Abstract

Models based on economic theory have serious problems at forecasting exchange rates better than simple univariate driftless random walk models, especially at short horizons. Multivariate time series models suffer from the same problem. In this paper, we propose to forecast exchange rates with a large Bayesian VAR (BVAR), using a panel of 33 exchange rates vis-a-vis the US Dollar. Since exchange rates tend to co-move, the use of a large set of them can contain useful information for forecasting. In addition, we adopt a driftless random walk prior, so that cross-dynamics matter for forecasting only if there is strong evidence of them in the data. We produce forecasts for all the 33 exchange rates in the panel, and show that our model produces systematically better forecasts than a random walk for most of the countries, and at any forecast horizon, including at 1-step ahead.

1 Introduction

Is it possible to devise a model able to forecast exchange rates better than a simple no-change Random Walk forecast? Generations of economists have struggled with this question, since the seminal work of Meese and Rogoff (1983), who provided evidence that exchange rate models based on economic theory produce forecasts strikingly outperformed by a simple driftless Random Walk.

Several papers have tried to build and estimate models able to outperform the Random Walk in out of sample forecasting performance, and some papers documented progress in this respect (Mac Donald and Taylor (1994), Chinn and Meese (1995), Mark (1995), MacDonald and Marsh (1997)).

However, typically such evidence of predictability is limited only to very long forecast horizons, and reasonable gains in forecasting performance begins at around 3 years ahead. Chinn and Meese (1995) estimate several structural exchange rate models and their findings confirm that fundamental exchange rate models forecast no better than a random walk model for short-term prediction horizons, but for longer horizons error correction terms can explain exchange rate movements significantly better than a no change forecast. Mark (1995) shows that the deviation of the log exchange rate from its fundamental value contains relevant information for forecasting long-horizon changes in log nominal exchange rates, and the out-of-sample point predictions generally outperform the driftless random walk at the longer horizons.

Moreover, several papers have claimed that even the rather limited existing evidence supporting fundamental-based forecasts of the exchange rates is either very weak, not robust to the inference procedures used, or very sensitive to the choice of the sample and the data vintage (see Kilian (1999), Berben and Van Dijk (1998), Groen (1999), Berkowitz and Giorgianni (2001) and Faust, Rogers and Wright (2003)).

All the papers cited above share one key feature, namely, they try to forecast the exchange rates using economic fundamentals and models based on economic theory. Having a model which is both theory consistent and forecasts well is very appealing, as the economic foundations allow economists to explain the forecasts and a good forecasting performance provides evidence in favour of the theory itself.

However, the simple task of forecasting is important in his own rights.

In this paper we take a completely different perspective, and consider the task of forecasting the exchange rates per se, using a purely time series approach that exploits information in a rather large panel of exchange rates. Given that the best forecasts of exchange rates seem to be produced by a driftless Random Walk, it is natural to believe a priori that exchange rates do follow such a process, and to incorporate such information in the forecasting model. This can be done by using a Bayesian Vector Autoregression (*BVAR*), in which the *VAR* coefficients are shrunk towards a Random Walk representation.

Besides giving the opportunity of including a-priori information into the picture, the *BVAR* approach efficiently summarizes the information contained in large datasets, whereas using a simple multivariate linear model would encounter curse of dimensionality problems. Although the good forecasting performance of *BVAR* has been documented years ago by Litterman (1986) and Doan, Litterman, and Sims (1984), only recently Banbura et al. (2007) have shown that the Bayesian *VAR* is a natural and effective tool for forecasting and performing structural analysis with a large information set.

We propose to forecast exchange rates using a large information set (a panel of 33 exchange rates) and a *BVAR* with a driftless Random Walk prior. The proposed prior takes a Normal-Inverted Wishart form, and closed form solutions for the posteriors are available. Moreover, the prior features a Kronecker structure, which dramatically reduces the computational costs involved in using a large information set. The overall tightness of the prior is chosen by using a data-driven procedure.

We produce forecasts for the whole panel of 33 exchange rates vis-a-vis the US Dollar, and we provide evidence that this strategy may systematically outperform the Random Walk for most of the variables. The forecast gains are on average in the range of 2%-3% but in some relevant cases such as the Euro-Dollar and the GBP-Dollar can go up to 6%-9%. Importantly, the forecast gains arise at any forecast horizons, including the 1-step ahead. Given this, *BVAR* forecasts might also become the new benchmark for the evaluation of more economic theory based models of the exchange rates.

The paper is structured as follows. Section 2 describes the *BVAR*, with a focus

on the specification of the prior distribution for the VAR parameters. Section 3 describes the forecasting exercise and discusses the results. Section 4 summarizes and concludes.

2 The BVAR with the driftless random walk prior

A random walk without drift is overall a very competitive model in forecasting exchange rates. Therefore, it is reasonable to build a forecasting model in which exchange rates are a-priori following such a process. However, the model should not completely discard potentially useful information from dynamic comovements in exchange rates. Hence, in this paper we adopt a Bayesian approach, imposing a univariate driftless random walk prior on the parameters of a Vector Autoregression for a large set of exchange rates. Such a prior can be considered as a Normal-Inverted Wishart version of the traditional Minnesota prior, proposed originally by Doan et al. (1984) and Litterman (1986), which has the advantage of avoiding the inconvenient assumption of fixed and diagonal residual variance matrix. The use of this prior for forecasting has been originally proposed by Kadiyala and Karlsson (1993, 1997), and recently Banbura et al (2007) have shown that it performs well in forecasting with large datasets. Sims and Zha (1998) have provided additional results for such priors in the context of structural Vector Autoregressions.

In what follows we denote the exchange rate of currency i vis-a-vis the US Dollar at time t as $y_{i,t}$, and we collect all the exchange rates in the N -dimensional vector $Y_t = (y_{1,t}, y_{2,t}, \dots, y_{N,t})'$. Consider the following Vector Autoregression:

$$Y_t = \Phi_{0,h} + \Phi_{1,h}Y_{t-h} + e_t; \quad e_t \sim IIDN(0, \Psi). \quad (1)$$

Note that, differently from Kadiyala and Karlsson (1993, 1997), in the above model Y_t is regressed directly onto Y_{t-h} , which means that for each forecast horizon h , a different model is employed. Such an approach, which is known as "direct" forecasting, focuses on minimizing the relevant loss function for each forecast horizon, i.e. the h -step ahead forecast error, while the traditional powering up strategy implies that the only loss function considered is based on the 1-step ahead forecast error. For a discussion and a comparison of these alternative methods see, e.g.,

Marcellino, Stock and Watson (2006).

The h -step ahead forecast produced by a driftless random walk forecast is $\hat{y}_{i,t+h} = y_{i,t}$. In order to devise a model which *a priori* produces such a forecast, we just need to impose *a priori* that $\Phi_{0,h} = 0$ and $\Phi_{1,h} = I$. The restriction $\Phi_{0,h} = 0$ imposes the absence of drift, while the restriction $\Phi_{1,h} = I$ sets to zero all the coefficients but the own lag in each equation, which is set to 1, and clearly enforces a univariate random walk representation for each of the variables at hand.

We assume, a very tight prior for $\Phi_{0,h}$. In particular, we set its prior mean to zero, with a variance of 10^{-20} . As for Φ_1 , we assume that it is conditionally distributed as:

$$\Phi_{1,h}|\Psi \sim N(I, V[\Phi_{1,h}]); V[\Phi_{1,h}^{(ij)}] = \theta\sigma_i^2/\sigma_j^2, \quad (2)$$

where V is the variance operator and $\Phi_1^{(ij)}$ denotes the element in position (i, j) in the matrix Φ_1 .

The prior variance matrix $V[\Phi_{1,h}^{(ij)}]$ depends on the shrinkage parameter θ and on the scaling factors σ_i^2/σ_j^2 . The scaling factors account for the different scale and variability of the data, and to set the scale parameters σ_i^2 we follow common practice (see e.g. Litterman, 1986; Sims and Zha, 1998) in setting them equal to the variance of the residuals from a univariate autoregressive model for the variables.

The parameter θ measures the tightness of the prior. When $\theta = 0$, the prior is imposed exactly, the data do not influence the estimates, and the model produces the random walk forecasts, while as $\theta \rightarrow \infty$ the prior becomes loose and the posterior estimates approach the *OLS* estimates. To set the parameter θ we adopt a data driven procedure, based on past forecasting performance, which we shall describe in detail in the next Section. For the time being, we stress the fact that the parameter θ will be set to small values, i.e., we will use a tight prior. This allows to put a lot of weight on the a-priori belief that exchange rates follow a driftless random walk. Besides this, as the number of variables in the *VAR* increases, smaller values of the tightness parameter θ are needed in order to avoid overfitting (see Banbura et al (2007)).

Finally, the prior specification is completed by assuming an Inverted Wishart prior distribution for the variance covariance matrix of the errors in (1), $\Psi \sim iW(\Psi_0, \alpha_0)$, where α_0 and Ψ_0 are such that the prior expectation of Ψ is equal to

a fixed diagonal residual variance matrix, as in the traditional Minnesota prior, namely, $E[\Psi] = \text{diag}(\sigma_1^2, \dots, \sigma_N^2)$.

To derive the posterior distributions, it is useful to rewrite the *VAR* in (1) in the form of a multivariate regression model. Defining $B = (\Phi_{0,h}, \Phi_{1,h})'$ and $X_t = (1, Y_{t-h})'$ equation (1) can be compactly written as:

$$Y_t = B'X_t + e_t. \quad (3)$$

Rewriting (3) in data-matrix notation yields:

$$Y = XB + E. \quad (4)$$

In equation (4) the observations are by row, and equations by column, so $Y = (Y_1, \dots, Y_T)'$ is a $T \times N$ matrix of dependent variables and $X = (X_1, \dots, X_T)'$ is a $T \times M$ matrix of explanatory variables. The matrix $E = (e_1, e_2, \dots, e_T)'$ is the matrix of disturbances, where the generic column is $\varepsilon_i \sim IIDN(0, \Psi \otimes I)$.

The Normal-Inverted Wishart prior takes the form:

$$B|\Psi \sim N(B_0, \Psi \otimes \Omega_0), \quad \Psi \sim IW(\Psi_0, \alpha_0), \quad (5)$$

where the subscript 0 denotes that parameters are those of the prior distribution. Integrating out Ψ , the marginal distribution of B can be obtained, and it is a matrixvariate t-distribution with α_0 degrees of freedom and prior mean B_0 : $B \sim MT(\Omega_0^{-1}, \Psi_0, B_0, \alpha_0)$. For a derivation and a description of the properties of the matrixvariate t distribution see Zellner (1973).

The prior at hand can be implemented in the form of dummy variable observations. In particular, the addition of T_d dummy observations Y_d and X_d to the system is equivalent to impose this prior with $\Omega_0 = (X_d'X_d)^{-1}$, $\Psi_0 = (Y_d - X_dB_0)'(Y_d - X_dB_0)$, $B_0 = (X_d'X_d)^{-1}X_d'Y_d$, and $\alpha_0 = T_d - M - N - 1$. Banbura et al. (2007) show in details how to construct the dummy variables needed to set B_0 equal to the desired values in equation (5).

The conditional posterior distributions are also of the Normal-Inverted Wishart form:

$$B|\Psi, Y \sim N(\bar{B}, \Psi \otimes \bar{\Omega}), \quad \Psi|Y \sim IW(\bar{\Psi}, \bar{\alpha}), \quad (6)$$

where the bar denotes that parameters are those of the posterior distribution. Also in this case, integrating out Ψ it is possible to obtain the marginal posterior distribution of B , which is again multivariate t: $B|Y \sim MT(\bar{\Omega}^{-1}, \bar{\Psi}, \bar{B}, \bar{\alpha})$. Given the prior parameters $\Omega_0, \Psi_0, B_0, \alpha_0$ and defining \hat{B} and \hat{E} as the traditional OLS estimates, the posterior parameters are given by $\bar{\Omega} = (\Omega_0^{-1} + X'X)^{-1}$, $\bar{\Psi} = \hat{B}'X'X\hat{B} + B_0'\Omega_0^{-1}B_0 + \Psi_0 + \hat{E}'\hat{E} - \hat{B}'\bar{\Omega}^{-1}\hat{B}$, $\bar{B} = \bar{\Omega}(\Omega_0^{-1}B_0 + X'X\hat{B})$, $\bar{\alpha} = T + \alpha_0$. For a complete derivation see Zellner (1973).

If the prior is specified in the form of dummy observations, the posterior parameters can be computed with a simple OLS regression, after augmenting the model in (4) with the dummy variables. Defining the augmented model as

$$Y_* = X_*B_* + E_*, \quad (7)$$

the posterior parameters are given by $\bar{\Omega} = (X_*'X_*)^{-1}$, and $\bar{B} = (X_*'X_*)^{-1}X_*'Y_*$ (details can be found in Kadiyala and Carlson 1997).

We will now use the BVAR model defined so far for forecasting a large set of exchange rates.

3 Forecasting Exchange Rates

In this Section we first describe the data and the forecasting exercise, then discuss the results of the forecast evaluation, and finally try to explain the good performance of our BVAR model.

3.1 Forecasting Exercise

The data used in the paper are the monthly averages of the exchange rates vis-a-vis the dollar for 33 currencies, and are described in Table 1. All data are taken from Datastream, from three different international sources. The source for each series is identified by an acronym in Table 1. The sources are WMR/Reuters (identified by the acronym WMR), Global Trade Information Services (acronym GTIS), and the New York FED (acronym FED). The second column in Table 1 contains a short code which is used to label the currencies. A plot of the data is displayed in Figure 1.

The forecasting exercise is performed in pseudo real time, using a rolling estimation window of 7 years (84 months), and projecting the models forward up to 12 steps ahead. Using a short rolling estimation window is a natural way to reduce problems of instability, see e.g. Pesaran and Timmerman (2005) for a discussion, and direct forecasting can be also helpful since it is in general more robust than the standard iterated method in the presence of model misspecification. The initial estimation window is 1995:1-2000:12 (with data for 1994 used for initialization), and the initial forecast window is 2001:1-2001:12. The last estimation window is 2001:4 to 2007:4, while the last forecast window is 2007:5 to 2008:4.

We will evaluate our results in terms of the Mean Squared Forecast Error (MSFE) generated by model M when forecasting the exchange rate (vis-a-vis the US Dollar) of currency i at horizon h . Defining $\hat{y}_{i,t+h|t}^M$ as the h -step ahead forecast of $y_{i,t+h}$ given the information available at time t , the h -step ahead forecast error at time t is:

$$FE_{h,t}^M = \hat{y}_{i,t+h|t}^M - y_{i,t+h}, \quad (8)$$

and the h -step ahead MSFE is defined as:

$$MSFE_{i,h}^M = \frac{1}{T_0} \sum_{t=1}^{T_0} (FE_{h,t}^M)^2 \quad (9)$$

where T_0 is the total number of computed forecasts.

Similarly, the Mean Absolute Forecast error (MAFE) can be defined as:

$$MAFE_{i,h}^M = \frac{1}{T_0} \sum_{t=1}^{T_0} |FE_{h,t}^M|, \quad (10)$$

and it is useful to include it in the evaluation since it assigns a smaller weight to larger forecast errors than the MSFE.

The benchmark model is a driftless random walk, which produces the following h -step ahead forecast of the exchange rate:

$$\hat{y}_{i,t+h} = y_{i,t} \quad (11)$$

In the case at hand, the *BVAR* forecast of the vector of exchange rates $Y_t =$

$(y_{1,t}, y_{2,t}, \dots, y_{N,t})'$ at time $t + h$ is:

$$\hat{Y}_{t+h} = \hat{\Phi}_{0,h} + \hat{\Phi}_{1,h}Y_t \quad (12)$$

where $\hat{\Phi}_{0,h}$ and $\hat{\Phi}_{1,h}$ are the posterior means of the matrices of coefficients in (1).

The shrinkage parameter θ is chosen period by period by using a real time data driven procedure as follows. At each point in time, the *BVAR* is estimated for a grid of values for θ , and then the h -step ahead forecast is produced with the model based on the value θ^* that provided the smallest total squared forecast error (computed over all the variables) in the previous period:

$$\theta_{t,h}^* = \arg \min_{\theta} \{ \sum_{i=1}^N (FE_{h,t}^{BVAR})^2 \}. \quad (13)$$

The used grid is $\theta \in 10^{-4} * \{0.01, 0.1, 0.5, 1, 1.5, 2, 2.5, 5\}$. Such a grid enforces a tight prior, putting a lot of weight on the a-priori belief that exchange rates follow a driftless random walk. Moreover, small values of the tightness parameter allow to avoid overfitting when the cross sectional dimension of the dataset is large (see Banbura et al (2007)). Finally, note that this data-driven procedure is not implementable at the beginning of the experiment, until the h -step ahead forecast error of the previous period is observed. Hence, until the forecast error for the desired forecast horizon becomes available, we set θ equal to $10^{-4} * 0.01$.

We include in the comparison also a simple Auto Regressive Model, where the lag length L^* is chosen according to the Bayesian Information Criterion (BIC). The reported results are based on $AR(L^*)$ forecasts of the exchange rate of currency i at time $t + h$ obtained as:

$$\hat{y}_{i,t+h} = \hat{\alpha}_{ih} + \hat{\beta}_{ih}(L^*)\hat{y}_{i,t}, \quad (14)$$

where $\hat{\alpha}_{ih}$ and $\hat{\beta}_{ih}(L^*)$ are the coefficients of a regression of $y_{i,t}$ onto $y_{i,t-h}, y_{i,t-h-1}, \dots, y_{i,t-h-L^*}$. We also considered a more parsimonious AR specification, with a fixed lag length of 1, but the resulting models are outperformed by those based on the BIC lag length selection. These additional results are available upon request.

We also report results for *VAR* based forecasts. As we will see in the next subsection, such forecasts are definitely worse than those of all the other models,

but they are of interest as they provide a good illustration of how shrinkage can solve the curse of dimensionality problem, even in large datasets. The *VAR* forecast at time $t + h$ is given by:

$$\hat{Y}_{t+h} = \hat{A}_h + \hat{B}_h Y_t, \quad (15)$$

where, again, \hat{A}_h and \hat{B}_h are a vector and a matrix of coefficients of a regression of \hat{Y}_t onto Y_{t-h} .

Finally, it is interesting to consider an alternative strategy to deal with the "curse of dimensionality" problem, i.e. using a factor model. In particular we consider the following specification:

$$\hat{Y}_{t+h} = \hat{A}_h^f + \hat{B}_h^f F_t, \quad (16)$$

where F_t are the first r principal components of the exchange rates at time t . When r is smaller than the cross sectional dimension, this reduces the number of parameters in the model which might lead to gains in out-of-sample forecast accuracy.

3.2 Results

To facilitate the comparison, we provide results in terms of Relative Mean Squared Forecast Error (RMSFE) of a given model against the driftless Random Walk:

$$RMSFE_{i,h}^M = \frac{MSFE_{i,h}^M}{MSFE_{i,h}^{RW}}. \quad (17)$$

An *RMSFE* below 1 denotes that the model at hand outperforms the RW in out of sample forecast accuracy. Results of the forecasting experiment are summarized in Tables 2, 3, and 4 for, respectively, the *BVAR*, the *AR(L*)*, and the *VAR* (each against the random walk). Each row of the Tables refers to a different variable (exchange rate of currency i vis-a-vis the US Dollar), and each column to a different forecast horizon, ranging from 1 to 12. The last row in the Tables reports the average *RMSFE* computed over all the currencies for each forecast horizon.

The main message from Table 2 is that, overall, the *BVAR* with the random walk prior produces fairly good forecasts. In particular, the average *RMSFE* across currencies is below 1 for all the forecast horizons, with gains ranging from 2 to 4%. The pattern of the gains has a U-shape, namely there are gains around 2% at very short and very long forecast horizons, and larger gains at intermediate forecast horizons.

These results are confirmed by a more disaggregate investigation, which reveals that the *BVAR* with the random walk prior outperforms the random walk for most currencies and forecast horizons. In particular, for $h = 1$ the BVAR outperforms the random walk in 30 cases out of 33 (the three exceptions being Mexico, Uruguay, and Taiwan). For $h=3$ and 6 the BVAR is better in 24 cases out of 33, and in 23 cases for $h = 12$.

It is also interesting to focus on the forecasting performance for some prominent currencies, such as the euro, the GB Pound, and the YEN. For the Euro-Dollar and the GBP-Dollar exchange rates, the *BVAR* outperforms the random walk at all horizons, with gains of respectively 2 and 1.4% for $h = 1$, 2.7% and 4.8% for $h = 3$, and up to 6.9% and 9.6% for $h = 6$. For $h = 12$, the gain in forecasting the Euro-Dollar rate is 2.4%, 1% for the GBP-Dollar rate. For the Yen-Dollar rate the evidence is more mixed, with the BVAR providing better forecasts only at longer horizons, with smaller gains.

For two major trading partners of the US, Canada and Mexico, the BVAR performs very well for the former country, with gains ranging from 1% for $h = 1$ to 17% for $h = 12$, and only slightly worse for the latter country at short horizons, with losses smaller than 4% and gains of about 1.5% for $h = 12$.

Finally, the stars in the table denote rejection of the null of equal forecast accuracy of the models at 1%, 5%, and 10%, according to the Giacomini and White (2006) statistic. This is a test of equal forecasting method accuracy and as such can handle forecasts based on both nested and non-nested models, regardless from the estimation procedures used in the derivation of the forecasts, including Bayesian methods. As is clear, although the *RMSFE* across currencies is below 1 in several instances, only in a few cases the differences in the forecasts are statistically significant.

Figure 2 displays the time path of forecast errors for these five currencies (re-

spectively Canadian Dollar, Euro, GB Pound, Yen, and Mexican Peso). Each figure plots the forecast errors for the BVAR and the RW, for 3- 6- 9- and 12-step ahead forecast horizon. Interestingly, the main differences in the errors from BVAR and RW arise at the end of the evaluation sample, i.e. around 2007-2008, which is a period characterized by large swings in the US Dollar exchange rate. As we shall see in the next Subsection, in this period the cross-sectional information plays a relevant role.

Next, we evaluate whether the good performance of the BVAR is robust to a change in the loss function. In Table 3 we report results for the RMAFE, where large forecast errors receive a smaller weight than in the RMSFE. The overall picture is unaffected. From the average across currencies results, the BVAR still outperforms the random walk at each forecast horizons, with gains in the range 1%-3%. From the detailed country by country results, the BVAR remains better for the vast majority of countries and forecast horizons. As for the statistical difference in the forecasts, it is again limited to only a few cases.

Moving now to the forecasting performance of the AR models, Table 4 shows that the average *RMSFE* is above 1 for all the forecast horizons, signaling that overall the AR model is not able to outperform the random walk. This finding is confirmed by the country by country results, in which the AR outperforms the random walk only in a few cases. However, interestingly, the AR performs well for Taiwan and Japan, with large gains for the Japanese Yen, two exchange rates where the BVAR was not so good. Looking at Figure 1, the rationale for this result seems to be the large variability in these two exchange rates that likely requires more dynamics in the model, which is allowed in the AR case but not for the BVAR specification where only one lag is included.

Table 5 shows that the *VAR* produces very poor forecasts for all the currencies in the panel. This finding, combined with the good performance of the *BVAR*, indicates that there is some relevant information in the joint dynamics of the exchange rates under analysis, which is lost in the random walk models but also in the large unconstrained parameterization of the *VAR*.

As discussed in the previous Section, an alternative way to efficiently summarize the information in a large dataset is to use a factor model. Table 6 reports the

results of the Factor model with four factors.¹ As is clear from the table, the Factor model is outperformed by the RW but is systematically (with some noticeable exceptions for some currencies at the 1-step ahead horizon) giving better forecasts than the unrestricted VAR. This confirms that using a factor structure does help in summarizing efficiently the information contained in the dataset, but also that shrinking towards a RW provides better results for the dataset at hand.

3.3 Understanding the BVAR results

To provide a better understanding of the BVAR results, we focus on the θ parameter that, as described in Section 2, controls the overall shrinkage of the BVAR parameters towards the random walk prior. As mentioned, empirically the value of θ is chosen period by period by using a real time data driven procedure. At each point in time, the *BVAR* is estimated for a grid of values for θ , and then the h -step ahead forecast is produced with the model based on the value which provided the smallest total forecast error in the previous period, see eq.13. Therefore, it is worth looking at the time path of the selected $\theta_{t,h}^*$, which is depicted in Figure 3. The Figure displays 12 panels, each corresponding to a different forecast horizon, and each panel reports the time path of the selected θ . The picture indicates that for shorter forecast horizons the tightness parameter changes substantially, while at longer horizons it tends to stay fixed at a given value, and noticeably for long periods an extremely tight prior is chosen. At the end of the sample, when large swings in the US Dollar exchange rate are observed, the selected value of θ tends to be higher, signaling a stronger effect of the information contained in the cross-section.

Then, one might wonder whether the BVAR forecasting gains come simply from the fact that choosing in real time the optimal value of θ allows more flexibility than the $\theta = 0$ choice underlying the random walk model. In other words, changing the value of θ allows to use the random walk when the cross-sectional information is not relevant or persistence is substantial (or when the random walk specification is convenient to reduce the negative forecasting effects of structural

¹We considered all the specifications from $r=1$ to $r=5$, but to economize on space we only report the results for the case $r=4$, as this specification provided the best overall forecasting performance. Results for the remaining specifications are available upon request.

changes), and switch to alternative models in the remaining periods. This consideration is correct, but it is important to stress that the alternative specifications (based on values of $\theta \neq 0$) have to be in any case strongly shrunk towards the random walk prior in order for this strategy to produce gains (i.e., θ has to be very small in any case).

To provide further evidence on this point, we have repeated the forecasting exercise for the random walk and the $AR(L^*)$ models only, selecting at each point in time between the two specifications based on their past squared forecast error averaged across all countries, as for the θ selection in the case of the $BVAR$. In practice, cross-sectional information is excluded a priori, but the persistence is allowed to vary, even more than in the $BVAR$ case. As a result, the $AR(L^*)$ model was *never* selected, and this strategy simply produces a random walk forecast. Therefore, the general forecasting advantages from the $BVAR$ are related to the possibility of using cross-sectional information when needed, rather than changing persistence in the exchange rate processes.

3.4 The role of emerging countries and trading strategies

This Section considers two issues. First, we explore in more detail the nature of the cross-sectional information picked up by the $BVAR$, in particular we try to assess whether there is cross-sectional dependence among groups of currencies. Second, we also evaluate the economic value of the $BVAR$ forecasts by implementing a very simple trading strategy based on the $BVAR$ forecasts.

As for the first issue, we split the sample into 'developed' and 'emerging' currencies, and run the forecasting exercise again using two $BVAR$ s (one for each group) of smaller dimensions. Such experiment allows us to explore the possibility that cross-sectional information among developed currencies is picked up by the $BVAR$, or cross-sectional dependence among the emerging currencies, or links from developed to emerging currencies or vice versa.

The results of the experiment are displayed in Table 7. An interesting pattern emerges. While the developed countries do systematically better when the large $BVAR$ is used (though the results are still better than the RW for the majority of cases), the results are more mixed for emerging countries. In particular, the

results of the emerging countries are often similar and in some cases better when the smaller BVAR of emerging countries only is used. This suggests that the information on the emerging countries is critical in improving the forecasting accuracy of the BVAR. Such a result is likely linked to the faster pace of globalization and the larger and larger role that the emerging countries are playing in the world economy, considering that our forecast sample covers the period after 2001 only.

We now turn to the second issue, namely considering the gains obtained by using a trading strategy based on the BVAR forecasts. Such exercise is close in spirit to that proposed by De Zwart et al. (2007), although we use a simpler strategy, working as follows.² The investor owns a capital in US dollars, and at each point in time takes the decision on whether to invest it in a foreign currency. The investment decision is based on the prediction made by a model (we consider the BVAR and the AR): if the model predicts the foreign currency will appreciate, then the investor will go short in dollars and long in the foreign currency, while if the model predicts a depreciation the investor will hold his position and stay long in dollars. We assume that at each point in time the investor realizes the gain/loss and reinvests the initial capital.

Table 8 displays the results of such trading strategy for the BVAR and the AR. For each of the two panels in the table the first column displays the average return, the second the standard deviation, and the third the Sharpe Ratio, which is a quick way of assessing the mean-variance trade-off. The last column in the table contains the difference between the Sharpe Ratio obtained by using the BVAR and that obtained by using the AR.

As is clear from the table, overall the strategy based on the BVAR provides positive returns. Moreover, the BVAR strategy performs better than the one based on the AR in terms of both returns and standard deviation, as shown by the Sharpe Ratios, which are higher in 26 cases out of 33. Finally it is worth noting that the BVAR strategy involved systematically fewer transactions with respect to the AR, i.e. the BVAR model induces the investor to change his position less often, which means that the transaction costs associated with such strategy would be smaller.

²See De Zwart et al. (2007) for a discussion of more complex trading strategies based on both fundamentals and chartists analysis.

4 Summary and Conclusions

Having a forecasting model which is both consistent with economic theory and forecasts well is very appealing, but the simple task of forecasting is important in his own rights. In this paper we focused on the task of forecasting a large panel of exchange rates, using a purely time-series approach.

As the random walk without drift has proven to be a very competitive model in forecasting exchange rates, it is reasonable to build a model in which exchange rates are a-priori following such a process. But the model should also take into account information from the large panel of exchange rates, when needed. Therefore, we have developed a Bayesian Vector Autoregression with a Normal-Inverted Wishart prior, imposing a -priori a univariate driftless random-walk representation, but allowing the data to speak about the relevance of other available information.

Besides giving the opportunity of including a-priori information into the picture, the Bayesian VAR approach allows the efficient handling of large datasets, whereas using a simple multivariate linear model would encounter curse of dimensionality problems.

We used the proposed BVAR model to forecast a panel of 33 exchange rates vis-a-vis the US Dollar, finding that it can lead to gains in forecast accuracy for the large majority of the exchange rates under analysis. The gains arise at *all* forecast horizons, including the very short ones where the random walk forecast is typically extremely hard to outperform. The forecast gains are typically in the range of 2-3%, but in some relevant cases, such as the Euro-Dollar and the GBP-Dollar, they can go up to 6%-9%. Moreover, a simple trading strategy based on the BVAR forecasts provides positive returns, higher than those from RW forecasts.

Finally, the good performance of the BVAR appears to be related more to the intermittent use of information in the large panel than to changes in the persistence of the exchange rates. In addition, in the post 2000 period the information in the exchange rates of emerging countries seems to matter for forecasting those of the developed countries more than viceversa, a finding that deserves additional research.
