The Institute for the Study of Labor (IZA) in Bonn is a local and virtual international research center and a place of communication between science, politics and business. IZA is an independent nonprofit organization supported by Deutsche Post Foundation. The center is associated with the University of Bonn and offers a stimulating research environment through its international network, workshops and conferences, data service, project support, research visits and doctoral program. IZA engages in (i) original and internationally competitive research in all fields of labor economics, (ii) development of policy concepts, and (iii) dissemination of research results and concepts to the interested public.

IZA Discussion Papers often represent preliminary work and are circulated to encourage discussion. Citation of such a paper should account for its provisional character. A revised version may be available directly from the author.
ABSTRACT

Differences by Degree: Evidence of the Net Financial Rates of Return to Undergraduate Study for England and Wales

This paper provides estimates of the impact of higher education qualifications on the earnings of graduates in the UK by subject studied. We use data from the recent UK Labour Force Surveys which provide a sufficiently large sample to consider the effects of the subject studied, class of first degree, and postgraduate qualifications. Ordinary Least Squares estimates show high average returns for women that does not differ by subject. For men, we find very large returns for Law, Economics and Management but not for other subjects. Quantile Regression estimates suggest negative returns for some subjects at the bottom of the distribution, or even at the median in Other Social Sciences, Arts and Humanities for men. Degree class has large effects in all subjects suggesting the possibility of large returns to effort. Postgraduate study has large effects, independently of first degree class. A large rise in tuition fees across all subjects has only a modest impact on relative rates of return suggesting that little substitution across subjects would occur. The strong message that comes out of this research is that even a large rise in tuition fees makes little difference to the quality of the investment – those subjects that offer high returns (LEM for men, and all subjects for women) continue to do so. And those subjects that do not (especially OSSAH for men) will continue to offer poor returns. The effect of fee rises is dwarfed by existing cross subject differences in returns.

JEL Classification: I23, I28

Keywords: rate of return, college premium

1. Introduction

This paper provides simple statistical estimates of the correlation between earnings and educational qualifications in England and Wales\(^1\). We adopt regression methods applied to a conventional specification of a model of the determination of earnings\(^2\). There is a long history of such research in economics, including work that focuses on the impact of academic qualifications – for example, on the impact of an undergraduate degree on earnings, on average: the so-called “college premium”. The literature on the returns to education is well known (see Walker and Zhu (2008)) and reports either the effects of years of schooling or the effects of qualifications. This paper updates the results in Walker and Zhu (2008) with more recent data and exploits information of degree subject and the recent availability of degree class to extend that paper. Dearden et al (2010) also models the lifecycles of earnings of graduates and our work complements theirs by decomposing the calculations by degree subject and degree class. Our work is also more closely focused on the student and we therefore consider the impacts net of the income tax liability that applies at the simulated earnings.

The contribution of this paper is fourfold. First, we provide estimates of the college premium, the effect of postgraduate qualifications, and the attainment level of first degree, broken down by the broad subject of the first degree. Secondly, because we wish to make present value calculations and are therefore particularly interested in the lifecycle of earnings, we adopt a simple method that allows our data to identify the effects of experience on earnings separately from cohort effects in wages. Thirdly, we provide Quantile Regression estimates across the distribution of wages. Finally, we use our estimates to make crude comparisons of rates of return to higher education investments by subject and gender under alternative tuition fees.

The existing literature on the effect of “college major” is very thin (see Sloane and O’Leary (2005) and references therein) but the studies that do exist report large differentials by major of study. No studies, to our knowledge, make any attempt to deal with the complex selection issues associated with major choice. Nor do they allow for the impact of taxation or tuition fees. The literature on the impact of postgraduate qualifications on earnings is

---

\(^1\) We drop Scotland and Northern Ireland because of differences in their education systems – although including them makes little difference to our analysis.

\(^2\) This is the so-called human capital earnings function that restricts (log) earnings to be a linear function of a set of characteristics, \(X\), and a quadratic function of age (to proxy for work experience). We include qualifications variables into this model as measures of human capital.
similarly thin. A notable exception is Dolton et al (1990) for the UK but this uses a 1980 cohort of UK university graduates with earnings data observed just six years later so that they only identify qualification effects at a single, and early, point in the lifecycle – which we show below is a poor guide to lifecycle effects. There is a literature on the impact of college quality (see Eide et al (1998)) for the US. But the UK studies (Chevalier (2009) and Hussain et al (2009)) are again limited to postal surveys of graduates early in their careers.

The paper aims to inform the debate on higher education funding in the UK. We use the latest and largest available dataset and allow our specification of the effects of qualifications on wages to be as flexible as the data can sustain. The major weakness of the research is that we provide estimates of only correlations, not causal effects of subject of study – the “major”. So far little progress has been made in this direction, so we share our weakness with the existing literature. There is an “ability-bias” argument that suggests that our estimates may be an upper bound to the true effect. However, there is a limited amount of evidence from elsewhere that this weakness may not be very important (see Blundell et al (2005)) – at least in the simpler specifications that have been a feature of the previous literature. A further weakness is that we are not able to control for institutional differences: the data does not identify the higher education institution that granted the qualifications obtained. Again, this is a weakness that we share with the existing literature although there is a small literature on the effect of attending an elite college in the US (see, for example, Hoxby (2009)). In the UK this is also an important issue because it seems likely that there are important differences in the quality of student entrant by institution. Unfortunately, there is very limited data available on institution – the only systematic data is earnings recorded some six years after graduation but the response rate is poor and, as we will see below, early wages are not a good guide to lifecycle effects.

Section 2 reviews the data used here. Section 3 provides econometric estimates of the effects of the key determinants of wages. Section 4 uses these estimates to simulate crude lifecycles of earnings net of tax and tuition fees to allow us to compute private financial rates of return. Section 5 concludes.
2. Data

Our estimation uses a large sample of graduates (i.e. individuals in the data have successfully completed a first degrees) together with individuals who do not have a degree but who completed high school and attained sufficient qualifications to allow them, in principle, to attend university. We think of the latter group as our controls. The data is drawn from the Labour Forces Surveys – the LFS is the largest survey that UK National Statistics conduct, with slightly less than 1% of the population, and contains extensive information about labour market variables at the individual level. We drop all observations who did not achieve high school graduation with the level of qualifications to enter university – i.e. less than 2 A-level qualifications. In the UK, HE entry is rationed by achievement recorded at the end of high school and those without the absolute minimum achievements to attend university are excluded here. We also drop Scotland and Northern Ireland residents and recent immigrants who were educated outside the UK. We use data pooled from successive Labour Force Surveys from 1994 (although information about class of degree was first collected only from 2005) to 2009 (the latest currently available). The resulting sample size of 25-60 year olds is 82,002. Wage data is derived from earnings and hours of work (converted to January 2010 prices using the RPI). Importantly for this work, LFS is a (albeit short) panel dataset from 1997 onwards. Postgraduate qualifications are categorised as either Masters level, PhD level, PGCE (a one year professional training for those entering teaching), and Other (we believe this will be largely qualifications associated with professional training that results in membership of chartered institutes and degrees such as MBA). Table 1 shows the simple breakdown of by gender and postgraduate qualification and Table 2 shows the corresponding average log wages. Women are twice as likely to have PGCE’s as men, but less likely to have Master or Doctoral degrees. Overall 29% of graduates in our data have postgraduate qualifications and around half of these are to Masters level. Average hourly wage differentials are pronounced: males (females) with first degrees only earn 20% (31%) more than those with 2+ A-levels only – reflecting the lower gender discrimination in the graduate labour market; males (females) with a Masters degree earn 12% (17%) more than those with a first degree alone; male (female) PhDs earn 4% (7%) more than Masters; male (female) PGCEs earn 6% less (7% more) than those with first degrees alone.

---

3 We would like to be able to test the stability of our estimates to this threshold but this is, unfortunately, all the data will allow us to do.

In the UK it is common for undergraduate students to study only a single subject – although this tendency is becoming less pronounced over time. Undergraduate degrees in the data are categorised into 12 subject areas which we, for reasons of sample size, collapse into four broad subject groups: STEM (Science, Technology, Engineering and Medicine which includes mathematics\(^4\)); LEM (Law, Economics and Management), OSSAH (other social sciences, arts and humanities which includes languages), and COMB (those with degrees that combine more than one subject - but we do not know what these combinations are in our data).

Table 3 shows the simple breakdown of log wage by gender and first degree subject of major. The average college premium for OSSAH majors relative to 2+ A-levels (in Table 3) is 10% (33%) for males (females); while for COMB it is 20% (33%) for males (females); for STEM it is 25% (38%) for males (females); and for LEM it is 33% (42%) for males (females). Table 3 is for all graduates, but similar differentials are obtained just looking at those with a first degree alone.

\(^4\)We have grouped architects and graduate nurses into STEM, although their sample size is small enough for this to make no difference to our broad conclusions.
In the UK first degrees are classified by rank: first class (9.7% of non-missing degrees), upper second class (45.5%), lower second class (33.8%), third class (5.0%) and pass (6.1%). Table 4 shows the simple breakdown of log wage by gender and class of first degree. The premium for an upper second class degree over a lower second degree or worse is 8% (6%) for males (females), and the premium for a first over an upper second is 4% (5%) for males (females).

Figures 1 and 2 shows the observed relationship between log wages and age for A-level students and by degree major for men and women respectively. We use local regression methods to smooth the relationship. There are very clear differences between graduates and non-graduates and these differences vary by age for both men and women. There are also differences between majors for graduates which again differ by age. Age-earnings profiles differ and the differences are complicated: they do not appear to be parallel, which is what typical specifications assume. The figure for males suggests that the usual quadratic specification for the age-earnings profile would be a reasonable approximation to the data – but that a single quadratic relationship would be unlikely to fit each major equally well. For example, male LEM students enjoy faster growth in wages early in the lifecycle compared to other majors including STEM. There is no single college premium: wage premia seem to differ by major and by age.

These figures suggest that econometric analysis will need to be sufficiently flexible to capture these differences across majors. Moreover, Figure 2 looks quite different from Figure 1. The age-earnings profiles for women are much flatter - age is a poorer proxy for work experience for women because of time spent outside the labour market. This suggests that the
conventional cross-section methods are probably not going to be able to provide a good guide to how the earnings of women evolve over the lifecycle.

**Figure 1** Smoothed Local Regression Estimates of Age – Log Earnings Profiles: Men

**Figure 2** Smoothed Local Regression Estimates of Age – Log Earnings Profiles: Women
3. Method and Estimates

The conventional approach to estimating the private financial return to education typically uses a simple specification such as:

\[ \log w_i = \alpha + \beta \text{Experience}_i + \gamma \text{Experience}^2_i + \delta \text{X}_i + \chi \text{Q}_i + e_i \quad \text{for} \ i = 1..N \]

where \( \text{X} \) is a vector of individual characteristics such as migrant status and region of residence, and \( \text{Q} \) is a vector that records qualifications but, in many studies, simply measures years of completed full-time education. Age is often used as a proxy for work experience.

Here, we focus on graduates, postgraduates and a subset of non-graduates (those that could, in principle, have attended university) and allow differentiation by major studies in \( \text{Q} \). Using a control group that consists of those who might have attended university seems likely to reduce the impact of ability bias on our estimates, and so get us closer to estimating causal effects, although it seems unlikely that it would eliminate it altogether and this needs to be borne in mind when interpreting the estimates.

Our estimates of such a simple specification as (1) reflect the stylised facts that we reported in Section 2 and are not reported here. Rather, since we wish to use our estimates to inform public policy we need to ensure that the specification has the flexibility to reflect the policy issues as well as the realities of the raw data. Section 2 strongly suggests that we should not impose parallel age–earnings profiles so we will provide estimates broken down by highest qualification: that is, separate estimates for those with 2+ A-levels from those with STEM first degree, LEM, etc. That is, we would prefer to estimate

\[ \log w_{iq} = \alpha + \beta_q \text{Experience}_i + \gamma_q \text{Experience}^2_i + \delta_q \text{X}_i + e_{iq} \quad \text{for} \ i = 1..N \quad \text{and} \ q = 0..4 \]

which does not impose age earnings profiles to be parallel in \( q \), qualification.

There are two further difficulties. First, as we saw in Section 2, age is a poor proxy for work experience for women. If we wish to model how wages evolve over the lifecycle conditional on continuous participation estimating such a cross section model is not likely to be helpful. The second problem is that it seems likely that there are cohort effects on wages and identifying cohort effects separately from lifecycle effects is impossible with a single cross-section of data and problematic with pooled cross sections over a relatively short span of time. We can resolve both of these difficulties by exploiting the panel element of the data. If we time difference equation (2) we obtain
which allows us to estimate the parameters of the age-earnings profiles, by major (and for the 2+ A-level group) separately from cohort effects providing such cohort effects are additive in equation (2). Indeed, it seems likely that differencing will eliminate some of the unobservable determinants of wage levels that might otherwise contaminate the estimates of the age earnings profile. This then provides independent panel data estimates that can then be imposed in equation (2) which can then be estimated on the pooled cross section data. Moreover, panel data estimation for employed women provides estimates that are likely to be much closer to the effects of experience. That is, we can then estimate

\begin{equation}
\log w_{iq} = \alpha(c_i) + \beta \gamma Experience_i + \gamma \delta Experience_i^2 + \gamma \delta X_i + \nu_{iq} \text{ for } i = 1..N \text{ and } q = 0..4
\end{equation}

from the pooled cross-section data. Tables 5a (men) and 5b (women) report our baseline OLS pooled cross-section estimates of equation (2) without cohort effects; together with estimates of (3), from the panel, and (4) from the pooled crossections which include additive cohort effects (we include a cubic in year of birth). For men, in Table 5a, we find that the estimated lifecycle age-earnings parameters, the $\gamma$'s and $\beta$'s, are reassuringly similar for men whether estimated using the pooled cross-section estimates of the levels equations or from the panel data estimation of the wage difference equations. Nonetheless we find statistically important cohort effects when we impose the lifecycle coefficients from the panel estimation on the pooled cross section estimation of the levels equations. However, for women in Table 5b, we find that the panel estimation provides much steeper age earnings profile estimates – the estimated $\beta$'s are, on average, approximately 20% higher than those found in the pooled cross section estimates of the levels equation. Moreover, there are larger differences in profiles across majors. Thus, separating the estimation of lifecycle and cohort effects is important, at least for women. The estimates age-experience profiles are plotted in Appendix Figures A1a and A1b for men the profile for LEM starts higher and is steeper and dominates all other subjects until late in the lifecycle when COMB catches up; for women, OSSAH and COMB are very close but, while other subjects are slightly higher at an early age, their profiles are flatter.

\footnote{We also include controls for region and immigrant status which are not reported but there are no significant differences in the estimates when we include them. We find that our estimates of the crucial effects are not affected by aggregating the PG qualifications so we group all PG qualifications into a single variable to capture the average effect across all PG qualifications.}

\footnote{See Appendix Table A7* for NPVs based on these estimated age-earnings profiles for full-time workers alone.}
We have included degree class and postgraduate degrees in the specification as simple intercept shifts and we find important differences across subjects. There is a significant premium for degree class that varies across majors: there are particularly large effects for LEM graduates for both men and women; although the differences between first class and upper second class are generally not significant. There is an effect of having PG qualifications over and above the effect of degree class: with PG premia at around 15% in all subjects for women. For men, the corresponding PG premia range between 5-10%, with higher returns for LEM and COMB.

Tables 6a and 6b reports Quantile Regression results for equation (4) (where the estimated experience-earnings profile is drawn from OLS estimates of the wage growth equation using the panel data). Our motivation for investigating the effect of HE across quantiles of the residual wage distribution is the presumption that the latter captures the distribution of unobserved skills. Thus, it is of interest to estimate the effect of HE across this distribution. It is difficult to predict what these effects might look like. On the one hand one might argue that unobserved skills, like perseverance, might complement observed skills (like a specific HE qualification) and that we would therefore expect the Net Present Value (NPV) of a HE qualification to be higher at the top of the distribution than at the bottom. Indeed, low unobserved skills associated with poor high school performance would typically be associated with admission to a low ranked institution that may add less value than a higher rated institution. On the other hand, one might argue that those with poor unobserved skills might attempt to compensate for them by investing (unobserved) greater effort as an undergraduate student. In which case, we might see higher returns at the bottom of the distribution of unobserved skills.

The male premium for a first class is close to 10% across the quartiles for STEM, and the results for women are similar. The upper second premia are also close to 10% for STEM men, but are not significantly different from zero for women. The male LEM first class premia are large for the bottom quartile at 25% and similar for the median, but somewhat smaller for the upper quartile. The LEM bottom quartile female first class premium is very similar to the male premium and are over 30% for the median and top quartile. The LEM upper second premia is slightly smaller than the first premia for men, while for women they are similar to the male premium at the bottom decile but around 15% for the median and top quartile. The upper second effects for COMB men is small across the distribution; and the

same is true for women. The first class effect for OSSAH is badly determined for men, while for women there is a 13% effect at the bottom, 9% at the median, but insignificant at the top. The PG effect is small for STEM men across the quartiles, but around 15% for STEM women across the quartiles. The PG effect for LEM males is 9% for the bottom quartile, slightly lower at the median and slightly higher at the upper quartile; while for women, the effect is 20% at the bottom, lower at the median and about half at the upper quartile. The effect of COMB women is in the mid to upper teen, and somewhat lower for men. The effect for OSSAH is 14% for men at the lower quartile, half this at the median, and half again at the upper quartile. A similar pattern holds for OSSAH women but from a higher level.

4. Lifetime impacts and rates of return

The implied college premia will vary with experience, degree class, cohort, and presence of PG qualifications. Thus, in Table 7 we present, using the estimates of equations (3) and (4) from Tables 5a and 5b, the NPVs associated with a lifetime (from 22 to 65) with each major and a lifetime with 2+ A-levels (from 19 to 65) using various discount rates. We also include the internal rate of return (IRR), obtained from grid search. The assumption throughout is that there are tuition fees of either £3,290 (the level for 2010/11) or £7,000 pa for three years and opportunity costs are the (discounted) net of tax earnings that they would have received had they not entered university (i.e. those given by the estimates for 2+ A-levels) from 19 to 21. We allow for income taxes and employee social security contributions using the 2010 schedules. We assume that individuals intend to work full-time throughout their working age lives. We view this as a prospective simulation and focus on a current cohort looking forward. The simulations in Table 7 are for an “up-front” fee scheme since it does not allow for the presence of a loan scheme. In Table 10 and Appendix Table A7 we make allowance for this. To the extent that this scheme allows students to shift their tuition costs forward in time with no virtually interest penalty (and that the scheme contains an element of debt forgives) we are underestimating the NPVs (except when the discount rate is zero) and IRRs in Table 7. However, even at a 10% discount rate the differences in NPVs in Table A7 compared to Table 7 are proportionately very small - just 3 to 4 thousand pounds.

---

7 Surprisingly, we find that the effects of qualifications do not differ across regions. In particular, the impact of major does not vary across regions: which is surprising given the concentration of LEM majors in London.

8 Welfare programmes and the minimum wage are hardly relevant over the range of data being considered here.

9 One might also want to incorporate some part of subsistence costs while studying. For example, many UK students study away from home and incur additional housing costs.

</table>
The IRRs are large for women for all majors and for both good and bad degrees. This increase in tuition fee, on the scale envisaged in the Browne Report, makes a not economically insignificant dent in the IRR - around 2 to 2.5%. The differences across majors are quiet small. For men, there is substantially more variation. The return to LEM is large for both good and bad degrees, and the tuition fee rise makes a sizeable difference of around 3%. STEM, Combined and OSAH all return modest levels according to the calculated IRRs.

In Table 8 we use the corresponding estimates from Tables 6a and 6b to show how the NPV results vary by quantile of the distribution at a given discount rate, 5%, by gender, degree class and major. The median figures in Table 8 are close to the average figures that OLS yields in Table 7. However, there are huge differences across the quantiles within Table 8. Even for women, it would appear that the effects of STEM on NPV at the bottom quartile are much lower and even negative. At higher fees even the LEM median goes negative for women. Huge negative effects are associated with OSAH for men. Note that the table demonstrates NPVs that rise across the distribution in some cases but not all. For example, for STEM and OSAH, NPVs rise as we move up the distribution, but the opposite is true for Combined. There is no strongly theoretical presumption that any particular pattern should manifest itself and the estimates allow for all possibilities. Table 9 translates the NPV findings across the quantiles into rates of return. This confirms the relatively modest effects of the tuition rise on the returns on student investments. Those subjects that offer low returns at fees of £3290, offer somewhat lower returns at fees of £7000. Subjects that offer high returns at £3290 suffer larger falls if fees rise to £7000, but still offer handsome returns.

We also analyse the impact of the additional maintenance costs that might reasonably be associated with higher education participation. It would not be appropriate for all of subsistence expenditure during studying for a degree to be counted as an opportunity cost – only that expenditure that is over and above what would normally be spent had the individual not attended university. We know little about what these expenditures might be but a convenient figure would be £3250 p.a. (say £2800 p.a. for rent\textsuperscript{10} and £450 p.a. for study materials). Under the current loan scheme students from low income backgrounds are eligible to a maximum maintenance grant of £2906 pa, while students from higher income backgrounds are eligible to a loan to cover such costs. So, in Table 10, we simulate the effect of adding this expenditure to the opportunity costs of a degree and the comparison between two adjacent columns tells us about the value of being eligible to a grant, as opposed to a

\textsuperscript{10} £70 per week for 30 weeks plus half rent for the summer vacation.
loan, to cover such spending. That is, the column headed “without maintenance” assumes that there is a grant to cover such costs, (i.e. this corresponds to a student from a low income household) while the column headed “with maintenance” assumes that students borrow (i.e. from a higher income household). Comparing the figures for the current loan scheme in Table 10 for those “without maintenance” (i.e. whose maintenance cost are covered by a grant) with the figures in the top half of Table 7 we see the effect of this additional expenditure makes very little difference to the IRR. Having to borrow to cover this maintenance expenditure (comparing the first and second columns of Table 10 for men, and the fifth and sixth form women) rather than having a grant to cover this, lowers the IRR - but by less than one percentage point in all cases. Figure 10 also simulates a version of the proposals put forward by the Browne Review (Browne, 2010). In those proposals a fee level of £7000 becomes a focal point (as opposed to the current £3290) and we adopt the other proposals – an interest rate of 2.2% (as opposed to zero), debt write off after 30 years (rather than 25), and payable at 9% of earnings above £21,000 p.a. (as opposed to £15,000). The results suggests a small, almost always less than one percentage point, fall in the IRR.

5. Conclusion

This paper has used the latest and largest dataset available to estimate as flexible specification as possible. We allowed for tuition fees and the tax system in calculating the NPV associated with higher education (and also the loan scheme). And we provide independent estimates for graduates with different degree majors. The results are large for women - reflecting the greater discrimination that women face in the sub-degree labour market. Indeed, they are large across the board.

The results for men vary considerably across majors: with LEM having very large returns for both good and bad degrees, although higher tuition fees knock around 3% off these figures. The return to STEM is around 7% for a bad degree and 9% for a good one; COMB degrees are slightly higher; while OSSAH degrees are only 5% in the case of a bad degree. The first notable feature of the results is that the scale of tuition fee rise envisaged does not change the relative IRRs across subjects very much. Such rises are dwarfed by the scale of life earnings differentials. These results suggest that we might not see much substitution across majors in the face of even quite large tuition fee changes. The second feature is that, while there is little variation in returns across majors for women, STEM

11 Arcidiacono et al (2010) provide estimates of the sensitivity of choice of college major to perceptions of differentials in returns of the US. No such research is available for the UK.
subjects do not seem to exhibit large returns for men. They are dominated by COMB degrees and vastly so by LEM degrees. Indeed, if we imagined that the IRR reflected relative scarcity there would not seem to be a compelling case for thinking that there was a STEM shortage. On the contrary, there would seem to be a case for wanting to encourage a switch from OSSAH to LEM for men. The results are, of course, simulations using averages. There is likely to be wide variation around the averages and this is confirmed when we use Quantile Regression to look across quantiles of the residual log wage distribution. The best way to think of these quantiles is differences in wages that reflect unobservable differences across individuals. We might imagine that the prime suspect behind these unobservable effects is “ability” – there is likely to be wide variation across individuals in their unobserved abilities to make money. This will be conflated with institutional effects and family background – low ability students are likely to attend lower perceived quality institutions. Unfortunately, we have no way of knowing how much of the large variation in returns across quantiles is due to individual differences and how much because of institutional differences. Only richer data will allow us to address this point.

However, we find consistently strong returns to a 2.1 vs a 2.2 – it would appear that, in all subjects, there is a strong return to effort. A good degree raises the IRR, ranging from 1% to 5.5% - although we are unable to say how much effort is required to generate such a better degree result.\footnote{Strinebricker and Strinebricker (2009) show that effort has a large effect on US degree scores – the GPA. We know of no UK work on this topic.}

Finally, a rise in tuition fees to £7000 would lower returns by about 1-3% - not economically insignificant. The strong message that comes out of this research is that even a large rise in tuition fees makes relatively little difference to the quality of the investment – those subjects that offer high returns (LEM for men, and all subjects for women) continue to do so. And those subjects that do not (especially OSSAH for men) will continue to offer poor returns. The Browne Report proposes slightly lower fees (£7000 is a focal point of the report) than originally envisaged but suggests an unsubsidized interest rate (of 2.2%) which is repayable only when incomes exceed a higher threshold (£21,000 rather than £15,000). Our analysis suggests that this proposal would have somewhat more modest detrimental effects on the soundness of an investment in higher education - but large cross subject differences will remain.

Notes: Current loan scheme: Fee of £3290, 0% real interest rate, repayment on 9% of annual earnings over £15k and writing-off after 25 years; Browne Proposal: Fee of £7000, 2.2% real interest rate, repayment on 9% of annual earnings over £21k and writing-off after 30 years; Maintenance: £2906 (£3250) added to tuition fees under current loan scheme (Browne Proposal).
References

Appendix

The 82,002 observations in Section 2 is a sample of 25-60 year olds pooled from 1994-2009 Wave 5. This is effectively the same sample as was used in Walker and Zhu (2008), updated with 3 more years.

The cross-sectional estimation sample relaxes the age range to 19-60 (22-60 for graduates), with the sample size increased to 90,388.

The panel data is a panel of addresses and ensuring it is a panel of individuals results in some attrition. The wage panel is based on post 1997 LFS, N=43,545 which can be matched to almost 75% of the post-1997 cross-sectional sample.

The sample with degree class information is post-2005, N=22,153. This sample of 19-60 (22-60 for graduates) year olds is the actual sample used for simulation. The age range 61-65 in the simulation results are extrapolated from the 19-60 sample, but we think we are probably justified in doing so because of selectivity issues (too few women are still working above 60 and the differential pension age in public/private sectors for men).
