs.

Figure A.2: AD Tariffs by Sector

Description: Figure A.2a shows, for each CNAE 4-digit sector, the average AD tariff of all product-countries that face positive AD tariffs. Figure A.2b shows, for each CNAE 4-digit sector, the average AD tariff of all product-countries that face positive AD tariffs. To compute the average AD tariff for each sector, first, we compute the imports of each product from each country in an average year during the sample period. Then, we compute the weighted average of the maximum product-country pair-specific AD tariff during the sample period, using these product-country-level imports as weights. When computing the average tariff, Figure A.2a only includes the product-countries that had positive AD tariffs, and Figure A.2b includes all product-countries.

Table A.3: **Statistics of AD Tariffs by Sector**

Sector Name	No. of 4-digit Sectors	No. with Positive AD	Uncond. Mean (%)	Cond. Mean (%)	Cond. p50	Cond. p95
Agriculture, Mining, Food and Textile	100	7	0.49	6.96	1.37	40.31
Wood and Paper	37	5	5.36	28.95	31.77	44.37

Description: This table presents summary statistics of AD tariffs by broad sectors. The same set of broad sectors is used in Section 6, where we estimate the cross-product and cross-country elasticities of substitution. The *Uncond. Mean* refers to, for each sector, the AD tariff faced by an average 4-digit sector when we account for the 4-digit sectors that never received an AD tariff. *Cond. Mean* refers to, for each sector, the AD tariff faced by an average 4-digit sector that received an AD tariff. *Cond. p50* and *Cond. p95* shows the 50th percentile and 95th percentile of the AD tariffs faced by 4-digit sectors within each broad sector.

A.2 Input-Output Table

A.2.1 Estimating an Input-Output Table

We base our sectoral findings on CNAE 2.0 4-digit level (CNAE4 level) sectors.⁷⁰ There is a total of 297 goods (agriculture, mining, and manufacturing) sectors and 375 service sectors. As there is no AD tariff variation in the service sectors, we combine all service sectors into one single sector. To identify a sector’s main upstream and downstream sectors, and to compute the weighted average upstream and downstream tariffs, we need to identify an input-output table for Brazil that has information about a sector’s input expenditure on all sectors from both domestic and foreign sources. We call such a table the **complete input-output table**. However, the most disaggregated complete input-output table for Brazil that is readily available is tabulated based on a different sector classification, Niv, which has only 67 sectors (among the Niv sectors, just 36 are goods and the rest are services).⁷¹ To acquire complete input-output information on the CNAE4 level, we take advantage of the following datasets: a CNAE4-level imports table (details described below), CNAE4-level gross output and expenditure on inputs, and a Niv-level complete input-output table. We then apply a generalized-RAS (GRAS) estimation algorithm (Temursho et al. 2021) on these databases

year during the sample period. We then compute the weighted average of the maximum of product–country pair specific AD tariff during the sample period, using these product–country-level imports as weights.

⁷⁰See <https://cnae.ibge.gov.br/> for the background information on this sector classification.

⁷¹Muendler (2002) discusses the relationship between CNAE sectors and Niv sectors. The Niv-level complete input-output table is available from IBGE (the Brazilian Institute of Geography and Statistics). As the Niv-level input-output table is only available for 2015, we fix all other datasets to the same year.

to estimate the desirable input-output matrix.

We proceed with the following steps. We start with a unique database acquired from the Secretary of International Trade of the Ministry of Economy on sector–product-level imports, showing the value of each HS 6-digit product that is imported by a domestic sector. Using a concordance table between HS 6-digit products and CNAE4 sectors from the Secretary of International Trade, we construct the input-output table for imports, i.e., CNAE4-level imports by each domestic CNAE4 sector. We call this the **imports table**. Many works in this literature, for example, Flaaen and Pierce (2024), and Handley et al. (2020), use the imports table directly to compute the domestic sectors’ exposure to upstream tariffs. However, due to the home bias, the input-output coefficients calculated with the imports table may not be equivalent to those calculated with the complete input-output table, which includes both domestic sales and imports.⁷² Using only the imports table, we may miss the sectors in which the domestic producers are mainly upstream and downstream to the protected sectors but do not import or export extensively. Therefore, we need to update the imports table with domestic input-output information.

In the third step, we apply the GRAS estimation algorithm to these datasets to estimate a CNAE4-level complete input-output table. RAS (Leontief 1949, Stone 1961) is an estimation algorithm that has been widely used to estimate input-output tables. It minimizes the weighted distance between the unknown matrix and an initial guess of it, subject to constraints on the row- and column-sums of the unknown matrix (sectoral gross output and total input expenditure in our setting). The GRAS algorithm (Günlük-Şenesen and Bates 1988, Junius and Oosterhaven 2003) extends RAS. It imposes additional constraints such that the unknown matrix, once aggregated to a set of broad sectors, is consistent with a known input-output matrix at the same broad sector level. The GRAS algorithm is recommended by the Brazilian government to estimate the national input-output table when such a table is not available for the current year (Guilhoto et al. 2010), as well as to estimate the regional input-output table using region–sectoral gross output, total input, and the national level input-output table (Guilhoto et al. 2010). In our setting, the initial guess is

⁷²For example, an upstream sector’s share in other sectors’ domestic expenditure can differ from its share in other sectors’ imports. Similarly, a downstream sector’s share in the sales of other sectors’ domestic producers may not be the same as its share in other sectors’ foreign producers.

the “normalized” imports table, where we multiply each entry in the imports table with the ratio of total input expenditure (the sum of all entries in the Niv-level input-output table) to total imported intermediate input (the sum of all entries in the imports table).⁷³ Our constraints are the data on CNAE4-level gross output, input expenditure, and the Niv-level input-output table. Following Temursho et al. (2021), we formulate the problem as:

$$\min_{\{z_{ij}\}} f(\mathbf{Z}) = \sum_{i=1}^{S+F} \sum_{j=1}^S |x_{ij}^O| z_{ij} \log(z_{ij}) \quad (\text{A.1})$$

$$\text{s.t. } \sum_{j=1}^S x_{ij}^O z_{ij} = u_i, \forall i \in \{1, \dots, S\} \quad (\text{A.2})$$

$$\sum_{i=1}^{S+F} x_{ij}^O z_{ij} = v_j, \forall j \in \{1, \dots, S\} \quad (\text{A.3})$$

$$\sum_{i \in \Omega_I} \sum_{j \in \Omega_J} x_{ij}^O z_{ij} = w_{IJ}, \forall I \in \{1, \dots, M\}, J \in \{1, \dots, M\}. \quad (\text{A.4})$$

$\{i\}_{i=1}^S, \{j\}_{j=1}^S$ denotes CNAE4 sectors. $i = F$ denotes the final sector (final demand and exports). I and J denote Niv sectors, and Ω_I and Ω_J denote the CNAE4 sectors in the Niv sectors. Niv sectors do not overlap: $\Omega_I \cap \Omega_J = \emptyset, \forall I \neq J$, and $\cup_{I=1}^M \Omega_I = \{1, \dots, S\}$. $\{x_{ij}^O\}_{i=1, j=1}^{i=S, j=S}$ (the initial guess) represents the normalized imports table: imports of sector j output by sector i . x_{Fj}^O denotes sales by sector j to the final sector.⁷⁴ z_{ij} represents the distance between the normalized imports table and the unknown complete input-output table. u_i denotes sector i total input expenditure. v_j denotes sector j supplies (imports and domestic products). w_{IJ} denotes Niv sector J total output used by Niv sector I .

The objective function minimizes the weighted distance between the imports table and the complete input-output table. The complete input-output table is consistent with the following information in the data: CNAE4-level total input expenditure according to constraint A.2, CNAE4-level gross output according to constraint A.3, and the cross-sector flows in the complete input-output table at the Niv level according to constraint A.4. Junius and Oost-

⁷³Consequently, total expenditure in the “normalized” imports table, as we add up all elements in the matrix, is equal to total input expenditure in the Brazilian economy.

⁷⁴This initial guess is set to sector j ’s gross output plus this sector’s imports minus $\sum_{i=1}^J x_{ij}^O$.

erhaven (2003), Miller and Blair (2009) and Temursho et al. (2021) show that the solution to this problem is unique, and Temursho et al. (2021) provide an iterative solver that can give the solution.

Armed with the solved $\{z_{ij}\}$, we recover the complete input-output table with $x_{ij} = z_{ij}x_{ij}^O$. We can then obtain the input-output coefficients. We define the sector expenditure share, $\gamma_{ij} = \frac{x_{ij}}{u_i}$, as the share of input that sector i spends on sector j . The numerator denotes the input demand of sector i from sector j and the denominator denotes the aggregate input demand of sector i . We define the sector output share, $S_{ij} = \frac{x_{ij}}{v_j}$, as the share of output that sector j sells to sector i . The numerator denotes the sales to sector i from sector j , and the denominator denotes the production of sector j . With these two sets of market shares, we can construct the main upstream and downstream sectors as well as the average downstream and upstream tariffs.

A.2.2 Main Upstream and Downstream

For each sector i , we define its main upstream sector $j(i)$ as the sector that sells the largest share of output to sector i :

$$j(i) = \arg \max_j S_{ij}.$$

For each sector j , we define its main downstream sector $i(j)$ as the sector that spends the largest share of input on sector j :

$$i(j) = \arg \max_i \gamma_{ij}.$$

In the event studies, we focus on non-service main upstream and downstream sectors.

A.3 Endogeneity of AD Investigations

We show that products and sectors that are targeted by an AD investigation are not similar to the ones that are not investigated. Investigated products have higher trade volumes and lower prices. Moreover, they have an increasing trend in trade volume and a decreasing trend

in prices. Investigated sectors have higher employment and wages, and have a decreasing trend in wages. Hence, one cannot compare investigated products to non-investigated ones, because one cannot tease out the effect of AD tariffs from product-level trends.

We use the following model to calculate the probability of investigation:

$$\mathbb{I}_{p,o,t} \{\text{Investigation}\} = \beta_0 \log(\text{Imports}_{p,o,t-1}) + \beta_1 \log(\text{Price}_{p,o,t-1}) + \mu_{p,o} + \mu_{t,o} + \epsilon_{p,o,t}, \quad (\text{A.5})$$

where $\mathbb{I}_{p,o,t} \{\text{Investigation}\}$ is a dummy taking one if there is an AD investigation against product p , from destination o , in year t ; $\text{Imports}_{p,o,t-1}$ are imports of product p from origin o in year $t - 1$; $\mu_{p,o}$ is a production–origin fixed effect, and $\mu_{t,o}$ is a time–origin fixed effect.

Columns 1 and 2 of Table A.4 show that AD investigations are more likely to target higher volume and lower priced product–destinations. Columns 3 and 4 show that investigations are more likely to target product–destinations in an increasing volume and decreasing price trend. Columns 5 and 6 show that AD tariffs are also more likely to be implemented on higher volume and lower priced product–destinations, and columns 7 and 8 show that they are also implemented on products in a decreasing price and increasing volume trend. As the investigated products are not in the same trend as non-investigated ones, a comparison between them would deliver a biased estimate: One cannot tease out the effect of an AD tariff from that of a pre-existing trend.

Description: This table shows the estimated parameters of model A.5. $\mathbb{I}\{\text{Investigation}\}$ is a dummy taking a value of 1 if that product–destination has an AD investigation starting at that year. $\mathbb{I}\{\text{AD Tariff}\}$ is a dummy taking a value of 1 if a product has an AD investigation starting that year. $\log(\text{Imports}_{t-1})$ is the lagged FOB imports in dollars, and $\log(\text{Price}_{t-1})$ is lagged prices. Trade data are from the Secretary of International Trade of the Ministry of Economy in Brazil, and AD data are from the Global Antidumping Database. Standard errors, clustered at the origin–product level, are in parentheses.

Table A.5 examines the relationship between AD investigations and firm-level labor market outcomes. Columns 1 and 2 show that investigations are more likely to start in sectors with higher wages, higher employment, and a smaller number of establishments. Column 3 shows that investigations are more likely to start in sectors that have increasing wages, an increasing number of workers, and a decreasing number of establishments. Columns 4–6 show that the same relationship holds between AD tariffs and firm-level labor market outcomes.

Description: This table shows the estimated parameters of a regression of AD policy and firm-level characteristics. $\mathbb{I}\{Investigation\}$ is a dummy taking a value of 1 if that product–destination has an AD investigation starting at that year. $\mathbb{I}\{AD\ Tariff\}$ is a dummy taking a value of 1 if a product has an AD investigation starting that year. $\log(N. Workers_{t-1})$ is lagged employment and $\log(N. Establishments_{t-1})$ is lagged number of establishments. Trade data are from the Secretary of International Trade of the Ministry of Economy in Brazil, and AD data are from the Global Antidumping Database. Standard errors, clustered at the origin–product level, are in parentheses.

A.4 Validation

A.4.1 Predicting Tariffs

According to the WTO regulations, AD tariffs should be equal to the price exporters charged in their home country minus the price they charged in Brazil. Therefore, if we had international data on prices, we could test whether WTO regulations are being followed with

$$\tau_{p,c} = \beta \frac{\pi_{p,c,c} - \pi_{p,c,BR}}{\pi_{p,c,BR}} + \epsilon_{p,c},$$

where $\tau_{p,c}$ is the AD tariff imposed on product p from country c , $\pi_{p,c,c}$ is the price charged by the exporter of product p , from country c , in country c , and $\pi_{p,c,BR}$ is the price of product

p , from country c , in Brazil. If WTO regulations are being followed, $\beta = 1$.

However, we do not observe the price charged by the exporter in its home market. Instead, we must approximate this with the distribution of prices and the AD policy of other countries. The idea is that the distribution of prices of product p from country c sold in different countries contain indirect information on the price charged in exporter home country c . We consider the following specification:

$$\tau_{p,c} = \beta_1 \tau_{p,c}^{avg} + \beta_2 \tau_{p,c}^{median} + \beta_2 \tau_{p,c}^{p25} + \beta_2 \tau_{p,c}^{p75} + \beta_2 \tau_{p,c}^{max} + \beta_2 \tau_{p,c}^{min} + X'_{p,c} \theta + \epsilon, \quad (\text{A.6})$$

where $\tau_{p,c}^{avg}$ is the AD tariff if the price charged in country c and product p was the average price charged for imports of product p from country c across all countries in the world except for Brazil. Similarly, $\tau_{p,c}^{median}$, $\tau_{p,c}^{p25}$, $\tau_{p,c}^{p75}$, $\tau_{p,c}^{max}$, and $\tau_{p,c}^{min}$ uses the tariff that would have been implemented if the price charged by the supplier in its home country had been the median, the 25th percentile, the 75th percentile, the maximum price, or the minimum price, respectively. $X_{p,c}$ is a set of fixed effects for the number of countries imposing AD tariffs on pair (p, c) or implementing an AD investigation against (p, c) .

Table A.6, which displays the coefficients of model A.6, shows that international prices are a good predictor of AD tariffs. The most relevant information is the R-squared, which shows that, with precision varying from 0.8 to 0.972, international prices alone can predict AD tariffs. It is worth mentioning that the relationship between international prices and AD tariffs is non-monotonic. Therefore, an R-squared of 1 would never be attainable.

A.4.2 Placebo Tests

In this section, we discuss the results of two placebo tests. First, we evaluate whether the results are driven by sectoral shocks. To do so, we match each sector that received an AD tariff, to another sector that did not receive an AD tariff but followed a similar trend before the introduction of the tariff. We take these matches as the fake treatment group and compare this group to the same control group as in the main specification. Second, we evaluate whether the results are driven by sectoral trends. To do so, we implement the difference-in-differences strategy, pretending that the AD tariff was implemented five years

Table A.6: AD Tariffs and the Distribution of Prices

	(1)	(2)	(3)	(4)

Level	Product X Origin	Product X Origin	Sector	Sector
Sample	All	Positive Tariff	All	Positive Tariff
N	129	100	62	49
R^2	0.800	0.904	0.830	0.972
adj. R^2	0.680	0.828	0.390	0.853

Description: This table shows the estimated parameters of a regression of AD policy on different values of predicted tariffs. $\tau_{p,c}^{avg} = \frac{\pi_{p,avg} - \pi_{p,c,BR}}{\pi_{p,c,BR}}$, where $\pi_{p,c,avg}$ is the average price charged by country c for good p to all other countries except Brazil, $\tau_{p,c}^{median} = \frac{\pi_{p,median} - \pi_{p,c,BR}}{\pi_{p,c,BR}}$, where $\pi_{p,median}$ is the median price charged by country c for good p to all other countries except Brazil, $\tau_{p,c}^{p25} = \frac{\pi_{p,p25} - \pi_{p,c,BR}}{\pi_{p,c,BR}}$, where $\pi_{p,p25}$ is the 25th percentile of prices charged by country c for good p to all other countries except Brazil, $\tau_{p,c}^{p75} = \frac{\pi_{p,p75} - \pi_{p,c,BR}}{\pi_{p,c,BR}}$ where $\pi_{p,p75}$ is the 75th percentile of prices charged by country c for good p to all other countries except Brazil, $\tau_{p,c}^{max} = \frac{\pi_{p,max} - \pi_{p,c,BR}}{\pi_{p,c,BR}}$, where $\pi_{p,max}$ is the maximum price charged by country c for good p to all other countries except Brazil, and $\tau_{p,c}^{min} = \frac{\pi_{p,min} - \pi_{p,c,BR}}{\pi_{p,c,BR}}$, where $\pi_{p,min}$ is the minimum price charged by country c for good p to all other countries except Brazil. $ADtariff$ is the AD tariff imposed at the product level. Trade data are from the the Secretary of International Trade of the Ministry of Economy in Brazil and the United Nations Comtrade, and AD data are from the Global Antidumping database. Standard errors, clustered at the origin-product level, are in parentheses.

before its de facto implementation. These placebo tests support that our results are not driven by sectoral shocks or trends.

To test whether the results are driven by sectoral shocks, we match each sector that faces an AD investigation to a sector that belongs to the same large sector group and had similar employment and international trade trends but did not face an AD investigation. More specifically, we match each 4-digit sector i that has an AD investigation to sector q , which is in the same 1-digit sector and had a similar level of employment and wage bill in the three years before the AD investigation commenced. Then, we treat each firm in sector

q as if they had been affected by the investigation and reproduce regression 4. If a sectoral shock that affected sectors in a particular trend were behind the results identified, the AD tariffs would also be correlated with employment movements in sector q .

The results of the placebo tests are presented in Figure A.3a. They indicate that there is no correlation between employment in sectors that did not receive an AD tariff but had a similar trend in employment and the wage bill, and AD tariffs. We conclude that the results are not driven by sectoral shocks affecting sectors with similar employment characteristics.

Figure A.3: **Placebo Tests with Fake Investigated Sectors and Fake Investigation Years**

Description: Figure A.3a shows the coefficients of regression 4 but using placebo firms. For each sector with an AD investigation, we match it to a sector in the same 4-digit classification that had similar employment and wage bill in the three years before the investigation. Then, we treat the matched sector as if it was subjected to the AD investigation and tariff. Figure A.3b shows the coefficients of regression 4 pretending that the AD investigation started five years before it actually did.

We also test whether the results are driven by sectoral trends. To do so, we implement regression 4 but pretend that the investigation started five years before its de facto implementation. Figure A.3b shows that, as expected, we find no difference in the wage bill between treatment and control five years before the introduction of the tariff.

A.4.3 Political Connection and Other Policies

We show that AD tariffs are not correlated with political engagement or other policies. If firms protected by a tariff are also targeted by other policies, we will not be able to tease out the effect of tariffs from the effect of these other policies. Table A.7 tests this for a series

of prominent policies. It shows that AD tariffs are not correlated with the firm's campaign contribution (Column 1) or receiving a subsidized loan (Column 3).

During the 2000s, the Brazilian government implemented policies facilitating access to the stock market, reducing taxes, and privatizing state-owned firms. Columns 4 to 7 show that these policies are not correlated with AD tariffs.

AD tariffs are not correlated with other international trade policies. Columns 8 and 9 show that the treatment and control groups are equally exposed to changes in MFN tariffs and preferential tariffs.

Description: This table presents the estimated parameters of model 3. The sample is composed of firms in sectors that produce a product under an AD investigation. We limit the sample to the set of firms observed for five years before and after the AD investigation. $\mathbb{I}\{\text{Campaign Contribution}\}$ is a dummy taking a value of 1 if the firm made a campaign contribution in the past election, $\mathbb{I}\{\text{Gov. Demand}\}$ is a dummy taking a value of 1 if the firm has won a government procurement contract, $\mathbb{I}\{\text{Subsidize Loan}\}$ is a dummy if the firm has collected a subsidized loan from the government, $\mathbb{I}\{\text{Publicly Traded}\}$ is a dummy if the firm is publicly traded, $\mathbb{I}\{\text{Public}\}$ is a dummy if the firm is owned by the government, $\mathbb{I}\{\text{Multinational}\}$ is a dummy if the firm is part of a multinational corporation, $\mathbb{I}\{\text{Simples}\}$ is a dummy if the firm is part of the Simples plan, which is a plan with lower taxes and simplified tax filing, MFN Tariff is the most favored nation tariff, i.e., the tariff imposed by Brazil on other WTO members, and Tariffs is the tariff imposed by Brazil excluding AD. $\tau_{s,t}^{mid}$ is the average AD tariff imposed on products produced by the sector of each firm. Standard errors are clustered at the firm level for columns 1 to 7 and at the sector level for columns 8 and 9. We cluster tariffs at the sector level because they do not vary at the firm level.

There is a weak correlation between AD tariffs and government procurement (column 2). Specifically, a 100 percentage point increase in AD tariffs raises the probability of a government contract by only 0.09 percentage points. We present two exercises suggesting that this correlation is likely spurious.

First, Table A.8 shows the correlation between AD tariffs and government procurement under alternative functional forms, rather than the dummy variable used in the main specification in Table A.7. The results show no statistically significant correlation between AD

tariffs and the number or value of government contracts across these functional forms. Second, Table A.9 shows that adding any control to the baseline specification eliminates the significance of the correlation between tariffs and government procurement. These results suggest that the correlation between AD tariffs and government procurement is spurious.

Firm FE	Yes	Yes	Yes	Yes	Yes	Yes
Year FE	Yes	Yes	Yes	Yes	Yes	Yes

Description: This table presents the correlation between AD tariffs and government procurement under different functional forms, following the estimated parameters of model 3. The sample is composed of firms in sectors that produce a product under an AD investigation. We limit the sample to the set of firms observed for five years before and after the AD investigation. *Value Procurement* is the total value (in reais) of government procurement contracts, *Number Procurement* is the total number of government procurement contracts, $\log(\textit{Value Procurement})$ is the logarithm of the total value of government procurement contracts, $\log(\textit{N Procurement})$ is the logarithm of the total number of government procurement contracts, $\log(\textit{Value Procurement}+1)$ is the logarithm of the total value of government procurement contracts plus one, and $\log(\textit{N Procurement}+1)$ is the natural logarithm of the total number of government procurement contracts plus one. $\tau_{s,t}^{mid}$ is the average AD tariff imposed on products produced by the sector of each firm. Standard errors are clustered at the firm level.

A.4.4 Business Cycle

If the government is more lenient in AD investigations during a recession, this could bias the estimates and indicate that the government is not following the WTO regulations. To investigate whether this is the case, we plot the following impulse response function:

$$Y_{t+j} = \beta_j \textit{GDP growth rate}_t + \theta_j + \textit{epsilon}_t, \quad (\text{A.7})$$

where Y_{t+j} is an outcome of the AD policy in quarter $t+j$. β_j is the correlation between the AD policy in j quarters and the GDP growth rate in quarter t . If recessions lead to more AD tariffs, β_j should be a negative significant coefficient for $j > 0$.

Figure A.4 shows that there is no correlation between the number of AD investigations,

2-digit Sector FE		X			X
# AD Products			X		X
Other Tariffs				X	X

Description: This table presents the correlation between AD tariffs and government procurement under different functional forms, following the estimated parameters of model 3. The sample is composed of firms in sectors that produce a product under an AD investigation. We limit the sample to the set of firms observed for five years before and after around the AD investigation. The first column is the baseline specification. The second column adds a 2-digit sector-year fixed effect. The third column adds a fixed effect for the number of products under AD investigation. The fourth column adds as control AD tariffs upstream or downstream. The last column adds all the controls. $\tau_{s,t}^{mid}$ is the average AD tariff imposed on products produced by the sector of each firm. Standard errors are clustered at the firm level.

the number of investigations resulting in AD tariffs, and the share of investigations leading to AD tariffs and the business cycle. This is exactly what should happen if the government is following the WTO regulations, which supports our identification strategy. Furthermore, these results are consistent with our main conclusion that AD tariffs have a minimal impact on aggregate GDP, although we do not interpret the impulse response function as causal.

A.4.5 Effect of Tariff on Import Prices

Figure A.5 shows that the treatment and control groups exhibit similar price trends. We estimate Equation (2) using the pre-tariff price as the dependent variable. The event study figure indicates that, although the treatment and control groups have different price levels, they experience similar price trends. This similarity mitigates endogeneity concerns regarding AD tariffs. The analysis also shows that AD tariffs do not significantly impact prices after their implementation, suggesting that Brazil faces an elastic export supply curve. This finding is consistent with our model's assumption that Brazil operates as a small open economy.

Figure A.4: Correlation Between AD Policy and Business Cycle

(a) IRF: Log Number of AD Investigations

(b) IRF: Log Number of Positive AD Investigations

(c) IRF: Share of Positive AD Investigations

Description: This figure shows the correlation between AD policy and GDP growth according to model A.7.

Figure A.5: Effect of AD Tariffs on Import Prices

Description: This figure contains the coefficients of the effect of AD tariff on import prices using the dynamic model 2 plotted against quarters relative to the beginning of the investigation on the x-axis. Imports are measured in FOB current dollars at the NCM product code level. Import data is from the Secretary of International Trade of the Ministry of Economy, and AD data are from the Global Antidumping Database. The sample is composed of product–origin combinations that had at least one AD investigation. The shaded area indicates the 95% confidence interval. Standard errors are clustered at the product–origin level.

A.5 Robustness

In this section, we present several robustness tests for the main results of the paper.

A.5.1 Trade Diversion

Table A.10: **Effects of AD Tariffs on Imports from Other Countries and on Other Products Relative to Targeted Imports**

# Product AD						X	
Tariffs							X

Description: This table presents the estimated parameters of model 3. The sample is composed of firms in sectors producing the product under AD investigation. We constrain the sample to the set of firms observed for five years before and after the AD investigation that have more than 10 observations and more than one worker. These sample restrictions are made to avoid compositional changes and special firms. Column 2 adds a 1-digit sector interacted with year as control. Column 3 has a 2-digit sector interacted with year as control. Column 4 has a 1-digit sector-year FE with dummies for the number of product investigated. Column 5 has a 2-digit sector–year fixed effect with dummies for the number of product investigated. Column 6 has as control a 1-digit sector–year fixed effect, number of products investigated, and number of products with AD investigations. Column 7 has as control a 1-digit sector–year fixed effect, number of products investigated, and AD tariffs upstream and downstream. $\log(\text{Wage Bill})$ is the log of the total labor expenditure of the firm. $\tau_{s,t}^{mid}$ is the average AD tariff imposed on products produced by the sector of each firm.

A.5.3 All Connected Sectors

In this section, we identify the effects of AD tariffs on protected firms and their propagation to upstream and downstream sector firms. Following Acemoglu et al. (2014) and Bown et al.

Tariffs							X

Description: This table presents the estimated parameters of model 5. The sample is composed of firms in sectors downstream to the product under AD investigation. We limit the sample to the set of firms observed for five years before and after the AD investigation. *log(Wage Bill)* is the log of the firm's total labor expenditure. Column 2 adds a 1-digit sector interacted with year as control. Column 3 has a 2-digit sector interacted with year as control. Column 4 has a 1-digit sector-year fixed effect with dummies for the number of product investigated. Column 5 has a 2-digit sector-year fixed effect with dummies for the number of products investigated. Column 6 has as control a 1-digit sector-year fixed effect, number of product investigated, and number of products with AD. Column 7 has as control a 1-digit sector-year fixed effect, number of products investigated, and AD tariffs upstream and midstream. $\tilde{\tau}_{d(s),t}^{down}$ is the tariff exposure faced by main downstream sector firms. $\tilde{\tau}_{d,t}^{down}$ is the average AD tariff imposed on the inputs used by downstream firms. Standard errors are clustered at the firm level.

(2021), our specification is given by:

$$y_{i,s,t} = \theta \tau_{s,t} + \theta^{up} \tau_{s,t}^{up} + \theta^{down} \tau_{s,t}^{down} + X'_{i,s,t} \kappa + \eta_i + \eta_t + \epsilon_{i,t}, \quad (\text{A.8})$$

where $\tau_{s,t}$ is the average AD tariff on sector s , $\tau_{s,t}^{up}$ is the average exposure of firm i in sector s to upstream tariffs (i being a downstream firm), and $\tau_{s,t}^{down}$ is the average exposure of firm i in sector s to downstream tariffs (i being an upstream firm). $X'_{i,s,t}$ is a set of controls, which include a 1-digit sector fixed effect interacted with year, and a dummy for the number of investigations. We run this regression on all firms—not only the ones exposed to AD investigation, as we studied before.

This specification has two drawbacks. The first is that to identify the causal effect of tariffs, we have to assume that all sectors follow parallel trends. Given that we expect sectors

Tariffs							X

Description: This table presents the estimated parameters of model 7. The sample is composed of firms in sectors that are upstream to a product under an AD investigation. We limit the sample to the set of firms observed for five years before and after the AD investigation. $\log(\text{Wage Bill})$ is the log of the firm's total labor expenditure. Column 2 adds a 1-digit sector interacted with year as control, column 3 has a 2-digit sector interacted with year as control, column 4 has a 1-digit sector-year fixed effect with dummies for the number of products investigated, column 5 has a 2-digit sector-year fixed effect with dummies for the number of product investigated. column 6 has as control a 1-digit sector-year fixed effect, number of product investigated, and number of products with AD. Column 7 has as control a 1-digit sector-year fixed effect, number of products investigated, and AD tariffs midstream and downstream. $\tilde{\tau}_{u(s),t}^{up}$ is the tariff exposure faced by main upstream sector firms. $\tilde{\tau}_{u,t}^{up}$ is the average AD tariff imposed on the sectors that upstream firms sell to. Standard errors are clustered at the firm level.

with AD investigations to be in a declining trend due to the institutions of AD investigations discussed in Section 2, this is a strong assumption. A second drawback is that we cannot test whether sectors were following similar trends before the introduction of the tariffs.

Still, despite these drawbacks, Table A.22 confirms the results that AD tariffs increase employment at midstream firms and tariffs in the downstream do not significantly affect employment.

Figure A.6: **Robustness of the Effect of AD Tariffs on Imports: Taking Investigation Conclusion Date as Time 0**

Description: This figure contains the coefficients of the effect of AD tariffs on imports using the dynamic model 2 plotted against quarters relative to the conclusion of the first AD investigation on the x-axis. Imports are measured in freight on board (FOB) current dollars at the NCM product code level. Import data are from the Secretary of International Trade of the Ministry of Economy, and AD data are from the Global Antidumping Database. The sample is composed of product–origin combinations that had at least one AD investigation. The shaded area indicates the 95% confidence interval. Standard errors are clustered at the product–origin level.

Figure A.7: **Midstream Wage Bill: Taking Investigation Conclusion Date as Time 0**

Description: This figure contains the coefficients of the effect of AD tariffs on the log wage bill using the dynamic model 4. The x-axis contains the number of years relative to the conclusion of the first AD investigation. Wage bill data are from RAIS, and AD data are from the Global Antidumping Database. The sample is composed of firms in sectors producing the product under AD investigation. We constrain the sample to the set of firms observed for five years before and after the AD investigation. These sample restrictions are made to avoid compositional changes. The shaded area indicates the 95% confidence interval. Standard errors are clustered at the firm level.

A.5.4 Sectoral Regressions

In this section, we study the effect of AD tariffs on sector-level aggregate variables. First, we show that AD tariffs do not lead to the entry or exit of firms. Second, we show that, even

Figure A.8: Downstream Wage Bill: Taking Investigation Conclusion Date as Time 0

Description: This figure contains the coefficients of the effect of AD tariffs on the log wage bill of firms downstream to the AD tariff using the dynamic model 6. The x-axis contains the number of years relative to the conclusion of the first AD investigation. Wage bill data are from RAIS, and AD data is from the Global Antidumping Database. The sample is composed of firms whose main input is under AD investigation. We constrain the sample to the set of firms observed for five years before and after the AD investigation. These sample restrictions are imposed to avoid compositional changes. The shaded area indicates the 95% confidence interval. Standard errors are clustered at the firm level.

Figure A.9: Upstream Wage Bill: Taking Investigation Conclusion Date as Time 0

Description: This figure contains the coefficients of the effect of AD tariffs on the log wage bill of firms upstream to the AD tariff using the dynamic model. The x-axis contains the number of years relative to the conclusion of the first AD investigation. Wage bill data are from RAIS, and AD data are from the Global Antidumping Database. The sample is composed of firms whose main input is under AD investigation. We constrain the sample to the set of firms observed for five years before and after the AD investigation. These sample restrictions are made to avoid compositional changes. The shaded area contains the 95% confidence interval. Standard errors are clustered at the firm level.

at the sector level (without exploiting firm-level variations as we did before), AD tariffs lead to an increase in employment midstream and a decrease in wages downstream.

Description: This table presents the estimated parameters of model 1. The investigation conclusion date is treated as time 0. The sample is composed of product–origin combinations that had at least one AD investigation. $\log(\text{Value Imports})$ is the log of FOB current dollar imports at the NCM level. $\log(\text{Quantity Imports})$ is the log of quantity imported, and $\log(\text{Price})$ is the log of price per unit. Import data are from the Secretary of International Trade of the Ministry of Economy, and AD data are from the Global Antidumping Database. The sample runs from 1995 to 2016. Standard errors are clustered at the product–origin level.

Description: This table presents the estimated parameters of model 5. The investigation conclusion date is treated as time 0. The sample is composed of firms in sectors downstream to the product under AD investigation. We limit the sample to the set of firms observed for five years before and after the AD investigation. Columns 1 and 2 limit the sample to the main downstream firms. Columns 3 and 4 contain all downstream firms. $\log(\# \text{ Workers})$ is the log of the total number of workers in the firm. $\log(\text{Wage Bill})$ is the log of total labor expenditure of the firm. $\bar{\tau}_{d,t}^{\text{down}}$ is the average AD tariff imposed on the inputs used by downstream firms. Standard errors are clustered at the firm level.

of firms in the midstream, main downstream, and main upstream sectors. None of these specifications show that tariffs lead to more or fewer firms in the sector. Column 2 of Table A.23 shows the effect of tariffs on the total number of establishments. Once again, we find that AD tariffs do not lead to more establishments midstream, downstream, or upstream.

The fact that AD tariffs do not cause the entry or exit of firms is important for two reasons: the identification of elasticities and our modeling assumptions. First, it guarantees that our estimates of the effect of AD tariffs are not biased. If AD tariffs did lead to the entry/exit of firms, our estimates would be conditional on survival. Second, in Section 5, based on the fact that AD tariffs do not affect entry or exit, we build a model without this margin.

We also find that AD tariffs increase employment midstream and decrease wages downstream using aggregate sectoral data, as shown in Table A.23.

Description: This table presents the estimated parameters of model 7. The investigation conclusion date is treated as time 0. The sample is composed of firms in sectors upstream to the product under AD investigation. We limit the sample to the set of firms observed for five years before and after the AD investigation. Columns 1 and 2 limit the sample to the main upstream firms. Columns 3 and 4 contain all upstream firms. $\log(\# \text{ Workers})$ is the log of the total number of workers in the firm. $\log(\text{Wage Bill})$ is the log of total labor expenditure of the firm. $\tilde{\tau}_{u,t}^{up}$ is the average AD tariff imposed on the sectors that upstream firms sell to. Standard errors are clustered at the firm level.

A.5.5 Instrumental Variables

Exploiting the institutional setting discussed in Section A.4.1, we propose an instrument for AD tariffs. We instrument AD tariffs in Brazil with the AD tariffs imposed in other countries. The rationale for this is outlined in the following. A supplier exporting with low prices to Brazil is likely to export with low prices to other countries as well. Therefore, if a supplier meets the requirements for an AD tariff in Brazil due to its low prices, it is also likely to meet these requirements in other countries. Since the AD policy outside of Brazil is unlikely to directly affect the Brazilian labor market, the instrument is exogenous to Brazilian employment.

We instrument $\tau_{s,t}$, the average AD tariff on products of sector s , with a set of dummies for the number of investigations and tariffs against products of sector s in year t in all other

Description: This table presents the estimated parameters of model 8. The sample is composed of firms in sectors downstream to the product under AD investigation. We limit the sample to the set of firms observed for five years before and after the AD investigation. Columns 1 and 2 limit the sample to the main downstream firms. Columns 3 and 4 contain all downstream firms. *log(# Workers)* is the log of the total number of workers in the firm. *log(Wage Bill)* is the log of total labor expenditure of the firm. $\tilde{\tau}_{d,t}^{down}$ is the average AD tariff imposed on the inputs used by downstream firms. Standard errors are clustered at the firm level.

countries except Brazil. The first stage is:

$$\tau_{s,t} = \sum_o \beta_o^I \mathbb{I}_t \{o \text{ Countries Investigated Sector } s\} + \sum_o \beta_o^T \mathbb{I}_t \{o \text{ Countries Imposed AD Tariff on Sector } s\} + X'_{s,t} \kappa + \epsilon_{s,t}, \quad (\text{A.9})$$

where $\mathbb{I} \{o \text{ Countries Investigated Sector } s\}$ equals 1 if countries except Brazil conduct o AD investigations against sector s in year t . $\mathbb{I} \{o \text{ Countries Imposed AD Tariff on Sector } s\}$ equals 1 if countries except Brazil impose o AD tariffs on sector s in year t . We instrument the exposure to tariffs downstream and upstream similarly.

The results in Table A.24 confirm the finding that AD tariffs increase employment midstream, with the effect propagating downstream, but they do not affect upstream firms. Columns 1 and 2 of Table A.24 show the effect of AD tariffs on midstream firms using as an instrument the AD policy of countries outside Brazil. As in the baseline model, we limit the sample to the firms that faced AD investigations. We find that imposing a 100% AD tariff causes a 3% increase in employment. Columns 3 and 4 show the effect of tariffs downstream,

showing that a 100% AD tariff on all the inputs of a firm causes a 60% decrease in employment. This is an order of magnitude larger than what we found with the main regressions. An instrumental variables regression identifies the effect of AD tariffs on compliers, i.e., on the set of sectors that were targeted by tariffs both in Brazil and outside of Brazil. These sectors are not necessarily representative of the set of sectors targeted by tariffs in Brazil. Columns 5 and 6 show that there is no effect of tariffs upstream.

The sample is composed of sectors that produce a product under an AD investigation. $\log(\# \text{ Firms})$ is the log of the total number of firms in the sector. $\log(\# \text{ Establishments})$ is the log of the total number of establishments in the sector. $\log(\# \text{ Workers})$ is the log of the total number of workers in the sector. $\log(\text{Wage Bill})$ is the log of the sector's total labor expenditure. $\tau_{s,t}^{mid}$ is the average AD tariff imposed on products produced by the sector of each firm. $\tilde{\tau}_{d,t}^{down}$ is the average AD tariff imposed on the inputs used by downstream firms. $\tilde{\tau}_{u,t}^{up}$ is the average AD tariff imposed on the sectors that upstream firms sell to. Standard errors are clustered at the sector level.

A.5.6 Regional Variation

In this section, we study the effect of AD tariffs on local labor markets. We exploit heterogeneous sectoral composition across regions to create a measure of heterogeneous exposure of regions to AD tariffs. We find that midstream tariffs significantly increase employment but the propagation of tariffs through the input-output connection of firms is not significant.

Denote the AD tariff imposed on sector s in year t with $\tau_{s,t}$. The exposure of region r to

Mean Ind. Var	1.07	1.07	.07	.07	.29	.29

Description: This table presents the estimated parameters of models 3, 5, and 7. The sample is composed of firms in sectors that produce a product under an AD investigation. We limit the sample to the set of firms observed for five years before and after the AD investigation. $\log(\# \text{ Workers})$ is the log of the total number of workers in the firm. $\log(\text{Wage Bill})$ is the log of the firm's total labor expenditure. $\tau_{s,t}^{mid}$ is the average AD tariff imposed on products produced by the sector of each firm. $\tau_{d,t}^{down}$ is the average AD tariff imposed on the inputs used by downstream firms. $\tau_{u,t}^{up}$ is the average AD tariff imposed on the sectors that upstream firms sell to. Standard errors are clustered at the firm level.

tariff $\tau_{s,t}$ is:

$$\tau_{r,t}^{reg} = \frac{\sum_s \text{Employment}_{r,s,t-1} \tau_{s,t}}{\sum_s \text{Employment}_{r,s,t-1}},$$

where $\text{Employment}_{s,t-1}$ is the previous year's employment in region r , sector s , and $\tau_{r,t}^{reg}$ is the exposure of region r to midstream tariffs. Similarly, we can calculate the exposure of region r to upstream tariffs (r being a downstream region), $\tau_{r,t}^{reg,up}$, and to downstream tariffs (r being an upstream region), $\tau_{r,t}^{reg,down}$.

The regional specification is the following:

$$y_{r,t} = \theta^{mid} \tau_{r,t}^{reg} + \theta^{up} \tau_{r,t}^{reg,up} + \theta^{down} \tau_{r,t}^{reg,down} + X'_{r,t} \kappa + \epsilon_{r,t}, \quad (\text{A.10})$$

where $y_{r,t}$ is the log of a labor outcome in region r and year t , and $X_{r,t}$ is a set of controls containing the weighted number of investigations, pre-period log employment interacted with year, and pre-period log wage interacted with year.

Table A.25 shows the main results of this section. Columns 1 and 2 show that midstream

tariffs have a large impact on employment and the wage bill in local labor markets. We also find that exposure to upstream tariffs has a large point estimate, but it is not significant. Columns 3 to 5 show that upstream tariffs decrease the employment of workers with a completed high-school education and beyond, but do not affect the employment of workers who did not complete high-school. Finally, once again, we find that tariffs do not propagate upstream.

Description: This table presents the estimated parameters of model A.10. $\log(\# \text{ Workers})$ is the log of total employment in the region, $\log(\text{Wage Bill})$ is the log of total wage bill in the region, $\log(\# \text{ HS Dropout})$ is the log of high-school dropouts in the region, $\log(\# \text{ HS Complete})$ is the log of employment of workers who completed high-school, and $\log(\# \text{ More HS})$ is the log of employment of workers who continued education beyond high-school. $\tau_{r,t}^{reg}$, $\tau_{r,t}^{reg,up}$, and $\tau_{r,t}^{reg,down}$ denote the regional exposure to midstream, upstream, and downstream tariffs, respectively. Standard errors are clustered at the firm level.

A.5.7 Other Shocks

In this section, we show that heterogeneous exposure to aggregate shocks cannot explain our results. In particular, we focus on important shocks to the Brazilian economy—the exchange rate fluctuation and trade liberalization, as discussed by Dix-Carneiro and Kovak (2015, 2017).

To control for heterogeneous exposure to exchange rate fluctuation, we use the following model:

$$y_{i,s,t} = \theta \tau_{s,t}^{mid} + \beta \mathbb{I}_{s,t} \{\text{After AD}\} + \alpha_s E_t + X'_{i,s,t} \kappa + \eta_i + \eta_t + \epsilon_{i,t}, \quad (\text{A.11})$$

where α_s is a parameter capturing the correlation between exchange rate fluctuation E_t and sector s labor outcomes. Equivalently, we write a similar specification for the effect of AD tariffs upstream and downstream. Tables A.26, A.27, and A.28 show that AD tariffs increase employment at midstream firms, decrease it downstream, and have no effect upstream, as we found with the main specification.

One could be worried that we are capturing traces of the Brazilian trade liberalization experience. To test if this is the case, we use the following functional form:

$$y_{i,s,t} = \theta \tau_{s,t}^{mid} + \beta \mathbb{I}_{s,t} \{\text{After AD}\} + \alpha_t Lib_s + X'_{i,s,t} \kappa + \eta_i + \eta_t + \epsilon_{i,t}, \quad (\text{A.12})$$

where Lib_s is the tariff change between 1995 and 1990 calculated by Dix-Carneiro and Kovak 2017. α_t is a year-specific parameter.

Description: This table presents the estimated parameters of models A.11 and A.12. The sample is composed of firms in sectors that produce a product under an AD investigation. We limit the sample to the set of firms observed for five years before and after the AD investigation. Columns 1 and 2 control for the Brazilian exchange rate. Columns 3 and 4 control for Brazilian sectoral tariff changes. $\log(\# \text{ Workers})$ is the log of the total number of workers in the firm. $\log(\text{Wage Bill})$ is the log of total labor expenditure of the firm. $\tau_{s,t}^{mid}$ is the average AD tariff imposed on products produced by the sector of each firm. Standard errors are clustered at the firm level.

B Model Appendix

B.1 Model

Proof of Equation (13): Conditional on choosing sector s , the household's optimal sectoral consumption $c_r^s(\omega)$ and labor supply $l^s(\omega)$ are independent of their utility shocks that govern sector choice, $z^s(\omega)$. Ignoring ω , the within-sector problem implies that the household's sectoral consumption is the following:

$$P^r c_r^s = \begin{cases} \frac{d_r(P^r)^{1-\theta}}{(P)^{1-\theta}}(1-\delta)w^s l^s & , s > 0 \\ \frac{d_r(P^r)^{1-\theta}}{(P)^{1-\theta}}(1-\delta)b & , s = 0. \end{cases}$$

We denote the sectoral consumption shares with $\alpha^r = \frac{d_r(P^r)^{1-\theta}}{(P)^{1-\theta}}$, and the consumer price index with P :

$$P = \left(\sum_{r=1}^S d_r (P^r)^{1-\theta} \right)^{\frac{1}{1-\theta}}.$$

Within a production sector s , we solve the household optimal labor supply, which increases in the sector's real wage. The supply elasticity equals ψ^s :

$$l^s = \left(\frac{w^s}{P} \right)^{\psi^s}. \quad (\text{B.1})$$

Plugging Equations (10) and (B.1) into Equation (11) gives the nonrandom component of welfare associated with staying in sector s :

$$U^s = \begin{cases} (1 - \delta - \frac{\psi^s}{1+\psi^s}) \left(\frac{w^s}{P} \right)^{1+\psi^s} & s > 0 \\ \frac{(1-\delta)b}{P} & s = 0. \end{cases}$$

The elasticity of a household's welfare in sector $s > 0$ with respect to the sector's real wage is $1 + \psi^s$, and it is greater than that of the outside sector's welfare with respect to social insurance (which is 1). A real wage increase leads to a higher labor supply for households that work in the sector and a greater-than-unity increase in the total real income and welfare

of staying in the sector.

With the familiar property of the Fréchet distribution, we can solve for the probability that a household chooses each sector, π^s :

$$\pi^s = \begin{cases} \frac{\tilde{a}^s \left(\frac{w^s}{P}\right)^{\eta^s}}{\sum_{s=1}^S \tilde{a}^s \left(\frac{w^s}{P}\right)^{\eta^s} + \tilde{a}^0 \left(\frac{b}{P}\right)^\mu} & , s > 0 \\ \frac{\tilde{a}^0 \left(\frac{b}{P}\right)^\mu}{\sum_{s=1}^S \tilde{a}^s \left(\frac{w^s}{P}\right)^{\eta^s} + \tilde{a}^0 \left(\frac{b}{P}\right)^\mu} & , s = 0, \end{cases}$$

where $\eta^s = \mu(1 + \psi^s)$, $\tilde{a}^s = \left(a^s(1 - \delta - \frac{\psi^s}{1 + \psi^s})\right)^\mu$, $s > 0$, and $\tilde{a}^0 = (a^0(1 - \delta))^\mu$ are parameters.

The population in all sectors adds up to the total population:

$$\sum_{s=0}^S \pi^s l^s = L. \quad (\text{B.2})$$

This implies that the share of the population in each sector, i.e., sectoral labor supply L^s , is the following:

$$L^s = \frac{\pi^s l^s}{\sum_{s=0}^S \pi^s l^s} L = \begin{cases} \frac{\tilde{a}^s \left(\frac{w^s}{P}\right)^{\lambda^s}}{\sum_{s=1}^S \tilde{a}^s \left(\frac{w^s}{P}\right)^{\lambda^s} + \tilde{a}^0 \left(\frac{b}{P}\right)^\mu} L & , s > 0 \\ \frac{\tilde{a}^0 \left(\frac{b}{P}\right)^\mu}{\sum_{s=1}^S \tilde{a}^s \left(\frac{w^s}{P}\right)^{\lambda^s} + \tilde{a}^0 \left(\frac{b}{P}\right)^\mu} L & , s = 0. \end{cases}$$

B.2 Additional Model Equations

In this section, we provide additional equations for Section 5. The Brazilian firm output price, P_0^s , can be given as the following:

$$P_0^s = \frac{1}{A^s} \left(e^s (w^s)^{1-\rho} + \sum_{s'=1}^S f^{ss'} (P^{s'})^{1-\rho} \right)^{\frac{1}{1-\rho}}, \quad (\text{B.3})$$

where $P^{s'}$ denotes the price of input from sector s' .

Sector s producer's expenditure share on the input from sector s' with $s_M^{ss'}$ is the following:

$$s_M^{ss'} = \frac{f^{ss'}(P^{s'})^{1-\rho}}{e^s(w^s)^{1-\rho} + \sum_{s'=1}^S f^{ss'}(P^{s'})^{1-\rho}}. \quad (\text{B.4})$$

Profit maximization and competitive markets imply that Brazilian sector s has the following expenditure function for country i :

$$x_i^s = \frac{g_i^s(P_i^s)^{1-\sigma^s}}{(P^s)^{1-\sigma^s}} X^s, \quad (\text{B.5})$$

where P_i^s is the price of a composite good of sector s from country i , $x_i^s = P_i^s Y_i^s$ denotes the expenditure by sector s on country i , and $X^s = P^s Q^s$ denotes the total expenditure by sector s . The relationship between the sectoral input price and the sector-origin-level output price can be established as follows:

$$(P^s)^{1-\sigma^s} = \sum_{i=0}^N g_i^s (P_i^s)^{1-\sigma^s}. \quad (\text{B.6})$$

Brazil imposes tariffs τ_{li}^s on the products. The ex-tariff import price of product l is denoted with p_{li}^s . As mentioned before, we assume that Brazil is a small open economy. Therefore, p_{li}^s can be treated as exogenous to Brazilian AD tariffs. The competitive market and the profit maximization assumption imply the following expenditure function on product l of sector s from country i :

$$x_{il}^s = \frac{h_{il}^s (p_{il}^s t_{il}^s)^{1-\zeta^s}}{(P_i^s)^{1-\zeta^s}} x_i^s, \quad (\text{B.7})$$

where $t_{il}^s = 1 + \tau_{li}^s$. We denote product l 's share in the expenditure on sector s of country i : $s_{il}^s = \frac{p_{il}^s t_{il}^s y_{il}^s}{P_i^s Y_i^s}$.⁷⁵ The sector-origin-level output price, P_i^s , can be written as a function of product-level prices and tariffs:

$$(P_i^s)^{1-\zeta^s} = \sum_{l \in \Omega_i^s} h_{il}^s (p_{il}^s t_{il}^s)^{1-\zeta^s}. \quad (\text{B.8})$$

⁷⁵The demand for product l of sector s imports from country i is denoted by the following: $y_{il}^s =$

Market Clearing. The market clearing condition for Brazilian sector s output is:

$$Y^s = (P_0^s)^{-\sigma^s} \left(\frac{1}{(P^s)^{-\sigma^s}} Q^s + E_F^s \right). \quad (\text{B.9})$$

On the right-hand side, $\frac{(P_0^s)^{-\sigma^s}}{(P^s)^{-\sigma^s}} Q^s$ denotes the domestic demand for Brazilian output. The rest, $Y_{F0}^s = (P_0^s)^{-\sigma^s} E_F^s$, denotes the foreign demand.

The sectoral input, Q^s , is used for both the consumption and the production of tradable output. Therefore, the market clearing condition is:

$$Q^s = \sum_{s'=1}^S M^{s's} + C^s, \quad (\text{B.10})$$

where $M^{s's}$ is the quantity of composite goods from sector s and used by sector s' , and C^s refers to the total consumption by all households of sector s composite good:

$$P^s C^s = \alpha^s (1 - \delta) \left(\sum_{s=1}^S w^s L^s + b L^0 \right).$$

Labor is hired to produce the tradable output. The market clearing condition for labor equates the labor supply to labor demand in each production sector:

$$L^s = \frac{1}{w^s} s_L^s P_0^s Y^s. \quad (\text{B.11})$$

We finally relate the trade deficit and tariff revenue. Trade deficit equals total imports minus total exports:

$$TD = \sum_{s=1}^S \sum_{i=1}^N \sum_{l \in \Omega_i^s} p_{il}^s y_{il}^s - \sum_{s=1}^S (P_0^s)^{1-\sigma^s} E_F^s. \quad (\text{B.12})$$

Furthermore, the tariff revenue equals tariff import values multiplied by tariffs:

$$TR = \sum_{s=1}^S \sum_{i=1}^N \sum_{l \in \Omega_i^s} p_{il}^s y_{il}^s \tau_{il}^s.$$

Equilibrium Given the government's fiscal and tariff policy, $\{\delta, b, \{\tau_{il}^s\}_{i,l,s}\}$, and foreign prices and demand, $\{\{p_{il}^s\}_{i,l,s}, \{E_F^s\}_s\}$, the equilibrium is defined as a set of sectoral input prices, $\{P^s\}_s$, and sectoral wages, $\{w^s\}_s$, such that the following hold:⁷⁶

1. Firms maximize profit (Equation B.3);
2. The price index satisfies Equations (B.6) and (B.8);
3. The goods markets clear, satisfying Equations (B.9) and (B.10);
4. The labor market clears, satisfying Equation (B.11);
5. The government budget constraint (Equation 14) holds.

B.3 Model in Changes

To compute counterfactuals, we rewrite the model in terms of changes. This approach eliminates the need to directly calibrate or estimate economic fundamentals, which are often challenging to determine. These fundamentals include productivity, foreign prices, and country and product preferences, among others. We use V' to denote the post-tariff-shock value of a variable V , and $\hat{V} = \frac{V'}{V}$ to represent the variable in terms of changes.

First, the change in sectoral labor supply is the following:

$$\hat{L}^s = \begin{cases} \frac{\left(\frac{\hat{w}^s}{\bar{P}^C}\right)^{\lambda^s}}{\sum_{s=1}^S \kappa^s \left(\frac{\hat{w}^s}{\bar{P}^C}\right)^{\lambda^s} + \kappa^0 \left(\frac{1}{\bar{P}^C}\right)^\mu} & , s > 0 \\ \frac{\left(\frac{1}{\bar{P}^C}\right)^\mu}{\sum_{s=1}^S \kappa^s \left(\frac{\hat{w}^s}{\bar{P}^C}\right)^{\lambda^s} + \kappa^0 \left(\frac{1}{\bar{P}^C}\right)^\mu} & , s = 0, \end{cases} \quad (\text{B.13})$$

where $\kappa^s = \frac{L^s}{L}$ denotes the population share in sector s in the baseline equilibrium. κ^0 denotes the fraction of the population that does not work.

$\frac{(p_{il}^s t_{il}^s)^{-\zeta^s}}{(P_i^s)^{-\zeta^s}} Y_i^s$.

⁷⁶The equilibrium also depends on fundamentals, $\{\{\tilde{a}^s\}_s, \{d^s\}_s, \{A^s\}_s, \{e^s\}_s, \{f^{ss'}\}_{s,s'}, \{g_i^s\}_{i,s}, \{h_{il}^s\}_{i,l,s}\}$.

The change in sectoral Brazilian output price is the following:

$$\hat{P}_0^s = \left(s_L^s (\hat{w}^s)^{1-\rho} + \sum_{s'=1}^S s_M^{ss'} (\hat{P}^{s'})^{1-\rho} \right)^{\frac{1}{1-\rho}}. \quad (\text{B.14})$$

The change in input-output shares is:

$$\hat{s}_M^{ss'} = \frac{(\hat{P}^{s'})^{1-\rho}}{(\hat{P}_0^s)^{1-\rho}}.$$

Therefore, the ex-post input-output shares is: $s_M^{ss'} = \hat{s}_M^{ss'} s_M^{ss'}$.

The change in sector s expenditure shares on country i is:

$$\hat{s}_i^s = \frac{(\hat{P}_i^s)^{1-\sigma^s}}{(\hat{P}^s)^{1-\sigma^s}},$$

where the change in sectoral input price is:

$$(\hat{P}^s)^{1-\sigma^s} = \sum_{i=0}^N s_i^s (\hat{P}_i^s)^{1-\sigma^s}. \quad (\text{B.15})$$

The change in expenditure share on product l in sector s imported from country i is:

$$\hat{s}_{il}^s = \frac{(\hat{t}_{il}^s)^{1-\zeta^s}}{(\hat{P}_i^s)^{1-\zeta^s}},$$

where the change in sector–origin-level output price is:

$$(\hat{P}_i^s)^{1-\zeta^s} = \sum_{l \in \Omega_i^s} s_{il}^s (\hat{t}_{il}^s)^{1-\zeta^s}. \quad (\text{B.16})$$

The ex-post market clearing condition for sector s labor equates labor demand to labor supply:

$$\frac{1}{w^{s'}} s_L^{s'} \left(s_0^{s'} X^{s'} + E_{F0}^s (\hat{P}_0^s)^{1-\sigma^s} \right) = L^{s'} = \hat{L}^s L^s. \quad (\text{B.17})$$

Similarly, the ex-post market clearing condition for sector s input is the following:

$$X^{s'} = P^{s'} C^{s'} + \sum_{s'=1}^S s_M^{s's'} \left(s_0^{s's'} X^{s's'} + E_{F0}^{s'} (\hat{P}_0^{s'})^{1-\sigma^{s'}} \right), \quad (\text{B.18})$$

where ex-post consumption is:

$$P^{s'} C^{s'} = \alpha^{s'} (1 - \delta) \left(\sum_{s=1}^S w^{s'} L^{s'} + b L^{0'} \right),$$

in which $\alpha^{s'} = \alpha^s \hat{\alpha}^s$ is the ex-post consumption expenditure share, and the expression for $\hat{\alpha}^s$ is the following:

$$\hat{\alpha}^s = \frac{(\hat{P}^s)^{1-\theta}}{(\hat{P})^{1-\theta}},$$

where $(P)^{1-\theta} = \sum_{s=1}^S \alpha^s (\hat{P}^s)^{1-\theta}$.

The ex-post budget constraint for the government is:

$$b L^{0'} = \delta \left(\sum_{s=1}^S w^{s'} L^{s'} + b L^{0'} \right) + T D' + T R', \quad (\text{B.19})$$

in which the ex-post trade deficit and ex-post tariff revenue are:

$$T R' = \sum_{s=1}^S \sum_{i=1}^N \sum_{l \in \Omega_i^s} X^{s'} s_i^{s'} s_{il}^{s'} \frac{\tau_{il}^{s'}}{t_{il}^{s'}}, \quad (\text{B.20})$$

$$T D' = \sum_{s=1}^S \sum_{i=1}^N \sum_{l \in \Omega_i^s} X^{s'} s_i^{s'} s_{il}^{s'} \frac{1}{t_{il}^{s'}} - \sum_{s=1}^S (\hat{P}_0^s)^{1-\sigma^s} E_{F0}^s. \quad (\text{B.21})$$

Equilibrium in changes Given the government's fiscal and tariff policy, $\{\delta, b, \{\tau_{il}^s\}_{i,l,s}\}$, baseline export, $\{E_{F0}^s\}$, market shares, $\{\kappa^s, \alpha^s, s_L^s, s_M^{ss'}, s_i^s, s_{il}^s\}$, and elasticities $\{\lambda^s, \mu, \theta, \rho, \sigma^s, \zeta^s\}$, the equilibrium is defined as a set of changes in sectoral input prices, $\{\hat{P}^s\}_s$, and changes in sectoral wages, $\{\hat{w}^s\}_s$ such that

1. Firms maximize profit (Equation (B.14));
2. The price index satisfies Equations (B.15) and (B.16);
3. The goods market clears in the counterfactual equilibrium, satisfying Equation (B.18);
4. The labor market clears in the counterfactual equilibrium, satisfying Equation (B.17);
5. The government budget constraint in the counterfactual equilibrium (Equation (B.19)) holds.

B.4 Changes in the Aggregate Variables

In this section, we present the formula used to compute the different aggregate variables.

Aggregate Employment. The change in aggregate employment is equal to a weighted average of changes in sectoral employment:

$$\text{dlog}(L^e) = \sum_{s=1}^S \frac{L^s}{\sum_{s=1}^S L^s} \text{dlog}(L^s).$$

AD tariffs that protect a sector draw additional labor from both the nonworking population and other sectors. As a result, the protected sectors experience an increase in employment. Given the interconnected nature of multiple sectors, we must solve the counterfactual equilibrium to determine the aggregate effect.

GDP. The change in real GDP can also be written as a weighted average of the changes in sectoral employment. However, different from the aggregate employment effect, the weights are sector value-added shares in nominal GDP:

$$\text{dlog}(rGDP) = \sum_{s=1}^S \frac{w^s L^s}{\sum_{s=1}^S w^s L^s} \text{dlog}(L^s). \quad (\text{B.22})$$

Proof: A country's nominal GDP is equal to the product of real GDP and GDP deflator. Alternatively, it can be written as the difference between the country's gross output and

total intermediate input used:

$$\text{GDP} = P^{\text{rGDP}} \text{rGDP} = \sum_{s=1}^S \left(P_0^s Y^s - \sum_{s'=1}^S P^{s'} M^{ss'} \right),$$

where P^{rGDP} is the price index for real GDP. Consider the first-order approximation of changes in real GDP while holding fixed the prices P^{rGDP} , P_0^s , and P^s :

$$\text{dlog}(\text{rGDP}) = \sum_{s=1}^S \frac{P_0^s Y^s}{\text{GDP}} \text{dlog}(Y^s) - \sum_{s'=1}^S \frac{P^{s'} M^{ss'}}{\text{GDP}} \text{dlog}(M^{ss'}).$$

Note that the first-order approximation of the production function is:

$$\text{dlog}(Y^s) = \text{dlog}(A^s) + s_L^s \text{dlog}(L^s) + \sum_{s'=1}^S s_M^{ss'} \text{dlog}(M^{ss'}).$$

As tariffs are the only exogenous shock to the model, we set $d \log(A^s) = 0$. Further note that $P^{s'} M^{ss'} = s_M^{ss'} P_0^s Y^s$ and $w^s L^s = s_L^s P_0^s Y^s$. These imply that:

$$\text{dlog}(\text{rGDP}) = \sum_{s=1}^S \frac{w^s L^s}{\text{GDP}} \text{dlog}(L^s).$$

Real Income. We measure real income (real GNI) with the ratio of nominal income (the sum of labor income, foreign transfer, and tariff revenue) to the consumer price index:

$$\text{rGNI} = \frac{\sum_{s=1}^S w^s L^s + TD + TR}{P}.$$

Decomposition 1. Extending Caliendo and Parro (2015) by considering varying aggregate labor supply, the first-order approximation of changes in real GNI is the following:

$$\text{dlog}(\text{rGNI}) = \underbrace{\sum_{s=1}^S \frac{w^s L^s}{\text{GNI}} \text{dlog}(L^s)}_{\text{Labor Supply}} + \underbrace{\frac{1}{\text{GNI}} \left(\sum_{s=1}^S \sum_{i \in \Xi_F} \sum_{l \in \Omega_i^s} T_{il}^s t_{il}^s \text{dlog}(T_{il}^s) - \sum_{s=1}^S E_{F0}^s \text{dlog}(Y_{F0}^s) \right)}_{\text{Terms of Trade}}. \quad (\text{B.23})$$

On the right-hand side, the employment effect summarizes changes in real income associated with sector employment changes. This term is identical to changes in real GDP. The only difference is that the denominator for changes in real GNI is nominal GNI, whereas the denominator for changes in real GDP is nominal GDP.

While sectoral employment changes are sufficient to summarize changes in real GDP (and aggregate employment), the terms of trade effect indicates that tariffs contribute to real GNI through not only the employment effect but also changes in foreign and domestic prices. In this term, $T_{il}^s = p_{il}^s y_{il}^s$ denotes the product–country-level import value before tariffs, $t_{il}^s = 1 + \tau_{il}^s$, where τ_{il}^s denotes tariffs, E_{F0}^s denotes the value of sectoral exports, and Y_{F0}^s denotes its quantity. Lower import prices are associated with more import and higher export prices are associated with less export. Both cases imply improvements in the terms of trade and an increase in real GNI.

Decomposition 2. Alternatively, we can decompose the real income change with the following formula:

$$\begin{aligned} d\log(rGNI) = & \underbrace{\sum_{s=1}^S \frac{w^s L^s}{GNI} d\log(L^s)}_{\text{Labor Supply}} - \underbrace{\frac{1}{GNI} \sum_{s=1}^S \sum_{i \in \Xi_F} \sum_{l \in \Omega_i^s} T_{il}^s t_{il}^s d\tau_{il}^s}_{\text{Importer}} + \underbrace{\frac{1}{GNI} \sum_{s=1}^S E_{F0}^s d\log(P_0^s)}_{\text{Exporter}} \\ & + \underbrace{\frac{1}{GNI} dTR}_{\text{Tariff Revenue}} + \underbrace{\frac{1}{GNI} dTD}_{\text{Foreign Transfer}}. \end{aligned} \quad (\text{B.24})$$

Proof: The first-order approximation of GNI is the following::

$$d\log(rGNI) = \sum_{s=1}^S \frac{w^s L^s}{GNI} (d\log(w^s) + d\log(L^s)) + \frac{dTD}{GNI} + \frac{dTR}{GNI} - d\log(P). \quad (\text{B.25})$$

The change in trade deficit is:

$$dTD = \sum_{s=1}^S \sum_{i \in \Xi_F} \sum_{l \in \Omega_i^s} T_{il}^s d\log(T_{il}^s) - \sum_{s=1}^S E_{F0}^s (1 - \sigma^s) d\log(P_0^s).$$

The change in tariff revenue is:

$$dTR = \sum_{s=1}^S \sum_{i \in \Xi_F} \sum_{l \in \Omega_i^s} \tau_{il}^s T_{il}^s d \log(T_{il}^s) + \sum_{s=1}^S \sum_{i \in \Xi_F} \sum_{l \in \Omega_i^s} T_{il}^s t_{il}^s d \log(t_{il}^s).$$

The change in consumer price is:

$$d \log(P) = \sum_{s=1}^S \alpha^s d \log(P^s), \quad (\text{B.26})$$

in which the change in sectoral input price is:

$$d \log(P^s) = s_0^s d \log(P_0^s) + \sum_{i \in \Xi_F} \sum_{l \in \Omega_i^s} s_i^s s_{li}^s d \log(t_{il}^s).$$

Now substitute the final expenditure share in Equation (B.26). Note that:

$$X^s = P^s C^s + \sum_{s'=1}^S s_M^{s's} P_0^{s'} Y^{s'},$$

where $P_0^s Y_0^s$ denotes sector s output. Therefore,

$$\alpha^s = \frac{P^s C^s}{GNI} = \frac{1}{GNI} (X^s - \sum_{s'=1}^S s_M^{s's} P_0^{s'} Y^{s'}).$$

Plug this into Equation (B.26):

$$d \log(P) = \sum_{s=1}^S \frac{X^s}{GNI} \left(s_0^s d \log(P_0^s) + \sum_{i \in \Xi_F} \sum_{l \in \Omega_i^s} s_i^s s_{li}^s d \log(t_{il}^s) \right) - \frac{1}{GNI} \sum_{s=1}^S \sum_{s'=1}^S s_M^{s's} P_0^{s'} Y^{s'} d \log(P^s).$$

We can simplify the last term:

$$\begin{aligned} \sum_{s=1}^S \sum_{s'=1}^S s_M^{s's} P_0^{s'} Y^{s'} d \log(P^s) &= \sum_{s'=1}^S P_0^{s'} Y^{s'} (d \log(P_0^{s'}) - s_L^{s'} d \log(w^{s'})) \\ &= \sum_{s'=1}^S P_0^{s'} Y^{s'} d \log(P_0^{s'}) - \sum_{s'=1}^S w^{s'} L^{s'} d \log(w^{s'}). \end{aligned}$$

Plug these into Equation (B.25):

$$\begin{aligned}
d\log(rGNI) &= \sum_{s=1}^S \frac{w^s L^s}{GNI} d\log(L^s) + \sum_{s=1}^S \frac{w^s L^s}{GNI} d\log(w^s) \\
&+ \frac{1}{GNI} \sum_{s=1}^S \sum_{i \in \Xi_F} \sum_{l \in \Omega_i^s} T_{il}^s d\log(T_{il}^s) - \frac{1}{GNI} \sum_{s=1}^S E_{F0}^s (1 - \sigma^s) d\log(P_0^s) \\
&+ \frac{1}{GNI} \sum_{s=1}^S \sum_{i \in \Xi_F} \sum_{l \in \Omega_i^s} \tau_{il}^s T_{il}^s d\log(T_{il}^s) + \frac{1}{GNI} \sum_{s=1}^S \sum_{i \in \Xi_F} \sum_{l \in \Omega_i^s} X^s s_i^s s_{li}^s d\log(t_{il}^s) \\
&- \sum_{s=1}^S \frac{X^s}{GNI} \left(s_0^s d\log(P_0^s) + \sum_{i \in \Xi_F} \sum_{l \in \Omega_i^s} s_i^s s_{li}^s d\log(t_{il}^s) \right) \\
&+ \frac{1}{GNI} \sum_{s=1}^S P_0^s Y^s d\log(P_0^s) - \frac{1}{GNI} \sum_{s=1}^S w^s L^s d\log(w^s).
\end{aligned}$$

Collecting terms, we get:

$$d\log(rGNI) = \sum_{s=1}^S \frac{w^s L^s}{GNI} d\log(L^s) + \frac{1}{GNI} \sum_{s=1}^S \sigma^s E_{F0}^s d\log(P_0^s) + \frac{1}{GNI} \sum_{s=1}^S \sum_{i \in \Xi_F} \sum_{l \in \Omega_i^s} t_{il}^s T_{il}^s d\log(T_{il}^s),$$

which is Equation (B.23). Alternatively, if we do not plug in the expressions for dTD and dTR , we get Equation (B.24).

Consumption-Equivalent Welfare. Since the model incorporates labor supply decisions, we measure welfare in consumption-equivalent terms, following Lucas (1987) and Jones and Klenow (2016). Given a welfare change $\hat{W}$, we determine the change in consumption while keeping labor constant at the baseline equilibrium level, ensuring that the model predicts the same welfare change.

The household's problem implies the following welfare function:

$$W = \left(\sum_{s=1}^S \left(C^s - \frac{\psi^s}{1 + \psi^s} (l^s)^{\frac{1+\psi^s}{\psi^s}} \right)^\mu \right)^{\frac{1}{\mu}}. \quad (\text{B.27})$$

The household budget constraint and labor supply decision, Equations (10) and (B.1),

imply that:

$$l^s = \left(\frac{C^s}{1 - \delta} \right)^{\frac{\psi^s}{1 + \psi^s}}.$$

Plugging this into Equation (B.27), the welfare when consumption becomes $\tilde{C}^s$ but leisure remains the same as before is:

$$\tilde{W} = \left(\sum_{s=1}^S \left(\tilde{C}^s - \frac{1}{1 - \delta} \frac{\psi^s}{1 + \psi^s} C^s \right)^\mu \right)^{\frac{1}{\mu}}.$$

The welfare change, $\hat{W}$, is given by the ratio of $\tilde{W}$ to W :

$$\hat{W} = \frac{\tilde{W}}{W} = \left(\sum_{s=1}^S s_L^s \left(\frac{1 - \delta}{1 - \delta - \frac{\psi^s}{\psi^s + 1}} \hat{C}^s - \frac{\frac{\psi^s}{1 + \psi^s}}{1 - \delta - \frac{\psi^s}{\psi^s + 1}} \right)^\mu \right)^{\frac{1}{\mu}},$$

where $\hat{C}^s = \frac{\tilde{C}^s}{C^s}$. We compute $\hat{W}$ in the counterfactual equilibrium. In the end, we solve $\hat{C}^s$, which is the consumption-equivalent welfare change.

B.5 Comparing the Model to Caliendo and Parro (2015) and Caliendo et al. (2019)

Our model and estimation strategy are different from those of Caliendo and Parro (2015) and Caliendo et al. (2019) in three significant ways. First, we incorporate the substitutability among the final output and the complementarity among the inputs. Second, we introduce flexible labor supply decisions, which enable us to better understand the aggregate employment outcomes. Third, we employ the difference-in-differences method to credibly estimate trade and labor supply elasticities.

Table C.5 shows that a model using Cobb-Douglas production and consumption functions (as in Caliendo and Parro 2015, Caliendo et al. 2019) significantly underpredicts downstream employment losses while significantly overpredicting midstream and upstream employment gains. When final goods are substitutable, an increase in downstream costs leads to substantial substitution away from the downstream sector, resulting in greater downstream

employment losses. This decline in downstream sales reduces the demand for midstream and upstream outputs, thereby reducing the employment effects in these sectors. Furthermore, with complementarity between labor and inputs from upstream sectors for midstream firms, an increase in midstream wages decreases the demand for inputs from upstream sectors, further reducing the upstream employment gains. Without accounting for final goods substitutability and input complementarity, the employment effects across the entire supply chain are biased upward.

Without incorporating labor supply decisions, the model cannot generate aggregate employment effects. The labor supply problem is flexible enough to accommodate sector-specific labor supply elasticities. Without accounting for such heterogeneity, the model overestimates the midstream wage response and underestimates the aggregate employment gains from AD policy.⁷⁷

For most sectors, our estimated trade elasticities are lower than those in Caliendo and Parro (2015), Caliendo et al. (2019) (Section C.2). For instance, their trade elasticity estimates exceed 10 for the computer, electrical, and machinery equipment sectors. A notable difference is that their estimates likely include the impact of both tariffs and trade policy uncertainties, leading to higher estimated trade elasticities.

C Calibration Appendix

C.1 Externally Calibrated Parameters

We calibrate the baseline economy to Brazilian macroeconomic statistics in 1995, which is the initial year of our database. We let each sector $s \in \{1, 2, \dots, S - 1\}$ refer to a Classificação Nacional de Atividades Econômicas (CNAE) 2.0 4-digit goods sector. $s = S$ represents the combined service sector. The input-output coefficient, $s_M^{ss'}$, is taken from the input-output table. We let each product l represent a Harmonized System (HS) 6-digit product. With a concordance table between HS codes and CNAE 2.0 4-digit sectors from the IBGE (the Brazilian Institute of Geography and Statistics), we calculate the sector-level exports E_{0F}^s .

⁷⁷See Tables C.5 and C.7.

We obtain the Brazilian population and the share of the population that is not working from the IPEA database, a macroeconomic, social, and regional database maintained by the Brazilian government.⁷⁸ We compute the sector population share κ^s with RAIS and the total population. We further compute both the sector-level consumption expenditure share α^s and the labor and input shares in gross output, s_L^s and s_M^s , from the estimated input-output table. We calibrate the expenditure shares on countries and products, s_i^s and s_{il}^s , by merging the estimated input-output table with sector- and product-level import data. We calibrate the social insurance tax rate to the variable “government transfer rate” (“Renda de transferências governamentais”) in the IPEA’s database, which was 10.3% in 1995. Using the government budget constraint (as denoted by Equation (14)), we calibrate social insurance b to be 668.54 (Brazilian reais).⁷⁹ We calibrate the elasticity of the non-working population with respect to the social insurance, μ , to the literature studying the cost of public funds (Kleven and Kreiner 2006) and set it to 0.2.

C.2 Estimation of Cross-Product, Trade, and Labor Supply Elasticities

We classify CNAE 2.0 sectors into six broad sectors based on their definition, and we estimate these elasticities for each broad sector.⁸⁰ Table C.1 presents the concordance between the broad sectors and CNAE 2.0 2-digit sectors.

Table C.1: **Concordance Between Broad Sectors and CNAE 2.0 2-digit Sectors**

No.	Broad Sector Name	2 Digit CNAE 2.0 Sectors
1	Agriculture, Mining, Food and Textiles	1-14
2	Leather, Wood and Paper	15-18
3	Petrochemicals	19-21
4	Mineral and Metal Products	22-25
5	Computer, Electrical and Machinery Equipment	26-28
6	Automobiles and Transportation Equipment	29-33
7	Service	35-97

Description: This table presents the concordance between (a) the broad sectors at which level we estimate the trade and labor supply elasticities and (b) the CNAE 2.0 2-digit sectors.

⁷⁸<http://www.ipeadata.gov.br/Default.aspx> is the link to the IPEA database.

⁷⁹More specifically, the unit of value for this amount is 1995 Brazilian Real per annum.

⁸⁰That is, we assume that the elasticities are heterogeneous across the broad sectors but remain the same

Elasticity of Substitution across Products. We estimate the elasticity of substitution across products, ζ^s , with the effect of AD tariffs on product-level imports from a given country. Taking the log of Equation (B.7) and adding controls as in our specification in Equation (1), we have:

$$\log(x_{i,l,t}^s) = (1 - \zeta^s) \log(t_{i,l,t}^s) + \beta_2^s \mathbb{I}_{i,l,t}^s \{\text{After AD}\} + \beta_3^s \mathbb{N}_{i,l,t}^s \{\text{No. of AD}\} + \Phi_{i,t}^s + \eta_{i,l}^s + \epsilon_{i,l,t}^s,$$

where $x_{i,l,t}^s$ are the imports of product l from country i in quarter t ; $1 - \zeta^s$ is the effect of AD tariffs on imports; $\Phi_{i,t}^s$ summarizes the sector–origin–quarter-level price index, the sector–origin-level expenditure, and other factors that are common to all products in the same sector from the same origin (see Equation (B.7)); and $\eta_{i,l}^s$ denotes the origin–product-level fixed effect. To address the potential correlation between the error term and tariffs, we implement a difference-in-differences strategy, as before, adding $\mathbb{I}_{i,l,t}^s \{\text{After AD}\}$ (a dummy that takes a value of 1 after the first AD investigation) and $\mathbb{N}_{i,l,t}^s \{\text{No. of AD}\}$ (the number of AD investigations) as the control. We constrain our sample to the set of products under investigation. The identification assumption is that, conditional on AD investigations, shocks to the origin–product-level consumer preference and the international price (including non-tariff trade barriers) are not correlated with contemporaneous AD tariff changes.

Elasticity of Substitution across Countries. We estimate the trade elasticity, σ^s , which captures how easily sector-level imports can be substituted across different countries. We show that σ^s can be identified from the effect of AD tariffs on imports at the country level.

Taking logs of Equation (B.5) and adding controls, we have:

$$\log(x_{i,t}^s) = (1 - \sigma^s) \log(t_{i,t}^s) + \beta_2^s \mathbb{I}_{i,t}^s \{\text{After AD}\} + \beta_3^s \mathbb{N}_{i,t}^s \{\text{No. of AD}\} + \Phi_t^s + \eta_i^s + \epsilon_{i,t}^s,$$

where $x_{i,t}^s$ denotes imports of sector s from country i in quarter t ; $t_{i,t}^s$ is the average AD tariffs at the country–sector–quarter level;⁸¹ $1 - \sigma^s$ captures the effect of AD tariffs on

within each broad sector.

⁸¹Formally, $t_{i,t}^s = \sum_{l \in \Omega_i^s} s_{i,l,t-1}^s t_{i,l,t}^s$, where $s_{i,l,t-1}^s$ denotes the share of product l in sector s imports from country i in year $t - 1$.

country-level imports; Φ_t^s is a sector–quarter fixed effect capturing the sectoral import price index, expenditure, and other factors that are common to all origin countries (see Equation (B.5)); η_i^s is an origin–sector fixed effect; $\mathbb{I}_{i,t}^s \{\text{After AD}\}$ is a dummy taking a value of 1 after the first AD investigation happens in sector s and targets country i ; and $\mathbb{N}_{i,t}^s \{\text{No. of AD}\}$ counts the number of AD investigations that target country i and sector s in quarter t . The identification assumption is that, conditional on AD investigations, shocks to the origin-level consumer preference and international price (including non-tariff trade barriers) are not correlated with contemporaneous AD tariff changes.

Table C.2: **Elasticity of Substitution across Products**

Sector name	ζ^s	Standard Err.
Agriculture, Mining, Food and Textile	8.005	(2.514)
Wood and Paper	2.185	(0.801)
Petrochemicals	1.547	(0.435)
Minerals and Metals	1.152	(0.451)
Computer, Electrical and Machinery Equipment	5.062	(1.714)
Automobiles and Transportation Equipment	1.808	(0.601)
All Sectors	1.633	(0.338)

Description: This table presents the elasticity of substitution across products for CNAE 2.0 4-digit sectors. The elasticities are assumed to be the same within each broad sector but vary across broad sectors. Standard errors are clustered at the product–origin level.

Table C.2 shows that the elasticities of substitution across products range from 1.152 for minerals and metals to 8.005 for agriculture, mining, food, and textiles. These results are consistent with the intuition that products in primary sectors (harvesting and extracting natural resources) are more substitutable than those in secondary sectors (manufacturing and processing). The cross-sector average elasticity of substitution across products is 1.633. This low estimate is consistent with the non-significant trade diversion to other products that we discovered, as noted in Section 4.1.

Table C.3: **Trade Elasticity**

Sector name	σ^s	Standard Err.
Agriculture, Mining, Food and Textile	2.044	(0.260)
Wood and Paper	3.060	(0.414)
Petrochemicals	1.339	(0.176)
Minerals and Metals	2.338	(0.171)
Computer, Electrical, and Machinery Equipment	5.158	(1.147)
Automobiles and Transportation Equipment	2.248	(0.350)
All Sectors	2.054	(0.091)

Description: This table presents the elasticity of substitution across countries for CNAE 2.0 4-digit sectors. The elasticities are assumed to be the same within each broad sector but vary across broad sectors. Standard errors are clustered at the CNAE 2.0 4-digit sector level.

Table C.3 shows that the elasticities of substitution across countries range from 1.339 for petrochemicals to 5.158 for computer, electrical, and machinery equipment. For all sectors except agriculture, mining, food, textiles, and petrochemicals, the cross-country elasticity is higher than the cross-product elasticity. This suggests that within each non-primary 4-digit sector, imports are more homogeneous across countries than across products. The cross-sector average elasticity of substitution across countries is 1.633, which is consistent with the limited trade diversion to other countries reported in Section 4.1.

Labor Supply Elasticity. The labor supply elasticity, λ^s , can be identified from the effects of AD tariffs on wages and employment. Equation (13) shows the relationship between sectoral employment and wages. Taking the log of that equation and adding controls, we get:

$$\log(w_{i,t}^s) = \frac{1}{\lambda^s} \log(L_{i,t}^s) + \beta_2^s \mathbb{I}_{i,t}^s \{\text{After AD}\} + \beta_3^s \mathbb{N}_{i,t}^s \{\text{No. of AD}\} + \eta_i + \Psi_t^s + \epsilon_{i,t}^s,$$

where $w_{i,t}^s$ is wages at firm i in sector s in year t ; $L_{i,t}^s$ is employment at firm i in sector s in year t ; η_i is a firm fixed effect; and Ψ_t^s is a year fixed effect. We implement the same identification strategy and control for exposure to an AD investigation with $\mathbb{I}_t^s \{\text{After AD}\}$.

We instrument employment at the firm, $L_{i,t}^s$, with AD tariffs in sector s , t_t^s .⁸² AD tariffs

⁸²Because the service sector has no product that is subject to an AD tariff, we instrument service sector

affect employment at the firm level, satisfying the relevance condition, and are unlikely to be correlated with other firm-level shocks, satisfying the exogeneity condition.

Table C.4 shows that labor supply elasticities are heterogeneous across sectors, ranging from 0.678 to 1.666. Our estimates are higher than the micro estimates, but lower than the macro elasticities (see Chetty et al. 2011 for a summary of these elasticities). Our numbers are close to those of Eckert (2019), who studies the elasticity of workers' sector choice to sector income and finds an elasticity of around 1.1 to 1.5.⁸³ Figure C.1 shows that relatively downstream sectors have weakly lower labor supply elasticities but larger elasticities of substitution across products and across countries.⁸⁴

Table C.4: **Labor Supply Elasticity**

Sector name	Implied λ^s	Standard Err.
Agriculture, Mining, Food and Textile	1.009	(0.199)
Wood and Paper	0.678	(0.354)
Petroleum and Chemicals	0.771	(0.572)
Minerals and Metals	1.666	(0.242)
Computer, Electrical and Machinery Equipment	1.592	(0.251)
Automobiles and Transportation Equipment	0.943	(0.123)
All Non-service Sectors	1.115	(0.083)
Service	0.431	(0.038)

Description: This table presents the labor supply elasticity for CNAE 2.0 4-digit sectors. The elasticities are assumed to be the same within each broad sector but vary across broad sectors. Standard errors are clustered at the firm level.

C.3 Model Estimation

We use the following algorithm to estimate the parameters. We guess a set of parameters, $\{\rho, \theta\}$, and we provide sector-level annual tariffs, $\{\tau_t^s\}$, to the model.⁸⁵ For each year, we solve the counterfactual equilibrium with the model in changes (Section B.3). Then, we run

employment with upstream tariffs, as discussed in Section 3.

⁸³Eckert (2019) assumes that labor supply elasticity is the same across all sectors but is heterogeneous across worker skill groups.

⁸⁴We measure how upstream a sector is by taking advantage of the procedure in Fally (2011), Antràs et al. (2012), and Antràs and Chor (2013). The upstreamness measure computes the average number of sectors that one dollar of a sector's output passes through to arrive at final demand (we present more details in Section C.4).

⁸⁵We construct the sector-level tariffs with the country–sector–product level tariffs, $\{\tau_{il}^s\}_{i,l,s}$, as we discussed in Section 6.

the same panel regression in the model as in the data:⁸⁶

$$y_{s,t}^u = \beta^u \tilde{\tau}_{s,t}^u + \eta_s^u + \eta_t^u + \epsilon_{s,t}^u, u \in \{mid, down, up\}. \quad (C.1)$$

On the left-hand side, $y_{s,t}^u$ denotes the sectoral variable of interest in the targeted and non-targeted moments. They include employment, the wage bill, imports, and exports in the midstream, main upstream, and main downstream sectors (all in logs). On the right-hand side, $\tilde{\tau}_{s,t}^u$ denotes the exposures to midstream, downstream, and upstream tariffs:

$$\tilde{\tau}_{s,t}^u = \begin{cases} \tau_{s,t}, & u = mid \\ \frac{\text{Input Demand of Sector } d(s) \text{ from Sector } s}{\text{Aggregate Input Demand of Sector } d(s)} \times \tau_{s,t}, & u = down \\ \frac{\text{Sales to Sector } s \text{ from Sector } u(s)}{\text{Production of Sector } u(s)} \times \tau_{s,t}, & u = up. \end{cases}$$

η_s^u denotes the sector fixed effect and η_t^u denotes the time fixed effect.

We also include in the non-targeted moments the elasticity of sectoral employment with respect to midstream, average upstream, and average downstream tariffs when the three tariffs enter the right-hand side of the regression at the same time. We apply the following specification to the model-simulated data:

$$y_{s,t} = \beta_1 \tau_{s,t}^{mid} + \beta_2 \tilde{\tau}_{s,t}^{up} + \beta_3 \tilde{\tau}_{s,t}^{down} + \eta_s + \eta_t + \epsilon_{s,t}, \quad (C.2)$$

where $\tilde{\tau}_{s,t}^{up}$ denotes the downstream tariffs faced by upstream firms and $\tilde{\tau}_{s,t}^{down}$ denotes the upstream tariffs faced by downstream firms. Similarly to how we construct these tariffs in the empirical section, they are calculated as follows:

$$\tilde{\tau}_{s,t}^{up} = \sum_k \frac{\text{Sales of Sector } s \text{ to Sector } k}{\text{Aggregate Sales of Sector } s} \times \tau_{k,t},$$

⁸⁶As AD tariffs are the only shock in this counterfactual exercise, parallel trends between the treatment and control groups in the model-simulated data are naturally guaranteed. Therefore, we do not control the investigations in these regressions with model-simulated data.

$$\tilde{\tau}_{s,t}^{down} = \sum_k \frac{\text{Input Demand of Sector } s \text{ from Sector } k}{\text{Aggregate Input Demand of Sector } s} \times \tau_{k,t}.$$

With the model moments computed with the model-simulated data and these regressions, we search for the parameters that minimize the sum of the squared normalized distance between these targeted moments in the model and in the data:

$$\min_{\rho, \theta} \left(\frac{\beta_{\text{data}}^{\text{mid,emp}} - \beta_{\text{model}}^{\text{mid,emp}}}{\beta_{\text{data}}^{\text{mid,emp}}} \right)^2 + \left(\frac{\beta_{\text{data}}^{\text{down,emp}} - \beta_{\text{model}}^{\text{down,emp}}}{\beta_{\text{data}}^{\text{down,emp}}} \right)^2$$

s.t. Equilibrium constraints in Section B.3.

To compute the standard errors of the estimated parameters, we bootstrap the AD tariffs on the year level; that is, for each bootstrapped sample, we randomly draw years (with replacement) from the original database and impose all sectoral tariffs in that year.⁸⁷ By doing so, we ensure that every sector in the bootstrapped sample faces the factual midstream, upstream, and downstream tariffs in the year when the sample was drawn. With the standard errors, we can compute the 95% confidence interval of our estimates.

In Table C.5, we present how the model matches the targeted and non-targeted moments. We also show how we calibrate alternative model specifications and their ability to match these moments. We find that the baseline model performs better than alternative models in matching most of the non-targeted moments.

⁸⁷See Blume et al. (2008) for a survey of indirect inference and bootstrap methods used in macroeconomics.

Table C.5: Targeted and Non-targeted Moments, Data and Model

Moment Names	(1) Data	(2) Baseline Model	(3) Same Input and Final Elasticity	(4) Sector-specific Input Elasticity	(5) Same Labor Supply Elasticity	(6) Same Trade Elasticity	(7) No Input-output	(8) Cobb-Douglas Input and Final Demand

Description: This table presents the targeted and non-targeted moments in the data and in the model. Moments 1–8 refer to the elasticities of midstream, main downstream, and main upstream employment, wage bill, exports, and imports with respect to midstream tariffs. Moments 9–11 refer to the joint impact of midstream, average downstream, and average upstream tariffs. The data moments (Column 1) refer to the corresponding estimated coefficients that are presented in the empirical section. The model moments (Columns 2–8) refer to those estimated with the model-simulated data. The row “Targeted Moments” shows the moments that the models target to estimate the parameters, the values of which are reported in the row “Estimated Parameter Values”. Specifically, Column 4 assumes that the sector-specific elasticity of substitution across inputs is log linear in sector upstreamness. The employment elasticity with respect to average tariffs refers to the joint impact of own sector, average upstream, and average downstream tariffs.

C.4 Sector Upstreamness

We follow the procedure outlined by Fally (2011), Antràs et al. (2012), and Antràs and Chor (2013) to compute sector upstreamness. Upstreamness measures the average number of sectors that one dollar of a sector’s output passes through to reach the final demand. If a sector’s output is used solely for the final demand, its upstreamness is equal to 1. If a sector sells to other sectors, its upstreamness exceeds 1. The higher the upstreamness measure, the greater the share of output sold to other sectors, indicating a more upstream position for the sector.

To compute the fraction of a sector’s output used in other sectors, we rely on the input-output coefficients $s_M^{ss'}$. Following the approach in the literature, we adjust the coefficients to take into account imports and exports with $\tilde{s}_M^{ss'} = s_M^{ss'} \frac{P_0^s Y_0^s}{P_0^s Y_0^s - E_{F0}^s + X^s(1 - s_0^s)}$, where $P_0^s Y_0^s$ denotes gross output, E_{F0}^s denotes total export in sector s , and $X^s(1 - s_0^s)$ denotes sector s total import. The denominator is therefore the total domestic absorption of sector s output.

Finally, the sector upstreamness is:

$$\vec{U} = (I - \tilde{\Gamma}')^{-1} \vec{Y} ./ \vec{Y},$$

where $./$ denotes element-wise division, the $s - s'$ element of $\tilde{\Gamma}$ is $\tilde{s}_M^{ss'}$, and I is an identity matrix.

In Figure C.1, we plot the correlations of the estimated elasticity of substitution across products, trade elasticity, and labor supply elasticity, with sector upstreamness.

Figure C.1: Correlation Between Product, Trade and Labor Supply Elasticities and Sector Upstreamness

Description: This figure shows the correlations of the estimated elasticity of substitution across products, trade elasticity, and labor supply elasticity, with sector upstreamness. To measure sector upstreamness on the broad sector level—the same level on which the elasticities are estimated—we first compute the upstreamness measure on the CNAE2.0 4-digit sector level with the input-output table and sectoral imports and exports (see Section C.4 for details). Then, we calculate the weighted average upstreamness for each sector for which the weight is equal to a CNAE2.0 4-digit sector’s share in the broad sector.

C.5 Optimal Tariffs Problem

A country’s policymaker maximizes changes in the following aggregate variables (defined in Section B.4):

1. Total employment: $d\log(L^e)$, or
2. GDP: $d\log(rGDP)$, or
3. Real income: $d\log(rGNI)$, or
4. Welfare: $d\log(W)$

subject to the following equilibrium constraints: changes in prices summarized in Equations (B.14), (B.15), (B.16), market clearing conditions (B.17) and (B.18), and the government

budget constraint (B.19). Furthermore, the government satisfies the additional fiscal constraint, in that the government collects the same tariff revenue as from the baseline tariffs:

$$TR' = TR'^{\text{benchmark}},$$

where TR' follows Equation (B.20) and $TR'^{\text{benchmark}}$ is the value of TR' under baseline tariffs.

C.6 Quantitative Results

C.6.1 Understanding the Greater Welfare Effects of AD Policy Compared to Previous Works

We find a greater welfare loss from AD policies compared to Egger and Nelson (2011) because we measure welfare in consumption-equivalent terms and account for input-output linkages. Since our model considers labor supply decisions, welfare should be measured in terms of consumption while holding the labor supply fixed (Lucas 1987, Jones and Klenow 2016). As AD policy increases employment and reduces the utility of leisure, consumption must decrease further for households to experience the same welfare change as if employment were fixed. This results in a greater consumption-equivalent welfare loss compared to real income. Furthermore, a model without input-output linkages ignores employment losses in downstream sectors and overestimates income and welfare. Figure C.2 shows that the loss in real income is lower than the consumption-equivalent welfare loss. Without input-output linkages, real income loss is reduced to -0.75%, similar to Egger and Nelson (2011)'s findings for developing countries. Substituting 1995's Brazilian trade shares with U.S. counterparts further reduces the real income loss to -0.49%, comparable to what they find for the U.S..

We also find a greater real income loss from tariffs than Gallaway et al. (1999) and Fajgelbaum et al. (2020), because we account for the endogenous decrease in foreign transfers (trade deficit) due to tariffs; however, both models (with and without endogenous trade balance adjustment) predict significant welfare loss in consumption-equivalent terms.⁸⁸ In our small open economy model, since foreign income is fixed, foreign transfers (trade deficits) endogenously respond to and decrease with tariffs. This assumption regarding the trade

⁸⁸Fajgelbaum et al. (2020) study the 2018 U.S.-China trade war, but the scope and magnitude of the

Figure C.2: **Welfare Effects of AD Policies in Different Models**

Description: This figure shows the welfare effects of AD policies as predicted by different models.

balance is also imposed in Dhyne et al. (2023). In contrast, their models assume that foreign transfers remain fixed regardless of tariff changes. To maintain a fixed trade balance in their models, the country needs to receive an extra transfer from abroad and workers need to work more to earn higher income and increase imports. This is accompanied by wage increases, which reduce exports. The lack of a decrease in foreign transfers and the increased income both significantly reduce the real income loss from tariffs. However, in this model, workers have to increase the labor supply more than tenfold compared to the labor supply increase in the baseline model, leading to significant welfare loss in consumption-equivalent terms, even with a fixed trade balance (-1.88%).

Welfare Effects of AD Policy in a Model with Fixed Trade Balance. We modify Equation (B.21) so that the trade deficit in the counterfactual equilibrium is equal to that in the baseline equilibrium, incorporating a transfer from the rest of the world:

$$TD = \sum_{s=1}^S \sum_{i=1}^N \sum_{l \in \Omega_i^s} p_{il}^{s'} y_{il}^{s'} - \sum_{s=1}^S (\hat{P}_0^s)^{1-\sigma^s} E_{F0}^s + T',$$

where variables with a “prime” denote their values in the counterfactual equilibrium. Specifically, T' represents the transfer from the rest of the world, ensuring that the trade balance remains fixed.

Table C.6: **Decomposing Welfare Changes in Baseline Model and Model with Fixed Trade Deficit**

	Labor Supply	Importer	Exporter	Tariff Revenue	Trade Deficit (Foreign Transfer)	Real Income	Consumption Equivalent Welfare
Baseline Model	0.03%	-1.46%	0.38%	0.69%	-0.96%	-1.32%	-2.43%
Model with Fixed Trade Deficit	0.37%	-1.46%	0.00%	0.73%	0	-0.3%	-1.88%

Description: This table shows the various components of the welfare effects of AD policy in the baseline model and in the model with fixed trade deficit. The decomposition is based on Equation (B.24).

As tariffs primarily reduce imports, without the additional transfer, the trade deficit must decrease. To maintain the same trade deficit, Brazil must receive an extra transfer from the rest of the world, which will likely reduce the real income loss from tariffs.

Table C.6 decomposes the effect of the AD policy on real income in both the baseline model and the model with a fixed trade balance. The model with a fixed trade balance predicts a much smaller real income loss but a similar welfare change in consumption-equivalent terms compared to the baseline model. This decomposition is based on Equation (B.24) and extends the analysis of Fajgelbaum et al. (2020).⁸⁹

In the baseline model, an increase in the household labor supply contributes weakly to real income. Importers lose, exporters gain, and the government collects tariff revenue. The increase in tariffs reduces foreign transfers (trade deficit), leading to significant income loss. Overall, the baseline model predicts a real income loss of 1.32% and a consumption-equivalent welfare loss of 2.43%.

In contrast, the model with a fixed trade balance is not affected by the income loss due to reduced foreign transfers and shows a larger increase in labor supply, resulting in a smaller predicted real income loss but still significant consumption-equivalent welfare loss. To maintain the same trade balance, workers need to work more to increase income and imports. This is accompanied by higher wages, which also reduce exports. These two channels cause the labor supply in this model to increase more than tenfold compared to the labor supply

trade war tariffs are comparable to those imposed under the AD policy in Brazil. The trade war tariffs affected 13% of U.S. imports, leading to an average price increase of 14% among the targeted varieties, while the U.S. import-to-GDP ratio was 15%. Similarly, in 1995, the AD policy in Brazil affected 6% of imports, with an average tariff increase of 14.3%, and Brazil's import-to-GDP ratio was 10.2%.

⁸⁹Neither Gallaway et al. (1999) nor Fajgelbaum et al. (2020) consider endogenous increases in the labor supply or trade balance adjustments in response to tariffs.

increase in the baseline model. Consequently, the real income loss from the AD policy in this model is much smaller (-0.3%) than in the baseline model, similar to Gallaway et al. (1999) and Fajgelbaum et al. (2020), who do not consider trade balance adjustment and income loss from reduced foreign transfers. However, due to a much larger decrease in leisure, the model with a fixed trade balance also predicts a significant consumption-equivalent welfare loss (-1.88%).

C.6.2 Impact of Brazilian Annual AD Tariffs

We calculate the AD tariffs imposed on each sector in each year by combining the product-country-level AD tariffs and using Equations (B.15) and (B.16). We simulate the model with these yearly tariffs and compute changes in the following aggregate variables: employment, real GDP, real income (GNI), and welfare.

Figure C.3 shows that in all years except 2004–2006, AD tariffs cause moderate aggregate employment gains and GDP gains. This indicates that the positive midstream employment effect outweighs the decline in downstream employment. However, AD tariffs cause larger annual real income and welfare losses. This indicates that the increase in consumer price due to more expensive imports dominates the rise in nominal income. Table C.3b shows that in an average year, the AD tariffs cause Brazil to gain 0.03% in employment and 0.02% in GDP, but lose 0.49% in real income and 0.92% in welfare..

Figure C.3: Aggregate Consequences of AD Tariffs

(b) Annual Average

Aggregate statistics	Employment	GDP	Real income	Welfare
Annual average	0.03%	0.02%	-0.49%	-0.92%
95%	0.02%	0.01%	-0.58%	-1.06%
Confidence interval	0.03%	0.04%	-0.40%	-0.78%

Description: Figure C.3a shows the impact of AD tariffs imposed in each year on aggregate employment, GDP, real income and welfare. Table C.3b shows the annual average of these aggregate consequences and the 95% confidence intervals of the means.

Alternative Model Specifications. Table C.7 shows that the alternative models (except for the one with sector-specific input elasticity) substantially misunderstand the aggregate effects of Brazilian AD policy.

Table C.7: Aggregate Consequences of Brazilian AD Policy in Different Model Specifications

Aggregate Consequence	(1) Baseline Model	(2) Same Input and Final Elasticity	(3) Sector-specific Input Elasticity	(4) Same Labor Supply Elasticity	(5) Same Trade Elasticity	(6) No Input-output	(7) Cobb-Douglas Input and Final Demand
Employment	0.06%	0.15% (126.97%)	0.06% (-2.35%)	-0.08% (-230.40%)	0.08% (22.02%)	0.15% (124.86%)	0.02% (-63.99%)
GDP	0.05%	0.11% (149.07%)	0.04% (-2.88%)	-0.13% (-377.84%)	0.12% (156.29%)	0.14% (199.65%)	0.08% (71.23%)
Real income	-1.32%	-1.35% (-2.48%)	-1.33% (-0.57%)	-1.54% (-16.45%)	-1.35% (-2.10%)	-0.75% (42.95%)	-1.36% (-3.08%)
Welfare	-2.43%	-2.40% (1.20%)	-2.44% (-0.58%)	-2.65% (-8.90%)	-2.68% (-10.13%)	-1.53% (37.10%)	-2.36% (2.83%)

Description: This table shows the impact of Brazilian AD policy in different model specifications. The value outside the parentheses refers to the level of the effect, and the value inside the parentheses refers to the percentage difference of the impact predicted by the alternative model relative to the absolute value of the impact predicted by the baseline model. For each sector, the Brazilian AD policy refers to the maximum AD tariff of all years.

C.6.3 Impact of Sectoral Tariffs

In Figure C.4a, we plot the aggregate consequences of 200% sectoral tariffs imposed on every CNAE 2.0 4-digit sector. We plot them against how upstream the sectors are. While the average impact of sectoral tariffs is small,⁹⁰ imposing tariffs on downstream sectors, for example, automobiles and transportation equipment as well as computer, electrical and machinery equipment, can significantly raise aggregate employment and GDP. At the same time, tariffs on upstream sectors, for example, petroleum and chemicals, significantly reduce aggregate employment and GDP. Table C.4b shows that the associations between aggregate employment and GDP effects of sectoral tariffs with sector upstreamness are negative (-0.3513 and -0.3193) and significant at 1% level. The negative correlations are robust to sector characteristic controls. In column 1 of Table C.8, we show the simple regression of the aggregate employment effects of sectoral tariffs on sector upstreamness. Columns 2 and 3 control for 2-digit sector fixed effects and broad sector fixed effects, respectively. Columns 4 to 6 show that protecting the sectors that are smaller, importing a larger share from abroad, and having a larger elasticity of substitution between domestic and foreign output can also lead to larger aggregate employment gains. Across all specifications, the correlation between aggregate employment effect and sector upstreamness is negative and significant.

In contrast, the impact of sectoral tariffs on real income and welfare is negative for almost all sectors. The associations between real income and welfare effects of sectoral tariffs with sector upstreamness are weakly positive. Taxing downstream sectors substitutes more imports with domestic labor, increases domestic prices, and harms domestic welfare. At the same time, taxing upstream sectors decreases employment in more downstream sectors by cutting wages, which leads to lower nominal income.

⁹⁰There are 297 CNAE 2.0 4-digit non-service sectors. Therefore, the average share of each of these sectors of the economy is small.

Figure C.4: **Aggregate Consequences of 200% Sectoral Tariffs**

(a) **Aggregate Consequences**

(b) **Correlation with Sector Upstreamness**

Aggregate statistics	Employment	GDP	Real income	Welfare
Correlation	-0.3513***	-0.3193***	0.0499	0.0350

Description: This figure shows the aggregate consequences of 200% sectoral tariffs imposed on every CNAE 2.0 sector. Panel (a) plots the employment, GDP, real income, and welfare effects on the vertical axis, and sector upstreamness on the horizontal axis. Each dot in the figure represents the average value in each 0.05 bin of sector upstreamness. Panel (b) shows the correlation between the aggregate consequences of sectoral tariffs and the upstreamness of the sector. *, **, and *** represent significance at the 0.1, 0.05, and 0.01 level.

To understand the sources of low correlation between sector upstreamness and the impact of sectoral tariffs on real income, in Figure C.5, we show that the impacts of these tariffs on both nominal income and consumer price are negatively correlated with sector upstreamness. Protecting downstream sectors leads to a greater increase in nominal income similar to the increase in total employment and GDP. However, it also increases the consumer price more. The higher nominal income and price offset each other in real terms, since real income equals nominal income divided by the consumer price level. Figure C.6 shows that the relationship also holds when we take the average of CNAE 2.0 4-digit sectors for each broad sector.

Figure C.5: Consequences of 200% Sectoral Tariffs on Nominal Income and Consumer Price

Description: This figure shows the impact of 200% sectoral tariffs imposed on every CNAE 2.0 4-digit sector on nominal income and consumer price. Changes in nominal income and consumer price due to the tariff changes are plotted on the vertical axis, and sector upstreamness is plotted on the horizontal axis.

Figure C.6: Consequences of 200% Sectoral Tariffs on Nominal Income and Consumer Price, Broad Sector Average

Description: This figure shows the impact of 200% sectoral tariffs imposed on every CNAE 2.0 4-digit sector on nominal income and consumer price. Changes in nominal income and consumer price due to the tariff changes are plotted on the vertical axis, and sector upstreamness is plotted on the horizontal axis. Averages are taken at the broad sector level.

Table C.8: **Correlation Between Aggregate Employment Effects of Sectoral Tariffs and Sector Characteristics**

VARIABLES	(1) Employment	(2) Employment	(3) Employment	(4) Employment	(5) Employment	(6) Employment
Upstreamness	-6.55e-05*** (1.01e-05)	-5.61e-05*** (1.97e-05)	-2.75e-05** (1.18e-05)	-6.59e-05*** (1.02e-05)	-4.09e-05*** (1.04e-05)	-4.11e-05*** (1.04e-05)
Employment share				-0.000133 (0.000207)		-3.84e-05 (0.000196)
Import share					4.38e-05 (3.85e-05)	4.35e-05 (3.86e-05)
Trade elasticity					3.97e-05*** (7.27e-06)	3.96e-05*** (7.29e-06)
Observations	298	295	297	298	298	298

Standard errors in parentheses						
*** p<0.01, ** p<0.05, * p<0.1						

Description: This table shows the correlation between the aggregate employment consequence of sectoral tariffs and sector characteristics including sector upstreamness, employment share in the economy, share of import, and trade elasticity.

C.6.4 Optimal AD Tariff Policy

Figure C.7a presents CNAE 2.0 4-digit sectoral optimal tariffs that maximize employment and GDP. They should be high for many downstream sectors in automobiles, transportation equipment, and agriculture, mining, food and textile. Sometimes, they even exceed 900%. Those on upstream sectors should be lower. For example, the employment-maximizing tariffs on petroleum and chemical sectors should be negative, which means that to increase employment, Brazil should decrease its MFN tariffs for these sectors. In contrast, optimal tariffs that maximize real income or welfare never exceed 100%, and they should be set as negative for many sectors.

Table C.7b shows that employment- and GDP-maximizing tariffs are strongly and negatively correlated with sector upstreamness, whereas real income- and welfare-maximizing tariffs are positively correlated with it. These findings are consistent with those discussed in Sections 7.2 and C.6.3, in that, compared to upstream sectors, imposing higher tariffs on downstream sectors increases employment and GDP but decreases real income and welfare.

In Table C.9 we present the correlations of these optimal tariffs with one another, with the benchmark tariffs, and with sector upstreamness. Employment-maximizing tariffs are positively correlated with GDP-maximizing tariffs and negatively correlated with real-income–

maximizing tariffs. They are weakly and positively correlated with welfare-maximizing tariffs.

Table C.9 also shows that the factual Brazilian AD tariffs are negatively associated with sector upstreamness, which suggests that employment may be a strong motivation driving AD tariffs. However, the levels of all actual tariffs stay below 500% (see the bottom right panel of Figure C.7a). This suggests that the Brazilian government is either prevented by WTO rules, bilateral/multilateral trade agreements, and domestic political institutions from further increasing tariffs, or concerned that raising tariffs may do additional harm to welfare.

Figure C.7: **Optimal Tariffs**

(a) **Sectoral Optimal Tariffs that Maximize Employment, GDP, Real Income, and Welfare**

(b) **Correlations of Sectoral Optimal Tariffs with Sector Upstreamness**

Optimal tariffs that maximize					
Correlation	Employment	GDP	Real income	Welfare	Benchmark tariffs
Sector upstreamness	-0.4979***	-0.4486***	0.4520***	0.1978***	-0.3381***

Description: This figure shows the sectoral optimal tariffs that maximize employment, GDP, real income, and welfare. The optimal tariffs solve a problem that maximizes the respective aggregate variable, subject to the equilibrium constraints and the additional constraint that the government collects the same tariff revenue as from the benchmark tariffs (see Section 7.3). The benchmark tariffs refer to, for each sector, the sector's maximum AD tariff for all years. Panel (a) plots these optimal tariffs against sector upstreamness, and Panel (b) presents the correlations.

Table C.9: **Correlations of Sectoral Optimal Tariffs**

		Optimal tariffs that maximize					
	Optimal tariffs that maximize	Employment	GDP	Real income	Welfare	Benchmark tariffs	Sector upstreamness
(1)	Employment	1.0000					
(2)	GDP	0.6754***	1.0000				
(3)	Real income	-0.3807***	-0.1054*	1.0000			
(4)	Welfare	0.0484	-0.2998***	-0.0936	1.0000		
(5)	Benchmark tariffs	0.2575**	0.1250	-0.1912	0.2005	1.0000	
(6)	Sector upstreamness	-0.4979***	-0.4486***	0.4520***	0.1978***	-0.3381***	1.0000

Description: This table shows the correlation of optimal tariffs that maximize employment, GDP, real income, and welfare, as well as benchmark tariffs and sector upstreamness. The optimal tariffs solve a problem that maximizes the respective aggregate variable, subject to the equilibrium constraints and the additional constraint that the government collects the same tariff revenue as from the benchmark tariffs (see Section 7.3) The benchmark tariffs refer to, for each sector, the sector's maximum AD tariff for all years.
