First Submission: March 2010; This Draft: April 2011

Abstract

We examine the “home bias” of knowledge spillovers (the idea that knowledge spreads more slowly over international boundaries than within them) as measured by the speed of patent citations. We present econometric evidence that the geographical localization of knowledge spillovers has *fallen* over time, as we would expect from the dramatic fall in communication and travel costs. Our proposed estimator controls for correlated fixed effects and censoring in duration models and we apply it to data on over two million patent citations between 1975 and 1999. Home bias is exaggerated in models that do not control for fixed effects. The fall in home bias over time is weaker for the pharmaceuticals and information/communication technology sectors where agglomeration externalities may remain strong.

Keywords: Fixed effects, home bias, patent citations, knowledge spillovers.

JEL Classification: O32, O33, F23

Acknowledgments: We would like to thank the European Research Council for research grants and the Economic and Social Research Council for its financial support for the Institute for Fiscal Studies, the Centre for Economic Performance and the Centre for Microdata Methods and Practice. Sharon Belenzon, Richard Freeman, Jerry Hausman, Bruce Meyer, Peter Thompson, seminar participants at Berkeley, Florida International University, and UCL/IFS, a co-editor, and two anonymous referees have offered several useful comments.

“When an industry has thus chosen a locality ... it is likely to stay there ... so great are the advantages ... The mysteries of the trade become no mysteries; but are as it were in the air,... inventions and improvements in machinery, in processes and the general organization of the business have the merits promptly discussed; if one man starts a new idea, it is taken up by others and combined with suggestions of their own...” (Marshall (1890), IV,x,3)

1 Introduction

The international diffusion of ideas lies at the heart of economic growth and the improvement of the welfare of nations. Unlike most commodities, knowledge is hard to appropriate by its inventors and “spills over” to other agents in the economy. Understanding how knowledge spreads is key to understanding a number of growth enhancing policies (for example, to work out the optimal subsidy to R&D or the degree of intellectual property protection). In this paper we revisit the question of whether geographic proximity plays an important role in the spread of knowledge and in particular how this has changed over time. In the popular imagination the notion of the “death of distance” (Friedman, 2005, Cairncross, 1997; Coyle, 1997) expresses the idea that information now travels around the globe at rapid speed. Under this view, ideas generated in California spread to Calcutta or Coventry through the Internet, conferences, telephone and other communication devices at an unprecedented rate, and international boundaries play little role. There is some empirical evidence to support this view (see, *inter alia*, Keller (2002) and Thompson (2006)).

There are also several counter-arguments that suggest that geographical proximity continues to exert a strong influence over knowledge flows. Indeed, in the trade literature there is little evidence that distance has become any less important for trade flows (e.g. the meta-analysis of Disdier and Head, 2008 or Leamer, 2007), and some evidence that its importance may have actually increased (e.g. Evans and Harrigan, 2005, and references therein). Distance may still matter if face-to-face interaction is important even in high tech sectors, because knowledge is tacit and hard to codify. Globalization may also

mean increasing specialization in the technologies where countries have comparative advantage, implying that they have “less to learn” from one another. So ultimately this is an empirical question - do technology spillovers increase with geographic proximity and has this changed over time?

Figure 1 presents some raw data that is consistent with the view that distance *has* become less important over time for the international transmission of ideas (we will discuss the data in much more detail later in the paper). We plot the relative speed of patent citations over time. For example, in the top left panel consider successful applications to the US Patent Office for inventors living in Germany in an “early” period (1975-1989) on the left and then in a “later” period (1990-1999) on the right. Looking first at the early period, the height of each bar indicates how much slower foreign inventors were in being first to cite German inventors relative to other German inventors. So American inventors were about 40% slower in citing Germans patents than Germans themselves and the French were about 25% slower. The fact that the bars are almost all positive suggests the well-known phenomenon of home bias in ideas - Germans are quicker at citing other Germans, British quicker at citing other British, etc. What is more interesting about Figure 1 is how home bias has *changed over time*. On average the bars in the later period are lower than the bars in the earlier period, suggesting that home bias in ideas has fallen, consistent with some “death of distance” ideas. In the post 1990 period, Americans are only about 20% slower in citing Germans and the French are only about 10% slower in citing Germans, than the Germans themselves. Table 1 holds the underlying data: the average time to the first citation in the early period from a German inventor to another German inventor was 1,383 days compared to 1,901 days for an American inventor. This shows that home bias exists. The speed of transmission within Germany increased over time - in the later period the average time to first citation was only 880 days. But the fall was even greater elsewhere: the time to

first American citation fell to 1,054.

Looking across Figure 1 as a whole, the pattern is repeated in most regions - foreigners became relatively much quicker at citing domestic patents after 1990.¹ There are, of course, many reasons why the simple patterns in the raw data might be misleading, and much of this paper is devoted to developing and implementing the appropriate econometric tools to show that the results in the raw data are essentially robust to controlling for confounding factors such as unobserved fixed effects and censoring.

In terms of related literature, it is well known that tracking international knowledge spillovers is a difficult task. One branch of the literature tries to identify the transfer of technology indirectly by examining changing rates of total factor productivity (TFP) growth across countries and assuming that the faster productivity growth rates of (some) countries or industries that lie further behind the frontier is due to the transfer of ideas.² While attractive in its simplicity, a drawback of this approach is that it only provides indirect evidence, the positive correlation between productivity growth and the lagged productivity gap could represent many statistical and economic mechanisms that have nothing to do with the spread of ideas.

A second branch of the literature takes a production function and includes the R&D of *other countries* as an additional variable. These papers tend to find that the R&D of other countries is valuable, but usually not as valuable as R&D in the domestic economy.³ Most closely related to this paper, Keller (2002) takes this approach and finds evidence

¹There are other interesting features in Figure 1 over and above the general fall in home bias. First, Japanese inventors appear particularly quick at citing other countries' inventors and this has grown stronger over time. Second, although home bias has fallen for the US with respect to the Rest of World, it has if anything increased with respect to the main EU countries (Germany, France and Britain). As we will see in the econometric section, once we control for other factors, there is not much evidence for home bias of US inventions in the later period.

²For example see Griffith, Redding and Van Reenen (2004).

³For an introduction to spillovers in general see Griliches (1992). At the cross country level see Coe and Helpman (1995) and Keller (1998). At the industry level see Bernstein and Mohnen (1998). Work at the firm level finds evidence that countries' behind the frontier benefit much more from frontier R&D than vice versa, see Branstetter (2001), Branstetter and Sakibora (2002) and Griffith, Harrison and Van Reenen (2006).

that technology has become more global over time. This approach has the advantage of using a direct measure of technology, however, it is necessary to identify the relevant external pool of information (i.e. to find a way to appropriately weight the R&D of other countries by order of importance) and the correlation of productivity with R&D is still a very indirect measure of the spillover itself.

A third branch is based around using patent citation information as a direct measure of the transfer of knowledge. The citation of one patent by another strongly suggests that the first patent contained useful knowledge which helped the second innovation. A classic paper in this field is Jaffe, Trajtenberg and Henderson (1993), which uses a matching methodology to show that inventors were far more likely to cite other inventors living in geographic proximity (e.g. the same state or country) when compared to inventors in other states or countries. Several papers have followed this approach, and a consensus has emerged that knowledge is subject to a significant degree of “home bias”. As with the R&D-production function, distance appears to matter.⁴ Most closely related to our work Thompson (2006) uses citation data to investigate the localization of knowledge spillovers and finds evidence to suggest that this has declined over time.

In this paper we also use citations to proxy knowledge spillovers but take a somewhat different approach. We consider the *speed* with which a patent is cited, and propose a duration modelling framework that explicitly deals with the problem of unobserved patent characteristics that may be correlated with location or other characteristics. To see how fixed effects could generate a bias consider the case of two countries - the US and Japan. Assume that higher quality patents will be cited more quickly than lower quality patents. If US inventors produce higher quality patents *and* inventors that produce higher quality patents are also more nimble at using the ideas of other countries then we

⁴For example, Jaffe and Trajtenberg (1999) found that inventors in one country were far more likely to cite inventors living in the same country than in other countries, although this difference tended to diminish over time. Thompson and Fox-Kean (2005) argue that using more disaggregated patent classes drives away localization effects within the US, but they still observe home bias between the US and other countries. See also Henderson, Jaffe and Trajtenberg (2005) for a rejoinder.

will observe that US inventors will tend to cite other US inventors more than they cite Japanese inventors. This will give the impression of “home bias” whereas in fact it is to do with the higher average quality of US inventors which leads to both the generation of new knowledge and the faster absorption of older knowledge. Controlling for fixed effects will therefore reduce the degree of “home bias” observed in naive estimators⁵.

Using a duration model without fixed effects we find evidence of large home bias, in line with the most of the existing literature. But, we find that home bias is partly a statistical artefact of the failure to control for unobserved heterogeneity (e.g. differences in patent quality). This heterogeneity has been found to be an important feature of patent values (e.g. Pakes, 1986). Our most important finding is that even after controlling for fixed effects, other covariates and censoring inter-country home bias appears to have *fallen* over time. This is consistent with the raw data shown in Figure 1 and Table 1. Other econometric evidence that we are aware of that shows that geography matters less over time is Keller (2002) and Thompson (2006), mentioned above, and Kim, Morse and Zingales (2006), who find that the lower apparent degree of spillovers within elite US university departments.⁶ Our work provides new evidence that the geographical localization of knowledge spillovers has fallen over time. Furthermore, the fall in home bias has been greater in the more “traditional” sectors (such as Chemicals and Mechanical Engineering) than the more “modern” technological sectors (such as the Information and Communication Technologies sector and the Pharmaceutical sector). This is consistent with the evidence for agglomeration and clustering in these high tech sectors as

⁵The bias is not easily signed. Consider a second scenario where inventions in Japan remain of lower quality on average than in the US, but Japanese inventors are faster at absorbing old knowledge than their US counterparts. This will make it appear that Japanese inventors cite US inventors a lot and could disguise the existence of home bias. In this case, controlling for fixed effects will remove the bias and *increase* the degree of home bias observed in non-fixed effects estimators. In summary, the fixed effects bias could go in either direction, but certainly could be important.

⁶A recent paper by Head, Mayer and Ries (2007) estimates a gravity model of trade for services. As with goods, they find no evidence of distance mattering less for services as a whole. However for one important sub-sector, “miscellaneous business services”, distance does appear to matter less in 2004 than in 1992.

suggested by some economic geography models (see Redding, 2009).

Our econometric method builds on Chamberlain (1985) and Ridder and Tunali (1999), which is based on a multiple-spell duration model, is new in the empirical literature on knowledge spillovers. Our method has several important advantages over previously used methods in the literature: first, we focus on the first few citations, for which we believe geography matters most (note that we are careful to show the sensitivity of our results to using the different numbers of citations). Second, we allow for a very general form of patent heterogeneity, thus providing new empirical evidence that is unlikely to be driven by different qualities or unobserved characteristics of cited patents. Third, we correct for the censoring problem, which is that newly granted patents are less likely to be cited by other patents, hence avoiding the standard problem in analyzing patent citation data. The method we apply has a number of potential applications beyond the one we investigate in this paper, for example, one could analyze the degrees of importance of geography within the United States across different states. Another possible application is to look at the extent to which knowledge spreads differently across institutions, such as universities, private firms and government labs.

The paper is laid out as follows. Section 2 sketches our econometric model. Section 3 details the data and Section 4 gives the results. Some concluding comments are in Section 5. Appendix A provides the details of our estimation method, the asymptotic distribution of our estimator, and comparisons between our econometric model and related models in the literature. Appendix B gives additional data description and estimation results.

2 Modelling Strategy

Consider that there are a set of inventions $i = 1, \dots, I$ and a set of inventors $j = 1, \dots, J$. We take this pool of inventions and inventors as exogenously determined⁷, with their numbers growing over time. The inventors will “learn”⁸ of invention i after a time period T_{ij} . We think of T_{ij} as the “diffusion lag” between invention i and inventor j .

T is a non-negative random variable with distribution $F(t)$ and density $f(t)$. There are several factors which determine the diffusion lag including characteristics of the invention Z_i , characteristics of the inventor Z_j and the joint characteristics of the invention-inventor match, Z_{ij} . There will be a set of non-geographical variables that will influence the speed at which information flows. For example news of a higher quality invention may travel more quickly as will inventions in a more established technological fields compared to newer areas. Similarly, lower quality inventors may be slow in picking up on news of new technologies. Finally, information will diffuse more quickly for inventors and inventions operating in the same technological field compared to those operating in different fields.

Our main interest is in geographical barriers to knowledge transfusion as proxied national boundaries. Thus, we hypothesize the non-geographical factors determine the expected diffusion lag, but there will be an additional cost of transmitting information depending upon whether inventors are located in the same country as an invention or are in a different country. To the extent that this slows down the diffusion of knowledge we will say that there is a “home bias”. Note that this home bias exists over and above any effect arising that inventions or inventors might be intrinsically faster (or slower) in picking up knowledge in general. We can control for these by linear country dummies

⁷Many general equilibrium growth models seek to derive the stocks of inventions and inventors as endogeneously related to the diffusion lag (e.g. Cabellero and Jaffe 1993), but we abstract from these considerations here.

⁸Learning can be interpreted in different ways. It is a combination of becoming *aware* of the invention, *understanding* it and then finding it *useful* enough to build on to develop new knowledge.

of invention (CTY_i) and inventor (CTY_j), with the key home bias term being terms in whether the particular pair of countries (CTY_{ij}) matters for diffusion.

The hazard function of the diffusion lag is defined as $\frac{f(t)}{1-F(t)}$ which we model as a function of observables, X_{ij} incorporating the empirically observable counterparts to Z_{ij} and Z_j , and an unobservable fixed effect, U_i which absorbs all the factors specific to the cited patent (such as quality).

In our application inventions will be measured by cited patents, inventors by citing patents and the diffusion lag by the duration of the citation lag between invention and inventor. We estimate the impact of home bias on knowledge spillovers using a multiple-spell duration model. Consider a patent that is taken out (the *cited* patent) and the patents that subsequently cite it (the *citing* patents) - if geography is important for the flow of information then we should expect to see that durations are shorter when the *citing* inventor is located near the *cited* inventor. We focus on the first few citations. Geography matters because most of the knowledge in a new invention is tacit, whereas over time this information becomes codified. Consequently, over time information about the invention is more easily transmitted across distances, and researchers with direct knowledge of the invention become more geographically disperse. We see evidence of this in the raw patents data. For example, if we look at all patents taken out by German firms, and we look at who first cites that patent, in 17% of cases it is another firm located in Germany, while if we look at the fifth time the patent is cited then 12% are firms located in Germany, while by the 10th time the patent is cited 10% are located in Germany. Looking across other locations we see that the share of cases where the cited and citing firm are in the same country falls monotonically, with a higher share of the 1st citations being in the same country.

As highlighted above, unobserved heterogeneity could confound our estimates as higher quality patents may be cited more quickly. To control for this we use an estimator

that is analogous to the linear difference estimator by comparing the first and second citations for each cited patent. By comparing the difference between the citing patents we are able to “difference out” the unobserved characteristics of the cited patent.⁹

Let subscript i index cited patents and subscript j citing patents. Under this convention, let Y_{ij}^* denote the j -th citation duration for the i -th patent, that is the number of days from the date when the i -th cited patent is granted to the date when the j -th citing patent is granted, where $i = 1, \dots, n$ and $j = 1, \dots, J$.¹⁰ Here n is the number of patents and J is the number of (potential) citations for each cited patent. Also, let X_{ij} denote the attributes of the j -th citing patent for the i -th cited patent and U_i denote unobserved characteristics of the cited patent. For example, U_i may represent unobserved quality of the cited patent.

We consider a multiple-spell version of the mixed proportional hazards model. The hazard that $Y_{ij}^* = y_{ij}^*$ conditional on $X_{ij} = x_{ij}$ and $U_i = u_i$ has the form

$$\lambda_i(y_{ij}^*) \exp(x_{ij}'\beta + u_i) \quad (1)$$

where β is a vector of unknown parameters and $\lambda_i(\cdot)$ is a cited-patent specific baseline hazard function.

The citation durations Y_{ij}^* are assumed to be independent of each other, conditional on the observed and unobserved characteristics (X_{ij}, U_i) . In addition, the observed covariates X_{ij} are assumed to be constant within each spell but to vary over spells. For example, X_{ij} may include the location of the inventor of the j -th citing patent for the i -th cited patent. We allow U_i to be arbitrarily correlated with X_{ij} and do not impose any distributional assumptions on U_i , and therefore, U_i is a *fixed effect*. The multiple-spell structure allows U_i to have a very general form, compared to unobserved heterogeneity

⁹See, for example, Chamberlain (1985), Ridder and Tunali (1999), Horowitz and Lee (2004), and Lee (2008).

¹⁰The notation Y_{ij}^* is used to reflect that Y_{ij}^* is a latent variable due to the usual right censoring problem. In fact, we observe $Y_{ij} = \min(Y_{ij}^*, C_i)$ and $\Delta_{ij} = 1(Y_{ij}^* < C_i)$, where $1(\cdot)$ is the usual indicator function and C_i denotes the censoring time. See Appendix A for details on how to handle censoring.

in the single-spell duration models. The functional form of the baseline hazard function $\lambda_i(\cdot)$ is unspecified and it can also vary across different cited patents. Therefore, the model also allows for unobserved heterogeneity in the shape of the hazard function.¹¹

The conditional independence assumption is indispensable in our econometric modelling strategy. The important implication of this assumption is that it requires that one citation does not *lead* to another citation. What would cause us problems is if the first citation of a patent provided information to other potential citers and therefore affected the duration to the next citation.¹²

Under the conditional independence assumption, such that Y_{ij}^* are independent of each other conditional on (X_{ij}, U_i) , we can estimate β using a conditional likelihood approach (e.g. Chamberlain, 1985; Ridder and Tunali, 1999). The idea behind the conditional likelihood approach is as follows. Assume that there are only two potential citing patents ($J = 2$). The probability that the observed first citation duration is first, conditional on the duration of the first citation, is given by

$$\begin{aligned} & \Pr[Y_{i1}^* \leq Y_{i2}^* | \min\{Y_{i1}^*, Y_{i2}^*\} = y_{1i}^*, X_{i1} = x_{i1}, X_{i2} = x_{i2}, U_i = u_i] \\ &= \frac{\lambda_i(y_{1i}^*) \exp(x'_{i1}\beta + u_i)}{\lambda_i(y_{1i}^*) \exp(x'_{i1}\beta + u_i) + \lambda_i(y_{1i}^*) \exp(x'_{i2}\beta + u_i)} \\ &= \frac{\exp(x'_{i1}\beta)}{\exp(x'_{i1}\beta) + \exp(x'_{i2}\beta)}, \end{aligned} \tag{2}$$

which does not depend on u_i or λ_i . Therefore, β can be estimated based on this conditional likelihood without the ‘incidental parameters’ problem.¹³

¹¹The heterogeneity term U_i is not separately identified from the baseline hazard function $\lambda_i(\cdot)$. The model in (1) can be re-written as $\tilde{\lambda}_i(y_{ij}^*) \exp(x'_{ij}\beta)$ with $\tilde{\lambda}_i = \exp(u_i)\lambda_i$.

¹²While this is of course possible we believe that it is not a major problem in our context because we are focussing on first and second (or third and fourth) citations. Due to the publication lag, the first citation is often not public by time when the second citation is made.

¹³Thompson (2006) uses Chamberlain’s (1980) conditional logit model to estimate the effects of localized knowledge spillovers. His paper is different from ours in two main ways. First, he uses pairs of citing and cited patents to construct the binary matching indicators (the dependent variable), whereas we start from a multi-spell duration model and then use only the first few citations. Second, Thompson (2006) uses an interaction term between the indicator variable for inventor citations and the cited patent age to identify the effects of knowledge spillovers, whereas we use the location of the inventor of a citing patent. See Appendix A.3.2 for more details.

A usual problem with analyzing such data is censoring. Given any dataset there will be some patents that have not (yet) been cited, but which could in future be cited. The standard conditional likelihood approach (see, e.g. Chamberlain, 1985) can handle censoring if one always observes covariates X_{ij} . In our application, like many others, X_{ij} are only observed when durations are uncensored. For example, we can identify the location of the inventor of a citing patent only in the case when it is observed. This problem forces us to use only uncensored spells and this may introduce a selection problem. In our data, citation durations are obtained by looking at all recorded citations at a particular date (December 31st 1999). We therefore treat the censoring as independent of citation durations and covariates (what we need is that the application and grant dates are independent of quality), and then weight the observations by the inverse of the propensity to observe complete spells. This is analogous to the way that missing data are treated in inverse probability weighted estimation (e.g. Wooldridge, 2007). See Appendix A for details of our estimation method.

There are two main differences between our approach and the more usual Jaffe and Trajtenberg (1999) approach. First, a major advantage is that we can control for unobserved heterogeneity in a way that they do not. Consistent with Thompson and Fox-Kean (2005) we find that using three digit technology classes is an inadequate control as the number of rejections of home bias fall substantially when we include our fixed effects over and above these technology dummies. Second, as with any fixed effect estimator a potential disadvantage of our approach is that we use only a sub-sample of the data that they use (two or more cites instead of all cites). We do not attempt to characterize the entire shape of the citation function, but rather focus on the first few cites. We believe that this is a natural approach to examining international spillovers, as localization effects should be strongest soon after a patent is granted when knowledge is still mostly tacit. Nevertheless, we see this approach as a complement rather than a

substitute for the Jaffe and Trajtenberg (1999) model.¹⁴ See Appendix A.3 for a more detailed comparison of our approach with others in the literature.

3 Data

To implement this estimator we use data from the NBER US Patent Citations Data File.¹⁵ These data include information on all patents taken out at the United States Patent Office (USPTO) and have been widely used in the economic analysis of spillovers.

Table 2 shows the sample sizes for our analysis. The NBER data consist of patents granted and citations made to these patents between 1975 and 1999. In total we use data on over 2.1 million cited patents. While these patents were all taken out in the USPTO, the assignees and inventors can be located anywhere in the world. We use the information on the inventors' addresses to identify the location of the patent.¹⁶ We focus on inventors located in the G5 countries - US, Japan, France, Germany and Great Britain. We group the remaining EU countries together,¹⁷ and then consider the Rest of the World ("RW") as the residual category. Unsurprisingly, the US is the leading country with nearly 1.2 million patents, and Japan is second with nearly 400,000. We split our sample into two sub-periods, 1975-1989 and 1990-1999, and consider whether the evidence for home bias differs over these two periods.

Crucially for our purposes, the NBER data contain information on all subsequent citations to each patent made by other patents. In our baseline results, we use the information contained in the first and second citations to implement the estimator described in the previous section. As highlighted above, an issue that arises with using citation

¹⁴See Belenzon and Van Reenen (2007) for evidence on the changing time patterns of citations using an approach closer to Jaffe and Trajtenberg (1999).

¹⁵See Jaffe (1986), Hall, Jaffe and Trajtenberg (2001), Jaffe and Trajtenberg (2002) and Hall, Jaffe and Trajtenberg (2005).

¹⁶Where there is more than one inventor we follow Jaffe et al (1993) and allocate patents to the country where the majority of inventors are located. In the case of ties we randomly choose one of the countries.

¹⁷These are Austria, Belgium, Denmark, Finland, Greece, Ireland, Italy, Luxembourg, Netherlands, Portugal, Spain and Sweden.

data is the problem that for some patents (those taken out near the end of the period) these citations will be censored - that is the first or second citation will not have occurred yet. This is a well documented problem with using citation data¹⁸. For example, in our data (see Table 3), for 28% of patents in the chemicals technology sector we never see a citation, for 15% we see only one citation, and for the remaining 56% we see two or more citations. Similar patterns are observed for other technology sectors. Because of this it is important that our empirical methods correct for censoring biases.

We control for whether or not the citation is a self-citation (i.e. whether the assignee is the same on the cited and citing patent) and whether or not the cited and citing patent are in the same technology class. We also control for the size of the base of potential citing patents, that is the number of patents in the citing country and technology sub-category for the citing year. We discuss the interpretation of this variable in sub-section 4.4. below, but it is there reflect the explosion of patenting which led to some diminution of average patent quality (see Kortum and Lerner, 1999; Jaffe and Lerner, 2004).

Table 3 reports some summary statistics for these control variables by technology category. In Chemicals, 22% of all first citations are self-citations, and this falls to 19% for the second citation. On average across technology sectors just under 20% are self citations and this declines by 2-4% from the first citation to the second citation. More than 65% of citations are from the same technology class. The proportions of self-citations, same technology class and the averages of the bases (potential cites) are characteristics of citing patents and thus they are obtained from only complete citation spells.

¹⁸For example, Hall, Jaffe and Trajtenberg, (2001) and Bloom and Van Reenen (2002).

4 Results

4.1 Basic Results

We implement the estimator described above on all patents granted by the USPTO between 1975 and 1999. We report results across seven regions and six technology categories, and allow all the coefficients to vary across these groups.

4.1.1 An example - Chemical Engineering

We begin by going through the results for one technology category in one country to illustrate our methodology. In Table 4 we show the coefficient estimates for the citing country dummies when we look at Chemical Engineering in Germany. Each column in Table 4 reports the results from a different regression. The omitted category is the own country - the location of the cited patent - which in this case is Germany (DE). There are potentially 46,697 cited patents in Chemical Engineering in Germany over this time period, and from this sample 25,016 patents are cited at least twice. The main variables of interest are the indicators of the country of the citing firm. Also included in the regression is an indicator of whether the citation is a self-citation, whether the cited and citing patent are in the same technology class (three digit), and the total number of citing patents in that country and technology class for the citing year.

In column (1) of Table 4 we estimate the coefficients using a proportional hazard model with only the first citation duration. This is equivalent to our model without fixed effects (and constraining the baseline hazard to be the same across patents), i.e. compared to equation (1) we assume,

$$\lambda(y_{ij}^*) \exp(x'_{ij}\beta). \quad (3)$$

To keep the sample the same as when estimating the fixed effects model we restrict the estimation to patents with at least two citations. The coefficients on the country dummies indicate whether inventors located in that country cite German inventors in

chemical engineering faster (a positive coefficient) or slower (a negative coefficient) than inventors from the omitted category (which is always the own country, in this case Germany). If there is home bias we expect *negative* coefficients on the other country dummies, i.e. they are slower to cite than home inventors. In column (1) we see negative and significant coefficients on four country dummies; these suggest strong support for home bias. Japanese inventors are the swiftest foreign group to cite German inventors - they are actually 3% faster than German inventors themselves, although the estimated coefficient is insignificant at the 5% level. By contrast inventors in France are 15% slower to cite German patents.

In column (2) of Table 4 we control for unobserved cited patent characteristics (e.g. quality) which may be correlated with the speed with which the patent is cited, by estimating the coefficients using the fixed effect estimator (without correcting for censoring).¹⁹ When fixed effects are included most coefficients become closer to zero and the all country dummies become statistically insignificantly different from zero, except for the rest of the world (RW). This suggests that failure to control for unobserved heterogeneity increases the degree of home bias.²⁰ The simple fixed effects estimator in column (2) ignores the problem of censoring. In column (3) we also allow for censoring, which leads to little change in most of the coefficients (but increases the standard errors a bit), and has relatively little effect on the qualitative findings. As would be expected, if the patent is taken out by the same assignee (a self-citation) the citation speed is significantly faster (about 48% faster than non self-citations in column (3)). Similarly, patents in the same technology class cite each other significantly faster (15% faster than patents in different technology classes according to column (3)). Patents in larger country-technology classes are cited less frequently.

¹⁹Specifically, the estimator maximizes the likelihood equation (A1) in the Appendix without the correction term $G_n(\max[Y_{i1}, Y_{i2}])$.

²⁰It is possible to have a case in which failure to control for unobserved heterogeneity decreases the degree of home bias since the direction of bias from failure to control for fixed effects cannot be signed *a priori*.

We continue to illustrate the method by looking across all countries but still restricting ourselves to patents in the Chemical Engineering category. In Table 5 each row contains parameter estimates from a separate multiple spell duration model for each country. For example, the first row shows the results from column (3) of Table 4 (the coefficients on self-citation, technology class and base are not reported). Table 5 shows only the results for the fixed effects and censoring model (denoted “FE + C”), i.e. the model shown in column (3) of Table 4.

What do the coefficients in Table 5 tell us? As before, the omitted base category is always the home country, and negative coefficients suggest home bias. Looking across the second row for France, we see that only inventors from the “rest of the world” (mainly developing countries) are significantly slower to cite French inventors than the French themselves: the coefficients for German, British, EU, Japanese, and US inventors are insignificant and inventors from the rest of the world are 33% slower to cite French inventors. So, just as in the German case, we do not see home bias after controlling for unobserved heterogeneity within the main developed nations. Note that all regressions include unreported controls for whether the citation is a self citation, whether it is in the same technology sub-category (three digit) and the total number of citing patents in that country and technology class (“base”). Most of these controls are highly significant and would lead to the impression of home bias if omitted.²¹ The story is different if we look at the US (row (6) in Table 5). All countries except Germany are significantly slower to cite US inventors than the American themselves: the French inventors are 15% slower to cite US inventors, British are 10% slower, other Europeans 22% slower, Japanese 6% slower, and the rest of world 24% slower. A similar pattern exists for Japan - the European countries are much slower to cite Japanese patents than the Japanese themselves.

We give a graphical representation of the results from Table 5 in Figure 2 to make

²¹This is true for all econometric models, as seen in all columns in Table 4.

it easier to eyeball the results. Each cell corresponds to the equivalent cell in Table 5. A circle represents a negative coefficient (home bias) and a cross represents a positive coefficient. The size of the circle or the cross corresponds to the level of statistical significance of a one-sided test for the null hypothesis that the corresponding coefficient is zero. A large circle represents significance at the 1% level, a medium circle significance at the 5% level, a small circle significance at the 10% level, and a tiny circle *insignificance* at the 10% level. The same ordering applies to crosses. The leading diagonal corresponds to the omitted variable in each regression and therefore no coefficient is estimated or displayed.²² So it is possible to immediately detect the degree of home bias for a country by looking at the number and size of circles across a row. The United States as country of cited patents, for example, has a full row of large circles indicating significant home bias, whereas European countries do not (this feature is not apparent from the raw data from all sectors in Figure 1). It is also clear from Figure 2 that there is less home bias among the EU countries (points in the top-left quadrant marked with the dashed line box), compared to between the non-EU countries and EU countries. The top right quadrant contains no rejections for the Japan and US columns, suggesting that Japan and the US are no slower in citing European patents than European own inventors; however, the bottom left quadrant contains many rejections for the Japan and US rows, suggesting that European countries (except Germany) are slower in citing Japanese and US patents. Hence, there exists an interesting asymmetry between the European block and the Japan/US block, in the sense that European inventors are slow to cite Japanese and American patents but Japan/US-located inventors are quick to cite European patents. Another interesting asymmetry exists - the rest of the world is slow to cite main developed countries, while the main developed countries are quick to cite the rest of the world²³.

²²A full set of results are available on request from the authors.

²³Germany is different to the other European countries in that it is particularly quick to cite other countries in Chemicals, but not other industries (see Figure 3). This may be because Germany has a

4.1.2 Main Results

We conduct the equivalent analysis across all seven regions and six sectors. Table 6 summarizes the results (full results available on request). The number of rejections of one-sided t -tests for the coefficients on country dummies are shown for each sector. Test results are shown for three levels (1%, 5%, and 10%) using the no fixed effect hazard model estimator (“No FE”), the fixed effect estimator (“FE”), and the censored fixed effect estimator (“FE+C”).

The first striking result in Table 6 is that there appears to be strong evidence for home bias when we consider the model that does not control for unobserved heterogeneity (columns (1)-(3)). Of the 252 tests²⁴ for no home bias, we reject 150 at the 5% level, or around 60%. This is consistent with evidence from the analysis of citations data in other econometric studies (Jaffe and Trajtenberg, 1999; Jaffe et al, 2005; Thompson and Fox-Kean, 2005). However, the picture changes when we control for unobserved heterogeneity (columns (4) through (6)). Comparing column (5) to column (2), for example, the rejection rate (the proportion of possible rejections that are in fact rejected) falls from 60% to 31%. In other words, there are far fewer rejections of home bias once we control for unobserved heterogeneity. Controlling for censoring makes relatively little difference to the total number of rejects in columns (7) through (9), the rejection rate is the same in column (8), where we control for censoring, as in column (5), where we do not, although it does affect some of the individual results.

The impact of controlling for unobserved cited patent effects can also be seen graphically in Figure 3. For each sector, the left hand side diagrams shows the pattern *without* controlling for fixed effects (no FE), whereas the right hand side presents results from

long standing comparative advantage in the Chemical industry. Arora, Landau and Rosenberg (1999) emphasise the historically strong international links of scientists working in organic chemistry in Germany. Another possible reason is that public sector investment in applied research in Germany has taken quite a different form than in other countries, notably the major investments by the government in the Fraunhofer Institutes, which has included several located in the US (see <http://www.fraunhofer.de/en/>).

²⁴Seven country regressions and six country dummies for each regression gives 42 tests for each sector.

our preferred specifications with controls for fixed effects and censoring (FE + C). It is clear that the proportion of large circles (evidence of significantly slower citations by another country) falls when moving from the no-fixed-effects specifications to the preferred specifications. This phenomenon is much less apparent in Computers and Communications - in Table 6 the number of rejections generally halves when we move between the no fixed effects specifications of column (2) to the fixed effects specifications of column (5), yet for Computers and Communications the number of rejections essentially remains the same. There are far fewer rejections even without fixed effects for Computers, while once we control for unobserved quality (column (5) Table 6) The number of rejections is quite similar across industries.

Why does unobserved heterogeneity not lead to the same sort of bias in Computers as it did in other industries? That is hard to say. The bias from omitted unobserved heterogeneity is not easily signed and could in principle go in either direction (see footnote 5). In the raw data (when we do not control for unobserved quality) it seems that the computer industry is very international compared to other industries, yet when we control for unobserved quality this wipes out most of this difference by reducing the evidence for home bias in other industries.

A second feature of Table 6 and Figure 3 is that the models without fixed effects suggest a sectoral pattern with less home bias in the “modern” sectors of Electrical and Electronic and Computers and Communications than in the more traditional sectors (e.g. Chemicals). This is similar to Peri (2005) who finds that knowledge spreads much more quickly across regional boundaries in the computer and communication sector. However, once we control for unobserved heterogeneity the sectors look relatively similar.

A third feature of Figure 3 is that the Rest of World (mainly non-OECD countries) are consistently slower in citing the patents of the OECD countries. This suggests that non-OECD countries are more “cut-off” from international pools of knowledge, either

because of their distance, infrastructure or development levels.

4.2 Falling home bias over time?

We now turn to the important issue of whether home bias has fallen over time, as some commentators have suggested (e.g. due to the falling costs of international communication and/or travel). We divide our sample into an “early” period (1975-1989) and a “late” period (1990-1999) where there are a similar absolute number of citations in each period (see Table 2). We re-estimate all of our models on these two sub-periods separately. We report a summary of these results in Tables 7 and 8 and Figure 4.²⁵ It is particularly important to control for censoring in this comparison, as the results from the second period will be much more affected by censoring than the former period.

In columns (1) and (2) of Table 7 we see that there is a large decline in rejection rates over time. No home bias is rejected in 48% of cases in the early period, but only for 28% of cases in the later period (in the table we report results at the 5% significance level). In columns (3) and (4) we repeat the exercise, but focus on OECD countries.²⁶ There is substantial home bias for the non-OECD countries, as noted above, so we wanted to check that the time series changes are not being driven by them alone. It is clear that the main patterns of results stand up. Although the absolute level of home bias is lower, the fall in the degree of home bias is dramatic. On average the rejection rate falls from 47% to 24%. The final two columns look within the European countries (counting rejections only on European country dummy coefficients of European-country-cited-patent regressions). The patterns are similar, with a large decline in home bias.

As we saw above, controlling for unobserved heterogeneity is important. In Table 8 we find that in most cases in both periods, the level of home bias is lower when we control

²⁵The full results of these estimations are available on request from the authors.

²⁶In other words we report the number of rejections for country dummy coefficients dropping the “Rest of the World” coefficients and also dropping coefficients from the “Rest of the World” cited patent regressions.

for fixed effects (and censoring), but the reduction in home bias is more substantial in the early period than in the later period (the rejection rate falls from 30% to 22%). The reduction in home bias over time is less striking, because there is less evidence of home bias existing in the first place. Looking at the first two columns of Table 8 we see that home bias declined in Chemicals, Electrical and Mechanical. By contrast in Computers and Communication (ICT) and Drugs, the “modern” sectors, we see little change (if anything an increase in the number of rejections). At first glance this might seem surprising as it is commonly assumed that ICT leads to delocalization.

Our aim in this paper is to identify “stylized facts” on home bias; what we identify is a reduced form of various structural influences that could slow down knowledge diffusion. What might these structural influences be? First, there are explicit information acquisition and communication costs that make it harder for inventors in country A to learn about inventions in country B because of telecommunication prices. The advent of e-mail, cellular phones, the Internet, liberalization of state telephone monopolies, etc. has clearly reduced the costs of these explicit costs. In opposition to this there are various agglomeration effects which will tend to make local interaction more important (at least in some sectors). When technologies are complex and/or at an early stage then local communication to facilitate the transfer of tacit know-how may be particularly important.

ICT and pharmaceuticals are the two sectors where there has been the most discussion of “clustering” (e.g. ICT in Silicon Valley and biotechnology in Cambridge, Massachusetts)²⁷. These results are also shown in Figure 4, where the left hand side diagrams are of the early period and the right hand side diagrams are of the late period: the later period has far fewer “circles” (evidence for home bias) than the earlier period.

It is plausible that in Computers and Communications agglomeration effects may have become stronger over time (relative to other sectors) so as to offset the falling com-

²⁷For example see Zucker, Darby and Brewer (1998) on biotechnology.

munication costs that they would disproportionately benefit from. It is hard to produce direct evidence to support this case, but there is some indirect evidence consistent with this idea. First, in terms of technological complexity, the ICT-producing industries have enjoyed very rapid technological change over our sample period. Quality-adjusted prices for computers were falling at something like 15% per annum until the early 1990s after which the price falls accelerated to around 30%. This appeared to be partially driven by a speed-up in the technological cycle of the semi-conductor industry²⁸. Rapid technological change is thought to make face to face communication and geographically-based knowledge spillovers more important.

Second, the geographical clustering of the ICT industry appears to have strengthened rather than weakened over time. For example, despite high wages and land prices in Silicon Valley leading software companies such as Apple, Oracle or Google have not chosen to decamp en masse, but seem to benefit from proximity to other ICT-oriented firms.

Third, several recent papers have pointed to the rise of “superstar cities” with high skilled workers and high tech industries and workers increasingly co-located in the same localities (for example, Gyourko et al, 2006). These cities (such as San Francisco and New York) have an increasing concentration of graduate workers and high tech jobs and have lead to increasing spatial inequality. There are various hypotheses that could explain this, but one leading explanation is that high-tech sectors, such as ICT, are increasing clustered in certain areas and this generates demand for high skilled workers (for example, Moretti, 2010).

While we cannot be certain that these are the reasons that there we do not see a fall in home bias in some industries, the most likely rationalization seems to be an increased importance of agglomeration has offset the fall in explicit communication costs along

²⁸Some authors go so far to say that the productivity acceleration in the US was in large part due to accelerated technical progress in ICT (Jorgenson, 2001 and van Ark et al, 2008).

the lines discussed.

One of the things that Figure 4 shows quite clearly is that in the early period the US had a substantial advantage in terms of “absorptive capacity”, US firms were quick to learn from and cite European patents, while European firms were slower to cite US firms and each other. In the later period European firms now cite US patents more quickly, and the US has lost this advantage. We see this by comparing the “US” row for US cited patents in the early period (on the left-hand side) with the later period (the US row on the right-hand side). The evidence of home bias (large circles) has been replaced by evidence of no home bias (a dot) or in some cases even evidence of more speedy knowledge flows (indicated by pluses). This is true in all industries except Computers, where the US seems to have maintained its advantage in terms of absorptive capacity.

The obvious conclusion is that home bias has fallen, and it has fallen in those sectors where one would *a priori* expect it to fall. This seems to be the new concrete quantitative evidence for an aspect of globalization that is much discussed - the increasing propensity of knowledge to slip over geographic boundaries. Our conclusion is consistent with Keller (2002) who shows geographic localization declined over time between countries, using a model in which productivity depends on domestic and foreign R&D and the effectiveness of foreign R&D is negatively related to the distance from the foreign economy, and also consistent with recent evidence from Kim, Morse and Zingales (2006) that the “spillover” benefits that academics obtain from their colleagues within the same university are less important now than they were two decades ago.

4.3 Using longer lags of citations

Our baseline results use only the first two citations to measure home bias. Why not use the third, fourth, fifth, etc. citation? Our main reason is because we believe that the theoretically relevant information is contained in the first few citations. This is before the patent has become more general public knowledge, it is when information is the

most tacit. After the patent has been published and cited it becomes codified, and there is less reason to believe that geography should matter. In addition, we have argued for a smaller number of citations on grounds of theory (the first few cites are likely to be where home bias is greatest due to tacitness of knowledge) and parsimony (we need at least two observations to “difference out” the fixed effect, so the first two citations is the minimum number).

Nevertheless, to tackle this issue directly we also checked the robustness of our results to including the third and fourth cites. The conditional likelihood estimator developed in Section 2 can easily be extended for more than two citations. Suppose that $J = 3$, i.e. that there are three potential citing patents. Then it is straightforward to show that the probability that the observed second citation is second, conditional on the durations of the first and second citations, has the logit form as in equation (1), independent of unobserved heterogeneity. Thus, this implies that one can obtain another censored fixed effect estimator in exactly the same way as in equation (2) by replacing the subscripts 1 and 2 with subscript 2 and 3, respectively.²⁹

Our qualitative findings did not change.³⁰ For example, in Table 6, for the 5% level, the number of rejections falls from 150 (No FE) to 77 (FE+C) as we control for unobserved heterogeneity of citing patents and the censoring problem. When we use the second and third citations, for the same level, the number of rejections changes from 130 (No FE) to 75 (FE+C); when we use the third and fourth citations, the number falls from 121 (No FE) to 48 (FE+C). The larger decline with the third and fourth citations is consistent with our conjecture that geography is less important as the patent becomes more general public knowledge.

²⁹Similarly, if $J = 4$, one can show that the probability that the observed third citation is third, conditional on the durations of the first, second and third citations has the logit form again, independent of unobserved heterogeneity. Then one can obtain yet another censored fixed estimator exactly the same way as in equation (2) by replacing the subscripts 1 and 2 with subscript 3 and 4, respectively.

³⁰See Tables A7 and A8 in the Appendix.

4.4 The importance of controlling for base of citing patents

Our specifications include a control for the number of citing patents (the “base”) by country and technology class. Although this might seem natural, in our econometric specification we may not need to control for it because the partial likelihood estimator is based on the partial likelihood of the identity (including origin country) of the first citation, given the time of this first citation and the identities of the first two citations. However, our alternative interpretation is that the legal and organizational changes to the patent system led to large increase in patenting in some technology class/country pairs that led to falls in average patent quality. Indeed the coefficient on base is robustly negative, consistent with this interpretation.

We re-estimated all our regressions dropping base which led in the main to qualitatively similar results. In particular, we found evidence of home bias weakening both with fixed effects and over time. We did find, however, that other countries appeared to cite US inventors more quickly than inventors in their own countries when we failed to control for base (e.g. more crosses in the row marked “US” in Table 3). We suspect that this is because many countries took advantage of looser rules on US patenting to expand their portfolios and also cited more out of fear of litigation. Conditioning on the total number of cited patents controls for this bias and restores the result that (in general) other countries cite themselves more quickly than they do US inventors.

4.5 Further Robustness tests

Could there be other reasons why the apparent decline in home bias is spurious? Firstly, a concern may be that the number of rejections of home bias has fallen because the number of observations is lower in the late period. But Table 2 shows that if anything the number of patents is slightly higher in the later period (1.107 million vs. 1.031 million), so this cannot be the reason. Secondly, could it be that the differential quality of patents has

caused this to occur? For example, a lot of the decline in Figure 4 is because European firms have become relatively faster at citing US patents, and Japanese firms have become relatively slower. Our technique of using multiple cites to “difference out” the fixed effect means that we have controlled for cited patent quality. Consequently, differential quality cannot be the reason for the patterns we observe in Table 8 (but it might be the reason for the patterns observed in Table 7 which does not control for fixed effects). Thirdly, we also tried using different cut-off years and found that this lead to similar results. For example, we obtain qualitatively similar results using 1985 as a cut-off year with the censored fixed effect estimator - in chemicals the number of rejections using all countries decreases from 13 in the pre-1985 period to 8 in the post-1985 period and in mechanical engineering the fall was from 12 to 5.³¹ See Table A6 in the Appendix for the details.

A final concern is that our results might be driven by self-citations. Of course, the positive coefficient on self-citations may reflect some degree of localized knowledge spillovers and so is of interest in its own right. Nevertheless, self-citations could reflect a bias simply to over-cite oneself, so we re-estimated all models dropping self citations. This made little difference to the preferred results with fixed effects and censoring. For example, the number of rejections at the 5% level in Table 6 fell merely from 77 to 76. Dropping self-citations *did* make more of a difference for the no fixed effects models, however, with the number of rejections falling from 150 in column (2) to 118 when we drop self-citations. We conclude that another benefit of our methodology is that it helps correct for biases induced from self-citations. See Table A9 in the Appendix for the details.

³¹As before, the “modern” sectors have seen an increase in the number of rejections from 7 to 9 in pharmaceuticals and from 9 to 11 in electrical and electronic.

5 Conclusions

Patent citations have become an important source of information about the ways in which knowledge flows between firms and countries. But knowledge can spread more or less quickly due to the unobservable characteristics of patents, which may be poorly captured by observable characteristics. In this paper we propose an econometric technique for dealing with fixed effects in duration models that exploits the existence of multiple citations on the same patent, and implements this estimator on a database of over two million citations between 1975 and 1999. We have focused on the speed of knowledge flows between countries, which is a key feature of models of growth and international trade. Many papers have argued that there is substantial “home bias” in the way that knowledge is transmitted, in the sense that being geographically close makes knowledge transfers easier, and this has become accepted wisdom in government support for clusters and other forms of technology policy.

We find that controlling for unobserved heterogeneity makes a large quantitative and qualitative difference to estimates of home bias in innovative activity. First, the evidence for home bias is much weaker once we control for fixed effects (and censoring). The non-fixed effects models (which are standard in the literature) suggest home bias in a majority of cases, whereas our preferred models indicate home bias in only a minority of cases. Second, and perhaps most provocatively, we find evidence that home bias has declined over time, being much stronger in the pre-1990 period than the post-1990 period. We interpret this as suggesting that information flows more easily across national boundaries as the cost of international communication and travel has fallen. Furthermore, there is heterogeneity in the fall in home bias: it has not occurred in the more high tech sectors of ICT and pharmaceuticals, precisely those areas where clusters and agglomeration are believed to be important. This suggests that international boundaries may be less important, but that in many sectors distance is far from dead.

Figure 1: Time to first citation, by cited and citing inventor location

Notes: This graph shows the relative time (in mean number of day) from the date that a Germany inventor was granted a patent until the first citation of that patent, by the location of the inventor that made the first citation. For example, the first bar (diagonal bricks) for France in the early period indicates that when the first citation to a Germany patent was made by a French inventor this citation took on average 25% longer than when the first citation was made by a German inventor (i.e. the mean citation length to a German inventor was 1383 days compared to 1729 days ($1729=1383 \times 1.25$) to a French inventor). Table1 shows the raw numbers for all cells. 'DE' = Germany, 'FR' = France, 'GB' = Great Britain, 'EU' = remaining EU countries together, 'JP' = Japan, 'US' = United States and 'RW' = the rest of the world. In particular, 'EU' consists of Austria, Belgium, Denmark, Finland, Greece, Ireland, Italy, Luxembourg, Netherlands, Portugal, Spain and Sweden.

Figure 2: Graphical Representation of Estimation Results

Notes: Each cell in Figure 2 corresponds to the equivalent coefficient in column (3) of Table 4. A circle represents a negative coefficient (home bias) and a cross represents a positive coefficient. The size of the circle or the cross corresponds to the level of statistical significance of a one-side test for the null hypothesis that the corresponding coefficient is zero. A large circle represents significance at the 1% level, a medium circle significance at the 5% level, a small circle significance at the 10% level, and a tiny circle *insignificance* at the 10% level. The same ordering applies to crosses. The leading diagonal corresponds to the omitted variable in each regression and therefore no coefficient is estimated. The upper left quadrant with dashed lines contains the cross-citations from the European Countries. ‘DE’ = Germany, ‘FR’ = France, ‘GB’ = Great Britain, ‘EU’ = remaining EU countries together, ‘JP’ = Japan, ‘US’ = United States and ‘RW’ = the rest of the world. In particular, ‘EU’ consists of Austria, Belgium, Denmark, Finland, Greece, Ireland, Italy, Luxembourg, Netherlands, Portugal, Spain and Sweden.

Figure 3: No Fixed Effects (“No FE”) and Fixed Effects with Censoring (“FE+C”)

Panel A: No Fixed Effects

Panel B: Censored Fixed Effects

Notes: For each sector, the left-hand side diagram shows the pattern without controlling for fixed effects whereas the right-hand side presents results from our preferred specifications with controls for fixed effects and censoring. The upper left quadrant with dashed lines contains the cross-citations from the European Countries. ‘DE’ = Germany, ‘FR’ = France, ‘GB’ = Great Britain, ‘EU’ = remaining EU countries together, ‘JP’ = Japan, ‘US’ = United States and ‘RW’ = the rest of the world. In particular, ‘EU’ consists of Austria, Belgium, Denmark, Finland, Greece, Ireland, Italy, Luxembourg, Netherlands, Portugal, Spain and Sweden.

Figure 3: No Fixed Effects (“No FE”) and Fixed Effects with Censoring (“FE+C”) (Continued)

Panel A: No Fixed Effects

Panel B: Censored Fixed Effects

Notes: For each sector, the left-hand side diagram shows the pattern without controlling for fixed effects whereas the right-hand side presents results from our preferred specifications with controls for fixed effects and censoring. The upper left quadrant with dashed lines contains the cross-citations from the European Countries. ‘DE’ = Germany, ‘FR’ = France, ‘GB’ = Great Britain, ‘EU’ = remaining EU countries together, ‘JP’ = Japan, ‘US’ = United States and ‘RW’ = the rest of the world. In particular, ‘EU’ consists of Austria, Belgium, Denmark, Finland, Greece, Ireland, Italy, Luxembourg, Netherlands, Portugal, Spain and Sweden.

Figure 4: Early Period vs. Late Period

Panel A: Early Period (1975-1989)

Panel B: Late Period (1990-1999)

Notes: The left-hand side diagrams are estimation results for the early period (1975-1989) and the right hand side diagrams are for the late period (1990-1999). Estimation results are from our preferred fixed effects plus censoring specifications. The upper left quadrant with dashed lines contains the cross-citations from the European Countries. 'DE' = Germany, 'FR' = France, 'GB' = Great Britain, 'EU' = remaining EU countries together, 'JP' = Japan, 'US' = United States and 'RW' = the rest of the world. In particular, 'EU' consists of Austria, Belgium, Denmark, Finland, Greece, Ireland, Italy, Luxembourg, Netherlands, Portugal, Spain and Sweden.

Figure 4: Early Period vs. Late Period (Continued)

Notes: The left-hand side diagrams are estimation results for the early period (1975-1989) and the right hand side diagrams are for the late period (1990-1999). Estimation results are from our preferred fixed effects plus censoring specifications. The upper left quadrant with dashed lines contains the cross-citations from the European Countries. ‘DE’ = Germany, ‘FR’ = France, ‘GB’ = Great Britain, ‘EU’ = remaining EU countries together, ‘JP’ = Japan, ‘US’ = United States and ‘RW’ = the rest of the world. In particular, ‘EU’ consists of Austria, Belgium, Denmark, Finland, Greece, Ireland, Italy, Luxembourg, Netherlands, Portugal, Spain and Sweden.

Notes: The table shows the mean number of day from the date that a cited inventor was granted a patent until the first citation of that patent, by the location of the inventor that made the first citation. For example, the number in the top panel for the first French (FR) citation to a German (DE) patents in the early period indicates that when the first citation to a Germany patent was made by a French inventor this citation took on average 1729 days. The top and bottom panels show the average time to first citation for the period of 1975 to 1989 and that of 1990 to 1999, respectively. ‘DE’ = Germany, ‘FR’ = France, ‘GB’ = Great Britain, ‘EU’ = remaining EU countries together, ‘JP’ = Japan, ‘US’ = United States and ‘RW’ = the rest of the world. In particular, ‘EU’ consists of Austria, Belgium, Denmark, Finland, Greece, Ireland, Italy, Luxembourg, Netherlands, Portugal, Spain and Sweden.

Table 2: Sample Sizes of Patent Citation Data

Technological Category	Period	Country of Cited Patents							Total
		DE	FR	GB	EU	JP	US	RW

Notes: Data consist of patents that were granted between 1975 and 1999. The patents in the data were all taken out at the United States Patent Office (USPTO). A country of cited patents refers to the location of an applicant: ‘DE’ = Germany, ‘FR’ = France, ‘GB’ = Great Britain, ‘EU’ = remaining EU countries together, ‘JP’ = Japan, ‘US’ = United States and ‘RW’ = the rest of the world. In particular, ‘EU’ consists of Austria, Belgium, Denmark, Finland, Greece, Ireland, Italy, Luxembourg, Netherlands, Portugal, Spain and Sweden. Period ‘All’ includes years from 1975 to 1999 in which cited patents are granted. ‘Early’ and ‘Late’ Periods correspond to 1975-1989 and 1990-1999, respectively.

Table 3: Summary Statistics for Patent Citation Data

Variable	Chemical	Computers and Communications	Drugs and Medical	Electrical and Electronic	Mechanical	Others
Proportion of patents with two or more citations	0.56	0.62	0.49	0.60	0.54	0.49
Proportion of patents with only one citation	0.15	0.12	0.14	0.14	0.17	0.17
Proportion of patents with no citation	0.28	0.26	0.37	0.25	0.30	0.34
Proportion of self-citation (first citation)	0.22	0.15	0.19	0.15	0.17	0.14
Proportion of self-citation (second citation)	0.19	0.13	0.15	0.13	0.14	0.12
Proportion of same technology class (first citation)	0.65	0.71	0.76	0.67	0.68	0.68
Proportion of same technology class (second citation)	0.63	0.71	0.75	0.65	0.67	0.66
Average of Base (first citation)	0.20	0.18	0.15	0.11	0.13	0.16
Average of Base (second citation)	0.21	0.19	0.17	0.12	0.14	0.17

Notes: Data consist of patents that were granted between 1975 and 1999. The patents in the data were all taken out at the United States Patent Office (USPTO). The base variable is defined as the number of patents in the citing country and technology sub-category for the citing year. (1 unit = 1,000 patents).

Table 4: Estimation Results

Technological Category: Chemical Country of Cited Patents: Germany (DE) <i>Sample Size: 46697; Obs. with at least two citations: 25016</i>			
Variable	(1) No Fixed Effect	(2) Fixed Effect	(3) Fixed Effect plus Censoring
FR	-0.15 (0.04)	-0.03 (0.07)	-0.03 (0.08)
GB	-0.03 (0.04)	0.03 (0.06)	0.02 (0.08)
EU	-0.12 (0.03)	-0.04 (0.05)	0.04 (0.07)
JP	0.03 (0.02)	0.00 (0.04)	0.00 (0.05)
US	-0.08 (0.02)	-0.02 (0.04)	0.05 (0.05)
RW	-0.13 (0.03)	-0.12 (0.05)	-0.14 (0.07)
Self Cit.	0.38 (0.02)	0.39 (0.04)	0.48 (0.04)
Tech.Class	0.16 (0.01)	0.15 (0.02)	0.15 (0.03)
Base	-0.15 (0.06)	-0.53 (0.09)	-0.80 (0.12)

Notes: Standard errors are in the parentheses. The dummy variables for the location of an applicant of citing patent are ‘DE’ = Germany, ‘FR’ = France, ‘EU’ = remaining EU countries together, ‘JP’ = Japan, ‘US’ = United States and ‘RW’ = the rest of the world. In particular, ‘EU’ consists of Austria, Belgium, Denmark, Finland, Greece, Ireland, Italy, Luxembourg, Netherlands, Portugal, Spain and Sweden. The omitted category in citing patent country dummies is Great Britain (GB). The Self Citation and Technology Class variables are dummy variables. The Base variable is the number of patents in citing country and subcategory for the citing year (one unit = 1,000 patents). Different columns show different estimates. Column (1) shows no-fixed-effect estimates using the only first citation duration, Column (2) shows fixed-effect (FE) estimates using first two citation durations, and Column (3) shows FE estimates accounting for censoring.

Table 5: Estimation Results of Chemical (FE + C)

Chemical (FE + C) - Full Sample							
Country of Cited Patents	(1)	(2)	(3)	(4)	(5)	(6)	(7)
	DE	FR	GB	EU	JP	US	RW
DE		-0.03 (0.08)	0.02 (0.08)	0.04 (0.07)	0.00 (0.05)	0.05 (0.05)	-0.14 (0.07)
FR	0.03 (0.11)		-0.01 (0.17)	-0.25 (0.20)	-0.10 (0.12)	-0.02 (0.12)	-0.33 (0.14)
GB	-0.10 (0.09)	-0.32 (0.13)		0.00 (0.13)	-0.06 (0.09)	-0.05 (0.09)	-0.29 (0.11)
EU	0.07 (0.08)	-0.06 (0.12)	0.13 (0.13)		-0.06 (0.09)	-0.04 (0.09)	-0.18 (0.10)
JP	-0.03 (0.04)	-0.23 (0.08)	-0.17 (0.07)	-0.24 (0.07)		0.03 (0.03)	-0.24 (0.05)
US	0.01 (0.02)	-0.15 (0.04)	-0.10 (0.04)	-0.22 (0.03)	-0.06 (0.02)		-0.24 (0.03)
RW	0.15 (0.09)	-0.14 (0.16)	0.01 (0.12)	-0.12 (0.12)	0.03 (0.08)	0.08 (0.08)	

Notes: Each row contains parameter estimates and their standard errors (in parentheses) from a separate multiple-spell duration model for each country. The censored fixed effect estimator (FE+C) is used with the entire sample for a technology category called “Mechanical”. The country name in the first column corresponds to the location of the patent’s inventor, which is subsequently cited. The country names in columns (1) through (7) correspond to the inventor location of the patent which subsequently cites the original patent. The left-out base country dummy is the cited patent’s country. Country codes with corresponding country names are as follows: ‘DE’ = Germany, ‘FR’ = France, ‘GB’ = Great Britain, ‘EU’ = remaining EU countries together, ‘JP’ = Japan, ‘US’ = United States and ‘RW’ = the rest of the world. In particular, ‘EU’ consists of Austria, Belgium, Denmark, Finland, Greece, Ireland, Italy, Luxembourg, Netherlands, Portugal, Spain and Sweden. In addition to country dummies, each hazard regression includes, as explanatory variables, dummy variables for self citation and technology class and the number of patents in citing country and subcategory for the citing year.

Table 6: Number of Rejections of No Home Bias using Entire Sample

Technological Category	Max. # of rejections	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)
		10%	No FE 5%	1%	10%	FE 5%	1%	10%	FE+C 5%	1%
Chemical	42	34	32	23	16	12	9	14	14	12
Computers & Communications	42	18	17	10	16	14	14	17	15	15
Drugs & Medical	42	26	24	18	15	11	5	15	10	6
Electrical & Electronic	42	22	19	16	13	13	11	15	14	12
Mechanical	42	26	25	17	16	13	6	15	11	9
Others	42	36	33	30	20	14	11	15	13	11
Total	252	162	150	114	96	77	56	91	77	65
Percentage		0.64	0.60	0.45	0.38	0.31	0.22	0.36	0.31	0.26

Notes: The number of rejections of one-sided t -tests for individual coefficients is shown in each cell of the table. Three levels of tests are considered: 1%, 5%, and 10 %. Also, three different estimators are used: no-fixed-effect estimator (No FE) using only first citation duration, fixed-effect (FE) estimator using first two spells, and censored fixed effect (FE+C) estimator.

Table 7: Number of Rejections of No Home Bias using Sub-Samples

<i>Estimation Method: No Fixed Effect Estimator</i>						
Technological Category	(1) All countries Early	(2) Late	(3) OECD countries Early	(4) Late	(5) EU countries Early	(6) Late
Chemical	23	8	17	6	5	0
Computers and Communications	16	5	12	2	3	1
Drugs and Medical	18	9	12	7	4	3
Electrical and Electronic	16	17	11	9	2	2
Mechanical	18	14	12	9	2	1
Others	30	18	21	11	7	1
Total	121	71	85	44	23	8
Max. # of rejections	252	252	180	180	72	72
Percentage	0.48	0.28	0.47	0.24	0.32	0.11

Notes: The number of rejections of one-sided 5% t -tests for individual coefficients is shown in each cell of the table for the early period (1975-1989) and for the late period (1990-1999) separately. The columns under “All countries” show the number of rejections for all coefficients for country dummies (42 coefficients), those under “OECD countries” show the number of rejections for country dummy coefficients dropping the “Rest of the World” coefficients and also coefficients from “Rest of the World” cited patent regressions (as a result, 30 coefficients), and those under “EU countries” show the number of rejections for EU country dummy coefficients of EU cited patent regressions (hence, further reduced to 12 coefficients). The test results are based on the no fixed effect (No FE) estimator.

Table 8: Number of Rejections of No Home Bias using Sub-Samples

<i>Estimation Method: Censored Fixed Effect Estimator</i>						
Technological Category	(1) All countries Early	(2) Late	(3) OECD countries Early	(4) Late	(5) EU countries Early	(6) Late
Chemical	13	7	9	4	1	0
Computers & Communications	13	15	10	10	1	2
Drugs & Medical	9	10	6	7	1	4
Electrical & Electronic	12	6	9	5	0	1
Mechanical	15	8	12	5	4	1
Others	14	10	10	6	2	2
Total	76	56	56	37	9	10
Max. # of rejections	252	252	180	180	72	72
Percentage	0.30	0.22	0.31	0.21	0.12	0.14

Notes: The number of rejections of one-sided 5% t -tests for individual coefficients is shown in each cell of the table for the early period (1975-1989) and for the late period (1990-1999) separately. The columns under “All countries” show the number of rejections for all coefficients for country dummies (42 coefficients), those under “OECD countries” show the number of rejections for country dummy coefficients dropping the “Rest of the World” coefficients and also coefficients from “Rest of the World” cited patent regressions (as a result, 30 coefficients), and those under “EU countries” show the number of rejections for EU country dummy coefficients of EU cited patent regressions (hence, further reduced to 12 coefficients). The test results are based on the censored fixed effect (FE+C) estimator.

A Econometric Appendix

A.1 Likelihood Function with Censoring

The censoring time C_i for patent i is defined as the number of days from the date of patent i being granted to the common censoring date. We assume that the censoring time C_i is independent (Y_{ij}^*, X_{ij}, U_i) and identically distributed with an unknown probability distribution. Furthermore, we assume that the support of C_i is the whole real line. Under this censoring mechanism, our data consist of $\{(Y_{ij}, \Delta_{ij}, X_{ij}, C_i) : i = 1, \dots, n, j = 1, \dots, J\}$, where $Y_{ij} = \min(Y_{ij}^*, C_i)$ and $\Delta_{ij} = 1(Y_{ij}^* < C_i)$. Here, $1(\cdot)$ is the usual indicator function. Thus, we observe uncensored citation durations only when $\Delta_{ij} = 1$, that is citation durations are less than the censoring time.

In this paper, we propose a modified version of the conditional likelihood estimator to correct for the selection bias. Specifically, the proposed estimator of β , say $\hat{\beta}$, maximizes the following weighted conditional log-likelihood function with $J = 2$:

$$\begin{aligned} L(b) = & n^{-1} \sum_{i=1}^n \frac{\Delta_{i1} \Delta_{i2}}{G_n(\max[Y_{i1}, Y_{i2}])} \left\{ \left[1(Y_{i1} \leq Y_{i2}) \ln \left(\frac{\exp(X'_{i1} b)}{\exp(X'_{i1} b) + \exp(X'_{i2} b)} \right) \right] \right. \\ & \left. + 1(Y_{i1} \geq Y_{i2}) \ln \left[\frac{\exp(X'_{i2} b)}{\exp(X'_{i1} b) + \exp(X'_{i2} b)} \right] \right\}, \end{aligned} \quad (A1)$$

where $G_n(\cdot)$ is an estimator of the survivor function $G(\cdot)$ of the censoring time C_i , in particular $G_n(c) = n^{-1} \sum_{i=1}^n 1(C_i > c)$. Our econometric framework is based on a continuous-time duration model, which is suitable for our application since we have citation durations measured in days. However, it is possible to have ties and they are included in both contributed terms in (A1). Observe that the selection bias is corrected for by multiplying weights $G_n(\max\{Y_{i1}, Y_{i2}\})^{-1}$ in equation (A1). The reason why $G_n(\max\{Y_{i1}, Y_{i2}\})^{-1}$'s are proper weights is that

$$E \left[\frac{\Delta_{i1} \Delta_{i2}}{G(\max\{Y_{i1}, Y_{i2}\})} | Y_{i1}^*, Y_{i2}^*, X_{i1}, X_{i2} \right] = 1 \quad (A2)$$

In other words, (A1) converges in probability uniformly over b to a limiting function to which an infeasible log-likelihood function would converge under no censoring. In maximizing (A1), we trim away 0.5% of observations with the smallest values of $G_n(\max[Y_{i1}, Y_{i2}])$ to mitigate the leverage of outliers.

A.2 Asymptotic Distribution of the Censored Fixed-Effect Estimator

This section of the appendix describes regularity conditions under which the censored fixed-effect estimator is consistent and asymptotically normal. Also, it gives the form of asymptotic variance of the censored fixed-effect estimator.

Assumption A.1 (1) β is an interior point of a compact subset of $\mathbf{R}^d$ for some finite d . (2) The data $\{(Y_{i1}, Y_{i2}, X_{i1}, X_{i2}, \Delta_{i1}, \Delta_{i2}, C_i) : i = 1, \dots, n\}$ are independent and identically distributed. (3) Y_{i1}^* and Y_{i2}^* are independent of each other conditional on (X_{i1}, X_{i2}, U_i) . (4) $\lambda_i(\cdot)$ is strictly positive. (5) $E[\|X_{i1} - X_{i2}\|^2] < \infty$ and $E[(X_{i1} - X_{i2})(X_{i1} - X_{i2})']$ is nonsingular. (6) The censoring

variable C_i is random with an unknown continuous probability distribution. (7) C_i is independent of $(Y_{i1}^*, Y_{i2}^*, X_{i1}, X_{i2}, U_i)$. (8) The survivor function of C_i , $G(c) \equiv \Pr(C_i > c)$ is positive for every $c \in \mathbf{R}$, and furthermore, it is bounded away from zero.

These assumptions are not unrestrictive, but in our application, they might be viewed as plausible. Recall that citation durations are obtained by looking at all recorded citations as of December 31st, 1999. Hence, the censoring variable is defined as the difference between this particular end date and the date when a patent is granted. It is reasonable that the censoring time C_i is independent of potential citation durations Y_{ij}^* , the attributes of the citing patent X_{ij} , and the heterogeneity term U_i , because the dates of patents being granted may have little to do with underlying patent-citing processes.¹ Also, the full support condition (8) on the censoring time is not so restrictive in our application given that we follow patent citations over a long period and we focus mainly on the first two citations. The assumption that $G(\cdot)$ is bounded away from zero is useful to ensure that our estimator behaves regularly. For example, see Khan and Tamer (2010) for general issues regarding inverse weight estimation.

Let

$$\begin{aligned} H_i(b) = & 1(Y_{i1} \leq Y_{i2})[X_{i1} - X_{i2}] \frac{\exp(X'_{i2}b)}{\exp(X'_{i1}b) + \exp(X'_{i2}b)} \\ & + 1(Y_{i1} \geq Y_{i2})[X_{i2} - X_{i1}] \frac{\exp(X'_{i1}b)}{\exp(X'_{i1}b) + \exp(X'_{i2}b)}. \end{aligned} \quad (\text{A3})$$

Define

$$\Omega = \Gamma^{-1} \left\{ \text{Var} \left[\frac{\Delta_1 \Delta_2}{G(\max\{Y_1, Y_2\})} H(\beta) \right] - \text{Var}[\rho(C)] \right\} \Gamma^{-1},$$

where

$$\Gamma = E \left[-\frac{\partial^2 L(\beta)}{\partial b \partial b'} \right] \quad \text{and} \quad \rho(c) = E \left[\frac{\Delta_1 \Delta_2 H(\beta)}{G^2(\max\{Y_1, Y_2\})} 1(c > \max\{Y_1, Y_2\}) \right].$$

Then the following theorem gives the asymptotic normality of the censored fixed-effect estimator.

Theorem A.1 *Let Assumption A.1 hold. Assume that Ω exists and is finite. Then as $n \rightarrow \infty$,*

$$\sqrt{n}(\hat{\beta} - \beta) \rightarrow_d \mathbf{N}(0, \Omega). \quad (\text{A4})$$

The proof of Theorem A.1 is omitted and it can be proved as in the proof of Theorem 1 of Lee (2008). The asymptotic variance Ω can be consistently estimated by

$$\hat{\Omega} = \hat{\Gamma}^{-1} \left[n^{-1} \sum_{i=1}^n (\hat{\Phi}_i - \hat{\rho}_i)(\hat{\Phi}_i - \hat{\rho}_i)' \right] \hat{\Gamma}^{-1},$$

¹What we need is that the application and grant dates are independent of quality. However, the restriction that the application date is independent of quality can be violated if there is a cohort effect on cited patents such as technology waves. Another problematic case would be if the time lag between the application date and the grant date is systematically correlated with the quality of the patent. Then this would induce the dependence between the grant date and quality even when the application date is exogenous.

where $G_{ni} = G_n(\max\{Y_{i1}, Y_{i2}\})$,

$$\hat{\Gamma} = n^{-1} \sum_{i=1}^n \frac{\Delta_{i1}\Delta_{i2}}{G_{ni}} [X_{i1} - X_{i2}][X_{i1} - X_{i2}]' \frac{\exp(X'_{i1}\hat{\beta} + X'_{i2}\hat{\beta})}{[\exp(X'_{i1}\hat{\beta}) + \exp(X'_{i2}\hat{\beta})]^2}$$

$$\hat{\Phi}_i = \frac{\Delta_{i1}\Delta_{i2}}{G_{ni}} H_i(\hat{\beta}),$$

and

$$\hat{\rho}_i = n^{-1} \sum_{k=1}^n \left[\frac{\Delta_{1k}\Delta_{2k}H_k(\hat{\beta})}{G_{nk}^2} 1(C_i > \max\{Y_{1k}, Y_{2k}\}) \right].$$

A.3 Related Econometric Models in the Literature

A.3.1 Jaffe and Trajtenberg (1999)

In Jaffe and Trajtenberg (1999), the likelihood that a particular patent K (citing patent) granted in year T will cite some patent k granted in year t (cited patent) has the form

$$\alpha(k, K) \cdot \exp[-\beta_1(k, K) \cdot (T - t)] \cdot \{1 - \exp[-\beta_2 \cdot (T - t)]\},$$

where α is a shift parameter that depends on the attributes of patents k and K , β_1 is an obsolescence parameter that also depends on the characteristics of patents k and K , and β_2 is a diffusion parameter. The first exponential process, $\exp[-\beta_1(T - t)]$, describes how knowledge becomes obsolete and the second exponential process, $1 - \exp[-\beta_2(T - t)]$, models how knowledge diffuses. Since we focus on the first few citations, the aspect of knowledge obsolescence is far less important in our empirical work than in Jaffe and Trajtenberg (1999). Roughly speaking, a natural form of specializing the citation frequency of Jaffe and Trajtenberg (1999) to our setup would be

$$P_{JT} := \alpha(k, K) \cdot \{1 - \exp[-\beta_2 \cdot (T - t)]\}. \quad (\text{A5})$$

Note that our mixed proportional hazards model specification gives the following citation frequency

$$P_{MPH} := 1 - \exp[-\Lambda_i(T - t) \exp(x'_{ij}\beta + u_i)], \quad (\text{A6})$$

where $\Lambda_i(u) := \int_0^u \lambda_i(s)ds$ is the integrated baseline function. The Jaffe-Trajtenberg-style model in (A5) assumes proportionality in terms of the citation frequency P_{JT} ; however, our mixed proportional hazards model in (A6) takes the proportionality in terms of the hazard function. In general, these two models are non-nested; however, if we assume that $\alpha(k, K) \equiv 1$ but β_2 may depend on x_{ij} and u_i as in (A6), then (A5) is a special case of (A6) with $\Lambda_i(u) = u$ (no duration dependence in the baseline hazards).

As we mentioned in the main text, we control for unobserved heterogeneity in a way that Jaffe and

Trajtenberg (1999) do not. Still, we see our approach as a complement rather than a substitute for Jaffe and Trajtenberg (1999) since strictly speaking, both models are non-nested.

A.3.2 Thompson (2006)

Thompson (2006) reports estimates from conditional logits with fixed effects for each cited patent. Although our estimates are also from a conditional logit with fixed effects for cited patents, two methods are quite distinct.

First of all, we need to worry about the problem of censoring since our framework is based on a duration model; however, Thompson (2006) is free from censoring problems since he considers observed pairs of cited/citing patents for the conditional logit. Furthermore, our conditional logit estimates use an indicator whether citation from an inventor residing in the same country has a shorter duration as the dependent variable and country dummies as important explanatory variables; whereas Thompson’s logit estimates use an indicator whether both inventors of the cited/citing patents reside in the same country as the dependent variable and an indicator variable whether the citation is added by the inventor as the main explanatory variable.

Thompson (1996, Table 3)’s estimation results suggest that the localization of international knowledge spillovers has not declined over time. However, two different estimation results are associated with different samples of patent citation data. Thompson’s sample starts from all patents granted during the first week of January 2003 and having an institutional assignee and then pairs of cited/citing patents are constructed by all patents cited in this particular cohort of citing patents. Our sample consists of potentially cited patents between 1975 and 1999 and its corresponding first few citing patents. In short, Thompson’s data extract is based on citing patents; whereas, our data extract is based on cited patents.

B Additional Data Description and Results

In this Appendix we include several tables showing additional results.

Table A1 shows a tabulation of the country of the first patent citing each of the cited patents in our data. The diagonal elements show that there is substantial home bias in the raw data. A problem we face in evaluating the time taken until the first patent is that not all patents have been cited. Estimating on only those patents where observe two citations would lead to potential selection bias. Table A2 shows the number of patents that are censored, by industry. Table A3 splits this down into the early and late period, clearly showing that the censoring problem is much more significant in the later period. Table A4 shows this by cited country. This motivates our use of estimators that explicitly allow for censoring.

In investigating the change in home bias over time we have chosen 1990 as a cutoff year because this approximately balanced the number of citations in early and later years. In Table A5 and A6 we show the robustness of the results to using the middle year of our sample period, 1985. As also discussed in the main test, we focus on the first two citations for a patent. We can easily extend our method using also the third citation and quasi-difference between the second and third citation and we show the results from doing this in Table A7. Similarly we can use up to the fourth citation (see Table A8). Table A9 provides estimation results after dropping all self citations. Our results are robust to using these alternative citations.

Table A1: Raw data: home bias in first citation

Cited:	Citing: DE	FR	GB	EU	JP	US	RW

RW	7.17	2.64	2.47	4.63	12.49	49.00	21.61

Notes: Data consists of all patents that were granted between 1975 and 1999 (the cited patent) and the first patent to cite it (the citing patent). An element $\{i, j\}$ in the Table shows the proportion of patents granted to an inventor located in row-country i that are first cited by an inventor in a column country j . For example, element $\{1, 2\}$ indicates that 2.96% of patents from German inventors were first cited by an inventor in France.

Table A2: Censoring - many patents have not (yet) been cited

	Chemicals	Computer	Drugs	Electrical	Mechanical	Other	Total
obs 2 cites	241,799 (56.35)	152,557 (61.75)	90,718 (49.48)	220,584 (60.14)	250,258 (53.54)	217,545 (48.89)	1,173,461 (54.87)
obs 1 cite	65,969 (15.37)	29,483 (11.93)	25,348 (13.83)	52,985 (14.45)	78,875 (16.87)	774,91 (17.41)	330,151 (15.44)
obs no cites	121,364 (28.28)	65,009 (26.31)	67,274 (36.69)	93,192 (25.41)	138,318 (29.59)	149,939 (33.70)	635,096 (29.70)

Notes: Each row indicates the number of observations that had at least two cites (“obs 2 cites”), one cite (“obs 1 cite”) or no cites (“obs no cite”). The number in parentheses indicates the proportion of observations by industry that had different numbers of cites. For example, our dataset contains 254,301 cites to patents in the chemicals technology sector that had at least two cites.

Table A3: Censoring - by early and late time period

1975-1989	Chemicals	Computer	Drugs	Electrical	Mechanical	Other	Total

Max. # of rejections	252	252	180	180	72	72
Percentage	0.46	0.43	0.45	0.37	0.26	0.25

Notes: The number of rejections of one-sided 5% t -tests for individual coefficients is shown in each cell of the table for the early period (1975-1984) and for the late period (1985-1999) separately. Note that the tables in the main text use 1990 as the cut-off year. The columns under “All countries” show the number of rejections for all coefficients for country dummies (42 coefficients), those under “OECD countries” show the number of rejections for country dummy coefficients dropping the “Rest of the World” coefficients and also coefficients from “Rest of the World” cited patent regressions (as a result, 30 coefficients), and those under “EU countries” show the number of rejections for EU country dummy coefficients of EU cited patent regressions (hence, further reduced to 12 coefficients). The test results are based on the no fixed effect (No FE) estimator.

Table A6: Number of Rejections of No Home Bias using Sub-Samples
