Abstract

We analyze the effects of cognitive abilities on two examples of consumer financial decisions where suboptimal behavior is well defined. The first example refers to consumers who transfer the entire balance from an existing credit card account to a new account, but use the new card for convenience transactions, resulting in higher interest charges. The second example refers to consumers who face higher APRs because they inaccurately estimate their property value on a home equity loan or line of credit application. We match individuals from the US military for whom we have detailed test scores from the Armed Services Vocational Aptitude Battery test (ASVAB), to administrative datasets of retail credit from a large financial institution. We show that our matched samples are reasonably representative of the universes from which they are drawn. We find that consumers with higher overall composite test scores, and specifically those with higher math scores, are substantially less likely to make a financial mistake later in life. These mistakes are generally not associated with the non-mathematical component scores. We also conduct some complementary analyses using two other data sources. We use the National Longitudinal Survey of Youth (NLSY) to show that higher ASVAB math scores are associated with lower subjective discount rates. Finally, we use the Health and Retirement Survey (HRS) to demonstrate that particular forms of cognitive ability matter for specific types of suboptimal behavior. We find that the mathematical component of the test is what matters most for financial decision making and financial wealth. In contrast, *non-mathematical* aptitudes appear to matter for *non-financial* forms of suboptimal behavior (e.g. failure to take medicine). The HRS results also demonstrate the large ramifications of low math ability on long-term economic success.

1. Introduction

An emerging literature has documented that individuals commonly make financial decisions that would be considered suboptimal according to standard consumer finance theory. For example, individuals accept payday loans with astronomical APRs when other cheaper forms of credit are available (Agarwal et. al, 2009; Bertrand and Morse, 2009), and consumers with multiple credit card offers fail to optimally choose the right credit card (Agarwal et. al., 2006). More broadly, it is puzzling that less than 30 percent of U.S. households directly participate in equity markets (Cole and Shastri, 2009; Li, 2009) and among those who do hold stocks, many have highly concentrated portfolios and trade excessively (Korniotis and Kumar, 2009a, b).

Suboptimal household financial decision-making behavior has potentially important effects on individual welfare. The ability of families to adequately invest in their children's human capital or for older individuals to optimally secure retirement income is undoubtedly affected at least in part, by the quality of financial decision making. There are also potentially large social ramifications arising from poor financial decision making. The sharp decline in housing markets and the associated rise in mortgage defaults that helped precipitate the recent financial crisis suggests that poor financial decision-making behavior among some households may have contributed to large spillover effects on the aggregate economy. Despite the growing salience of the issue, our current understanding of exactly what factors might account for suboptimal financial decision making is limited.

One potential explanation is that some individuals may not possess the requisite levels of cognitive abilities for making optimal financial choices.¹ For instance, in choosing an investment portfolio, an investor must synthesize a wide range of information concerning economic conditions and the past performance of various assets, accounting for transactions costs, asset volatility, and covariance among asset returns. This task requires memory, computational ability, and financial sophistication. Cognitive limitations might also lead consumers to make suboptimal credit decisions, perhaps because they

¹ Analytic cognitive function can be measured in many different ways, including tasks that evaluate working memory, reasoning, spatial visualization, and cognitive processing speed.

overestimate their ability to repay loans or fail to translate monthly payment rates into annualized interest rates (Ausubel 1991, Agarwal et. al. 2006, and Bertrand and Morse, 2009). In general, there is now growing evidence that cognitive ability is an important predictor of financial outcomes (Benjamin et. al, 2006; Cole and Shastry, 2009; Frederick, 2005).

The evidence from the existing literature however, has some important shortcomings along several dimensions. Among the few studies that have used precise measures of suboptimal financial behavior, direct measures of cognitive ability have been lacking. For example, Agarwal et. al. (2009) and Korniotis and Kumar (2009a) link the effects of cognitive ability on specific financial decisions only *indirectly*, through the correlation of cognitive skills with other variables such as age. Some of the studies that have used direct measures of cognitive ability have relied on experimental outcomes rather than real world financial decisions (e.g. Dohmen et al., 2010). Other studies with good cognitive measures have relied on very broad financial outcomes such as stock market participation (e.g. McArdle et al. 2009, Grinblatt et al. 2009).² This raises the concern of omitted variable bias, as those with higher cognitive ability likely also have higher levels of socio-economic status or other positive endowments and may have been more likely to invest irrespective of their cognitive ability. In the absence of a compelling research design it is difficult to assess whether the estimated relationships using such broad outcome measures are truly causal. Finally, previous studies have generally been unable to shed much light on the mechanisms through which cognitive ability influences the decision making process.³

Our data and analysis attempt to address these shortcomings. We measure cognitive skills by using test scores from the Armed Services Vocational Aptitude Battery test (ASVAB). The ASVAB is used by the military as a screening tool and as a measure of trainability. In addition to testing subject matter knowledge in several specific areas, there are subtests that directly assess an individual's math, verbal and

² Further, the literature has focused disproportionately on investment decisions and on the extensive margin of financial market participation. Fewer studies have considered decisions regarding debt and on the intensive margin.

³ Information constraints and a variety of behavioral biases are sometimes cited as possible causes.

perceptual skills.⁴ Since the ability to process and synthesize written mathematical information likely affects an individual's financial decision making ability, it is plausible that these tests would capture the relevant cognitive skills. Two of the math subtest scores and two of the verbal subtest scores are combined to create the composite Armed Forces Qualifying Test (AFQT) score which is used as part of the selection criteria for entrance into the military.

Many previous studies have utilized AFQT scores to measure cognitive ability. For example, Neal and Johnson (1996) show that AFQT scores in adolescence can explain future earnings. Heckman et al. (2006) find that AFQT scores are associated with participation in crime and other risky behaviors. Warner and Pleeter (2001) evaluated a natural experiment during the downsizing of the US military where individuals were offered a choice between a lump-sum separation benefit or an annuity and used the results to infer personal discount rates. An ancillary finding in their study was that individuals with higher AFQT scores had lower discount rates.

We link this oft-used and well validated measure of cognitive ability to two very specific but distinct types of financial decisions where suboptimal behavior is clearly defined. The first example refers to consumers who transfer their entire credit card balance from an existing account to a new card but choose to use the new card for “convenience” transactions.⁵ As we explain in the next section, it is never optimal to use the new card for such purchases since it leads to finance charges that could be avoided by simply using the previous card. We refer to this as a “balance transfer mistake” and describe the point at which a consumer discovers the optimal strategy as experiencing a “eureka” moment. The second example is individuals who do not accurately estimate the value of their home on their loan application and are therefore penalized by being offered a higher APR. We refer to this as a “rate changing mistake”.

⁴ The ASVAB test for our sample consists of 10 subtests. We describe the test in further detail in section 2. The coding speed component of the test which is arguably a measure of perceptual skills has been dropped from the ASVAB.

⁵ Convenience purchases are those that the consumer intends to pay off in full within the grace period, thereby not adding to existing debt levels.

We match a subset of the universe of active duty military personnel in 1993 to administrative data from a large financial institution containing retail credit data from 2000 through 2002 and estimate statistical models linking suboptimal financial behavior to ASVAB test scores taken years earlier.

Our results show that consumers with higher overall AFQT scores, and specifically those with higher math scores, are substantially less likely to make balance transfer and rate changing mistakes. Specifically a one standard deviation increase in the composite AFQT score is associated with a 24 percent increase in the probability that a consumer will discover the optimal strategy immediately, and a 11 percent reduction in home equity loan mistakes that result in higher APRs. The fact that verbal scores are not at all associated with balance transfer mistakes and are much less strongly associated with rate changing mistakes provides a useful internal validity check and suggests that omitted variables bias is not of major concern. We also use a rich set of observable demographic characteristics and financial measures as controls and demonstrate that our matched sample is reasonably representative of both the overall military sample and the administrative dataset from the financial institution.

We further assess the external validity of our results by using a nationally representative sample, the National Longitudinal Survey of Youth (NLSY79) who were given the ASVAB in order to construct national norms. Although we do not have a measure of actual suboptimal financial behavior we use a survey based measure designed to elicit the degree of time preference. We find that this measure is strongly associated with only the math component of the test and those with higher math scores in adolescence have lower subjective discount rates later in life. These results are robust to the inclusion of family fixed effects providing further support for a causal interpretation of our results. However, we are cautious in our interpretation of these findings since it may be the case that causality may run in the other direction, that patient individuals tend to have better math skills.

We also use the Health and Retirement Survey (HRS) to further demonstrate the specific nature of the mapping between particular forms of cognitive ability and specific examples of suboptimal behavior. We replicate a finding from McCardle et al (2009) to show that among a broad set of measures of cognitive ability, only numerical ability matters for predicting wealth. We extend the analysis, however, to show

that numerical ability does not predict other forms of suboptimal behavior such as the failure to take medication. In contrast, other non-mathematical measures of cognitive skill can explain the failure to take medication as well as other examples of non-financial sub-optimal behavior. This exercise further reinforces our conclusion that math scores on the ASVAB are not simply a proxy for other omitted variables.

Although we believe our empirical approach represents a significant improvement in the literature by linking very specific aspects of cognitive ability to very tightly defined examples of suboptimal decision making, future work is needed to better interpret these findings and to identify the underlying mechanisms. One important policy question is the extent to which our results provide support for financial literacy programs. If the cognitive abilities that are measured by the ASVAB largely reflect skills that can be learned or acquired, this suggests that there may be scope for educational interventions. If on the other hand, ASVAB scores largely reflect innate intelligence then this may suggest that there is little room for policy. Our reading of the literature suggests that ASVAB scores are not measures of innate intelligence and can be affected by education and experience (Neal and Johnson 1996; Hansen et al., 2004; Cascio and Lewis 2006) or by early life access to health care (Chay et. al., 2009).⁶ A cursory examination of the test itself makes it clear that the ASVAB is at least, in part, a test of acquired knowledge.⁷

The main goal of our study is to show that financial decision-making, in general, is tightly linked to specific forms of cognitive ability. To that end we have deliberately targeted very “clean” examples of suboptimal behavior, irrespective of the dollar values of the costs of such mistakes. Nevertheless, one may question whether the *magnitudes* of the financial mistakes we have uncovered are quantitatively meaningful. We think that our analysis likely only touches the tip of the iceberg in terms of the effects of

⁶ Aaronson and Mazumder (2010) also show that increased access to schools and improved school quality for Southern rural blacks during the 1920s led to sharp improvements on the Army General Classification Test (AGCT), a precursor to the ASVAB.

⁷ The following is a sample question from the ASVAB word knowledge test. “Question 1. Antagonize most nearly means: A. embarrass. B. struggle. C. provoke. D. worship. The following is a sample question from the mathematics knowledge test: “Question 1. $\sqrt{\frac{27}{3}} = A. \sqrt{3} , B. 3, C. 9, D. 12$ ”

poor financial decision-making due to low cognitive ability on individual and social welfare. It is highly plausible that similar types of financial mistakes have played a role in explaining loan default, foreclosures and bankruptcies. In a highly complementary paper to ours, Gerardi et al (2010) find a strong association between numerical ability and mortgage delinquency and default during the recent financial crisis. We also note that our HRS results (which build upon McArdle et al 2009) also suggest that there are potentially huge ramifications for having poor mathematical cognitive ability on savings behavior and accumulated wealth. Once it has been clearly demonstrated that cognitive ability causally influences financial decision making in one specific area it becomes highly plausible that these causal effects also occur in other decisionmaking domains. Nevertheless, we think that further research on a range of outcomes employing credible research designs are needed to more conclusively establish the potential benefits to improvements in cognitive ability.

The rest of the paper is organized as follows. Section 2 provides an overview of the current literature relating financial decision making and cognitive ability. Section 3 describes the data and our measures. Section 4 discusses the empirical estimation and presents results. Finally section 5 concludes.

2. Literature Review

We describe some of the relevant literature linking cognitive ability to behavioral differences that may be relevant to our study. One major reason why cognitive ability might matter is because of the importance of information. In a seminal paper Tversky and Kahneman (1981) demonstrated that the way in which information is presented can affect an individuals' decision making. Several recent studies have specifically emphasized that information may be an important factor influencing financial behaviors. Stango and Zinman (2009) find that U.S. consumers regularly underestimate the APR of a loan if they are given only the loan principal and repayment stream. They further find that mistake-prone consumers hold loans with higher interest rates when borrowing from non bank lenders who are may be more likely to suppress interest rate information and emphasize monthly payment rates. Bertrand and Morse (2009) find that payday loan borrowers who are shown information on the aggregate cost of their loan or the time to

repayment frequencies, borrow significantly less per pay cycle. Korniotis and Kumar (2009a) present evidence that some deviations from standard portfolio choice theory are due to access to superior information among high cognitive ability investors. Finally, Li (2009) finds that information sharing may explain the correlation in financial market participation among family members.

Other studies have emphasized psychological biases in financial decision making. Heaton (1997) showed that managers tend to be overly optimistic about their firms' prospects which leads them make managerial decisions that might not have been chosen in the absence of emotional influences. Korniotis and Kumar (2009a) suggest that low cognitive ability investors have lower risk-adjusted performance due to overconfidence and familiarity. Firms tend to keep prices stable or even below marginal costs in part to avoid anger or regret from consumers (Rotemberg, 2007).

Several papers have found that individuals with higher cognitive ability demonstrate fewer and less extreme cognitive biases that may lead to suboptimal behavior. Benjamin et al. (2006) found that Chilean high school students with higher standardized test scores were less likely to exhibit small stakes risk aversion and short run discounting in a laboratory setting. Preference anomalies were greater when the complexity, or "cognitive load," of the choices increased, but smaller when subjects were asked to explain their decisions. Though financial decisions are made with larger stakes and over a longer time frame, these results suggest that cognitive limitations might be related to similar behavioral biases that influence financial decisions. Frederick (2005) documents similar phenomena with college students using a different measure of intelligence called the Cognitive Reflection Test (CRT), which evaluates an individual's ability to override initial but incorrect cognitive impulses. Subjects with high CRT scores were more patient with short term tradeoffs but not significantly more patient with long term tradeoffs, suggesting that these differences may be due to differences in cognitive reflection rather than underlying preferences.

It is clear that one important objective of future studies should be to distinguish the relative importance of information channels, psychological biases and other forms of cognitive bias. One potential avenue for investigating this is to use distinct measures of separate cognitive skills

simultaneously. One study that does attempt to distinguish between the information channel and other biases is Korniotis and Kumar (2009a). However, a major caveat to the analysis is that the study uses other characteristics (e.g. age, education, income, and wealth) to impute cognitive ability. Consequently, unlike many of the other studies which hold the effects of other key covariates constant, Korniotis and Kumar estimate the effect of cognitive ability on financial outcomes through its relationship with these control variables. Any separate effect of cognitive ability is *not* captured in their analysis.

A second relevant literature is concerned with the general importance of cognitive ability on economic outcomes and financial market outcomes. Studies have linked greater cognitive ability as measured by ASVAB scores to higher earnings (Neal and Johnson 1996) and to reduced criminal activity or other socially deviant behaviors (Heckman et. al., 2006). A few studies have utilized ASVAB scores from the NLSY to analyze financial market participation. Benjamin et al. (2006) found that individuals with higher AFQT scores were significantly more likely to own stocks, bonds or mutual funds. Cole and Shastry (2009) using the same data also find effects of AFQT scores on the intensive margin (e.g. amounts of stock ownership).

Grinblatt et al. (2009) use very detailed data on the daily portfolios and trades of Finnish households matched to test scores from the Finnish Armed Forces Intelligence Assessment taken by all males in Finland. They find a positive monotonic relationship between intervals of this score and stock market participation, for both the entire population and for a subsample of more affluent Finns. They further find that only 60% of this relationship can be explained by IQ's correlation with other control variables and that the results are also robust to household fixed effects. While Benjamin et al. (2006), Cole and Shastry (2009) and Grinblatt et al. (2009) all use family or household fixed effects, there still may be lingering concerns that sibling specific characteristics that could be correlated with cognitive ability (e.g. motivation, or other sibling specific endowments) may have an independent effect on financial market participation. This helps motivate the need for a much narrower measure of suboptimal financial decision making that would be more tightly related only to cognitive skills.

To our knowledge, the only paper that attempts to study the relationship between cognitive ability and credit decisions is Agarwal et. al. (2009). Similar to Korniotis and Kumar (2009b), Agarwal et al. use an indirect approach by analyzing how credit decisions vary with age. They find that middle aged borrowers pay lower interest rates and fees than their younger and older counterparts, creating a U-shaped age-price curve. This curve is consistent across ten financial products including home equity loans, auto loans, mortgages, and several credit card services, and is not explained by cohort effects, selection effects, or differences in borrower risk. Most interestingly, the authors find mechanisms related to experience and cognitive ability for the two forms of financial decision making mistakes also used in this paper –optimal use of credit card balance transfer offers, and the ability to correctly assess the values of one’s home. They find that the combined effects of increasing experience and declining cognitive ability drive the U-shape of the age-price curve (Agarwal et. al., 2009).

3. Data and Methodology

Our primary analysis combines information from three distinct datasets: U.S. military data, credit card data, and data on home equity loan/lines. We describe each of these datasets below. We also discuss the two samples that are formed based on the merging of the the military records with the two sets of financial records. We also describe the two forms of suboptimal behavior and our basic estimation strategy.

3.1 Military data

We begin with a universe of approximately 1.4 million active duty military personnel in 1993. Since the Armed Services Vocational Aptitude Battery test (ASVAB) has changed over time, we limited our sample to individuals who entered the military beginning in September 1986 and whose test form is between 35 and 47 so that the scores are measured on a consistent basis. This gives us a sample of approximately 840,000 individuals.

For our sample, the ASVAB consists of a total 10 different subtests including: numerical operations, word knowledge, arithmetic reasoning, mathematical knowledge, electronics information, mechanical

comprehension, general science, paragraph comprehension, coding speed and automotive and shop. The armed forces qualifying test (AFQT) is constructed by combining two of the math scores with the two of the verbal scores.⁸ The AFQT is used for enlistment screening and various subscores of the ASVAB are used for assigning jobs within the military. The ASVAB has undergone exhaustive analysis including a 1991 National Academy of Science study establishing the validity of the test as a predictor of job performance (Wigdor and Green, 1991). In addition to test scores, we have information on gender, age, education levels, branch of service, race, ethnicity, marital status and zipcode of residence. Summary statistics for this sample are shown in Appendix Table A1.

3.1 Credit Card Data

We use a proprietary panel data set from a large financial institution that made balance transfer offers to credit card users nationally.⁹ Our universe consists of 14,798 individuals who accepted the offers between January 2000 and December 2002. The data includes the main billing information listed on each account's monthly statement including total payment, spending, credit limit, balance, debt, purchases, cash advance annual percentage rates (APRs), and fees paid. We also observe the amount of the balance transfer, the start date of the balance transfer teaser rate offer, the initial teaser APR on the balance transfer, and the end date of the balance transfer APR offer. At a quarterly frequency, we observe each customer's credit bureau rating (FICO) and a proprietary (internal) credit 'behavior' score. In addition, we have credit bureau data on the number of other credit cards held by the account holder, total credit card balances, mortgage balances as well as age, gender, and self-reported income at the time of account opening.

We merge the credit card data with the military data using a unique identifier. We restrict the sample to individuals who transferred their entire balance out of the existing card and who only made convenience transactions on either the new or the old card after completing the balance transfer. We also

⁸ We use the 1989 metric of the AFQT which combines the scores from the arithmetic reasoning, mathematical knowledge, word knowledge and paragraph comprehension subtests. The current version of the ASVAB uses only 8 subtests.

⁹ Balance transfer offers were not made conditional on closing the old credit card account. In our sample, borrowers did not pay fees for the balance transfer.

require a full set of non-missing information on the military variables. This leaves us with a sample of 541. Appendix Table A1 presents summary statistics of the resulting sample and compares a common set of covariates to the full military sample in Panel A. The comparison shows that there are no significant differences in any of the test scores. The mean AFQT is just slightly lower in the matched sample (60.2 versus 61.3). For eight of the ten subtests the matched sample has slightly lower scores, the two exceptions are word knowledge and general science where the scores are slightly higher in the matched sample. On the other hand, average years of education are slightly higher in the matched sample (12.1 vs. 12.0), a difference which though tiny, is nonetheless statistically significant. The average age at entry into the military is also quite similar (19.7 versus 19.8). The share of males is a bit higher in the matched sample (88.9% vs. 87.6%). The most noticeable difference is with respect to race, where we find that our matched sample overrepresents blacks (25.3% vs. 19.8%) and slightly underrepresents whites (67.3% vs. 69.8%) and other racial groups (7.4% vs. 10.4%) compared to the full military sample. Overall, however, for the key dimension of our analysis --cognitive ability-- our sample is reasonably representative of the full military.

Panel B of Table A1 compares this matched sample to the full sample of borrowers. The average matched sample borrower is riskier as reflected by the FICO and behavior scores – they are 23 and 63 points lower respectively. Surprisingly, the income of the matched sample borrowers is \$14,242 higher. The balance transfer APR for the matched sample borrowers is 77 basis points higher than the full sample of borrowers. Although this difference is statistically significant it is not economically meaningful. The purchase APR for matched sample borrowers is 649 basis points lower. This is most likely due to the fact that the account age of these borrowers is less than half of the full sample borrowers and so they still have favorable lending terms. The majority of our matched sample of military members are only in their 30s in the 2000-2002 period when the balance transfer occurred compared to an older sample in the general population of borrowers.

3.2 Home Equity Loans and Lines Data

For home equity loans and lines of credit, we also use a proprietary panel dataset obtained from a

national financial institution. This company did not specialize in subprime loans or any other segment of the market. Between March and December 2002, the lender offered a menu of standardized contracts for home equity loans or lines of credit. Consumers chose the following: (a) either a loan or a credit line; (b) either a first or second lien; and (c) an incremental loan amount and an estimate of her property value, corresponding to a loan-to-value (LTV) ratio of less than 80 percent, between 80 and 90 percent, or between 90 and 100 percent. In effect, the lender offered twelve different contract choices. In the results below, we run regressions for home equity loans and lines of credit together, but have a dummy variable for home equity loans, not having a first mortgage and LTV bucket; hence we control for contract type. All loans have the same five-year maturity.

For 75,000 out of 1.4 million such contracts, we observe the contract terms, borrower demographic information (years at current job, home tenure), financial information (income and debt-to-income ratio), and risk characteristics (credit (FICO) score, and LTV).¹⁰ We also observe borrower estimates of their property values and the loan amount requested. We merge this data with the military dataset using a unique identifier producing a sample of 1393 borrowers who took out a home equity loan or line of credit and for whose home we have non-missing value on the key variables.

Panel A of Table A2 presents summary statistics comparing the matched sample to the overall military sample. Unlike the case with the credit card match, we find that test scores are generally higher in our matched sample and although the differences are not very large, they are statistically significant. We suspect that this is primarily driven by the fact that our matched sample is selected on home ownership status which likely reflects higher levels of socioeconomic status. We also find that unlike our credit card sample, our matched home equity sample contains a larger share of whites and a smaller share of males, although neither difference is statistically significant.

In panel B of the table, we compare the matched home equity sample to the full home equity sample. Borrowers in the matched sample are less risky, have higher income, and pay lower APR. Additionally,

¹⁰ We do not have internal behavior scores (a supplementary credit risk score) for these borrowers. Such scores are performance-based, and are thus not available at loan origination.

the FICO score in the matched group is 10 points higher, the APR is 196 basis points lower and the debt-to-income ratio is 6.5% lower than for the full sample. Finally, borrowers in the matched sample have been on their jobs 2.4 years longer and the appraised value of their homes is \$21,040 higher than the full sample borrowers.

3.3 Balance Transfer Mistake

Credit card holders frequently receive offers to transfer account balances on their current cards to a new card. Borrowers pay substantially lower APRs on the balances transferred to the new card for a six-to-nine-month period (a “teaser” rate). However, *new* purchases on the new card have high APRs. The catch is that payments on the new card first pay down the (low interest) transferred balances, and only subsequently pay down the (high interest) debt accumulated from new purchases.

For borrowers who have transferred the entire balance from one credit card and who subsequently only make “convenience” transactions, that is transactions that the consumer intends to pay off in full within the grace period, the optimal strategy during the teaser-rate period is for the borrower to only make new purchases on the *old* credit card. The borrower should make no new purchases with the new card to which balances have been transferred (unless she has already repaid her transferred balances on that card). Using this strategy will ensure that the borrower will not have to pay any interest fees irrespective of the interest rates on each account. Some borrowers will identify this optimal strategy immediately and will not make any new purchases using the new card. Some borrowers may not initially identify the optimal strategy, but will discover it after one or more pay cycles as they observe their (surprisingly) high interest charges. Those borrowers will make purchases for one or more months, then have what we refer to as a “eureka” moment, after which they will implement the optimal strategy. Some borrowers will never identify the optimal strategy.

This allows to categorize account holders in several ways including: whether they ever make a balance transfer mistake or not; or if they do make a balance transfer mistake, how long it takes them to adopt the optimal strategy and stop using the balance transfer card for new purchases. To operationalize this we track use of the balance transfer card for a six month period for consumers who continue to use at

least one card for a purchase. Our main dependent variable “eureka” will be defined as those who either never make the mistake during the six month period or if they do make a mistake at some point, whether they cease to make the mistake for the remainder of the sixth month window. Our second measure of eureka tracks how many months it takes for the consumer to adopt the optimal strategy and to stop using the balance transfer card for new purchases.

About one third of all customers who make a balance transfer do no spending on the new card, thus implementing the optimal strategy immediately. Slightly more than one third of customers who make a balance transfer will never experience a eureka moment. The remaining third of customers experience a eureka moment at some point between the first and sixth months.

In section 4 we will estimate the effect of overall AFQT scores as well as specific math and verbal subtests on the likelihood that a borrower will have a eureka moment. We run linear probability regressions where we include a variety of demographic and financial control variables. Figure 1 which plots the distribution of AFQT scores by whether the consumer ever has a eureka moment, provides a preview of the main results. We find that among those with AFQT scores above 70, everybody ultimately identifies the optimal strategy. In contrast, among those with an AFQT score below 50, the majority will not identify the optimal strategy. A full set of differences in the mean characteristics of those who experience eureka versus those that don’t are shown in Table A3. Of particular note is that blacks comprise a much larger fraction of the “no eureka” subsample. As we show later, however, our results are robust to dropping blacks.

3.4 Rate Changing Mistake

In determining the APR for a home equity loan or line of credit, the amount of collateral offered by the borrower, as measured by the loan-to-value (LTV) ratio, is an important determinant. Higher LTVs imply higher APRs, since the fraction of collateral is lower. At the financial institution that provided our data, borrowers first estimate their home values, and ask for a credit loan or credit line falling into one of three categories depending on the implied borrower-generated LTV estimate. The categories correspond to LTVs of 80 percent or less (80-); LTVs of between 80 and 90 percent (80+); and LTVs of 90 percent or

greater (90+). The financial institution then independently verifies the house value using an industry-standard methodology and constructs an LTV measure. The institution's LTV can therefore differ from the borrower's LTV.¹¹

Loan pricing (APR) depends on the LTV category that the borrower falls into and not on the specific LTV value within that category.¹² If the borrower has overestimated the value of the house, so that the financial institution's LTV (80+) is higher than the borrower's LTV (80-), the institution will direct the buyer to a different loan with a higher interest rate corresponding to the higher LTV (80+). In such circumstances, the loan officer is also given some discretion to depart from the financial institution's normal pricing schedule to offer a higher interest rate than the officer would have offered to a borrower who had correctly estimated her LTV. If the borrower has underestimated the value of the house (e.g. the borrowers' LTV category is 80+ while the bank's LTV category, 80-), the financial institution need not direct the buyer to a loan with a lower interest rate corresponding to the financial institution's LTV; the loan officer may simply choose to offer the higher interest rate associated with the borrower's LTV (80+), instead of lowering the rate to reflect the lower financial institution's LTV (80-).¹³

We define a Rate-Changing Mistake (RCM) to have occurred when the borrower-LTV category differs from the bank-LTV category (conditional on the bank LTV being greater than 80) — for instance, when the borrower estimates an LTV of 85 but the bank calculates an LTV of 95 (or vice versa).¹⁴ We find that, on average, making a RCM increases the APR by 269 basis points for home equity loans and lines. In the next section, we will estimate the effect of math and verbal ASVAB test scores on whether a borrower makes an RCM.

¹¹Agarwal (2007) provides evidence that younger households are more likely to overstate their house value and older households are more likely to understate their house values. Bucks and Pence (2008) present evidence that borrowers do not generally have accurate estimates of their house value or know their mortgage terms.

¹²We have verified this practice in our dataset by regressing the APR on both the level of the bank-LTV and dummy variables for whether the bank-LTV falls into one of the three categories. Only the coefficients on the dummy variables were statistically and economically significant. Ben-David (2007) also shows that there are discrete jumps in lending rates at LTV cutoff points.

¹³Even if the financial institution's estimate of the true house value is inaccurate, that misestimation will not matter for the borrower as long as other institutions use the same methodology.

¹⁴An example where misestimation does not lead to a higher APR is if the borrower's estimated LTV is 60, but the true LTV is 70. In this case the borrower would still qualify for the highest quality loan category (LTV<80) and would not suffer an effective interest rate penalty.

Table A4, Panel B highlights the significant differences between the borrowers with and without a RCM. The FICO score for the RCM borrowers is 24 points lower, the income is \$20,360 lower and the debt-to-income is 5% higher. However, to highlight the importance of RCMs, we estimated the effect of AFQT on the APR for consumers who do not make a Rate-Changing Mistake and found no statistically significant or quantitatively meaningful effect. When coupled with our findings below, this suggests that cognitive ability only affects the pricing of the loan through the rate changing mistake.

As with balance transfer mistakes, we find stark differences in rate changing mistakes by AFQT. Figure 2 shows that there are no cases of rate changing mistakes among those with scores above 60. Although rate changing mistakes are still relatively uncommon even among those with lower test scores they are concentrated in the lower half of the AFQT distribution. Table A4 provides more detailed summary statistics separately for those who experience an RCM versus those who don't. In section 4 we control for these demographic and financial factors using a linear probability model. We estimate the effect of composite AFQT scores and specific math and verbal subtests on the likelihood that a borrower will make a rate changing mistake.

4. Results

4.1 Balance Transfer Mistakes and AFQT Scores

In Table 1 we show the results of our first set of estimates that use the composite AFQT test score to predict whether consumers learn the optimal behavior after a balance transfer i.e. experience a eureka moment. In all of our estimations we have standardized all the test score variables to have a mean of zero and a standard deviation of one. In column (1) where we don't include any controls, the estimated effect of a one standard deviation increase in AFQT scores is to raise the probability of a eureka moment by about 23 percentage points. The effect is highly significant with a t-statistic over 12. In column (2) we add financial controls from our credit card dataset and find that this has almost an imperceptible effect on the AFQT score. Further, we find that most of the financial controls (e.g. FICO score, income) have no effect on the probability of a eureka moment. The one exception is the behavior score. The behavior

score is a measure of the borrowers payment and purchase behavior. Hence, it is not surprising that the behavior score is predictive in explaining the credit card purchases subsequent to balance transfers.

In column (3) we find the effect rises slightly to 0.24 when we include our demographic controls. Perhaps surprisingly, there is no effect of years of education. Further, we find that the effect for blacks is positive (0.064) once we control for AFQT scores, though this is not statistically significant. Those that were married at the time they were in the military are significantly less likely to have a eureka moment. In column (4) we include both sets of controls and again find that it has no effect on our main finding.

In columns (5) through (8) we use the four component scores (arithmetic reasoning, math knowledge, paragraph comprehension and word knowledge) that are used to calculate the AFQT score. In all four specifications the two math scores are both highly significant suggesting that quantitative skills are critical for avoiding suboptimal behavior. In contrast, we estimate that the effects of the two verbal test scores are a fairly precisely estimated 0. For example, the largest point estimate for a verbal score suggests that a one standard deviation increase in word knowledge would only increase the incidence of “eureka” moments by a little more than a tenth of a percentage point. We also find that once we include all of the covariates using this specification, we no longer find any of the demographic controls to be significant.

In other specifications (not shown) we also estimated the effect of AFQT on whether a borrower *immediately* adopts the optimal strategy. In these cases the coefficient on AFQT is consistently around 0.18. This suggests that about two thirds of the 0.24 effect of cognitive skills shown in Table 1 is due to an immediate effect and about a third of the effect is due to borrowers who learned the optimal strategy subsequent to initially making a financial mistake. We also found that when we used this dependent variable, that none of the financial or demographic controls were ever significant.

To illustrate how AFQT influences the speed at which individuals learn, in Figure 3 we plot the unadjusted mean AFQT scores for borrowers based on how many months it took them to discover the optimal strategy. The chart shows that AFQT is monotonically decreasing in the number of months it takes borrowers to learn. We estimate that a one standard deviation increase in AFQT is associated with a

1.5 month reduction in the number of months it takes to achieve optimal behavior speed. This analysis is akin to showing that cognitive skills also affects the “intensive” margin of optimal financial decision making behavior.

4.2 Rate Changing Mistakes and AFQT Scores

In Table 2 we report the effects of AFQT scores on the probability of making a rate changing mistake (RCM) for home equity loans or lines. The first four columns use the overall AFQT score and utilize: no controls in column (1), financial controls from the home equity data in column (2), demographic controls from the military data in column (3), and both sets of controls in column (4). The key finding is that a one standard deviation increase in AFQT lowers the probability that a borrower will make a rate changing mistake by between 10 and 11 percentage points. The unconditional average probability of making a rate-changing mistake is 14 percent in our sample so the effect size is over 70 percent.

Among the financial covariates, taking out a loan versus a line raises the likelihood of an RCM by about 10 percentage points as does an increase in the APR. The debt to income ratio has a small but perceptible effect. The FICO score also has a small effect but not economically significant. Education has virtually no effect once we condition on financial variables. Interestingly, blacks are actually significantly less likely to make an RCM controlling for AFQT while women are slightly more likely to (not shown).

When we use the four subtests that comprise the AFQT (columns 5 to 8), we again find that both math scores have large and significant negative effects on RCM. Among the verbal scores, paragraph comprehension has no effect but we do see a negative statistically significant effect of word knowledge. A one standard deviation increase in word knowledge lowers the probability of an RCM by about 2 to 3 percentage points.

Given the large costs associated with an RCM, one might ask why borrowers do not make greater effort to more accurately estimate their house values. One possibility is that potential borrowers may not be aware that credit terms will differ by LTV category; or, even if they are aware of this fact, they may

not know how much the terms differ by category. This particular aspect of loan pricing may thus be a shrouded attribute, in the sense of Gabaix and Laibson (2006).

4.3 Robustness Checks

An important finding is that it is specifically mathematical skills, as opposed to other dimensions of cognitive ability, that appear to matter for financial decision making. To reinforce this, we also show results that include the other 6 subtests from the ASVAB in Table 3. Columns (1) to (4) use the same specifications from the previous tables to examine the effect of the scores on eureka moments using the credit card data. Columns (5) to (8) estimate the effects on a rate changing mistake using the home equity borrower sample. For the credit card results, we find that the effects from two main math scores from Table 1 are unaffected by the inclusion of the other scores. For example, the results in column (4) imply that a one standard deviation increase in either of the main math scores alone, would raise the probability of a eureka moment by about 13 percent. We also find that a test called “coding speed” which measures how quickly and accurately individuals can recognize numerical patterns is statistically significant.

A third test of math skills called numerical operations enters *negatively* controlling for the other two math scores. However, the raw correlation between eureka moments and numerical operations is positive (0.18) but much lower than the raw correlations of eureka moments with arithmetic reasoning (0.50) or math knowledge (0.48) suggesting that numerical operations is picking up some factor that is orthogonal to the other two math scores.¹⁵

With our home equity borrowers we find that in addition to the arithmetic reasoning, math knowledge and word knowledge, that numerical operations has the correct sign and is marginally significant. We do not find that coding speed has any effect on rate changing mistakes. Overall, though not every effect is perfectly consistent across the two outcomes the two main math tests are highly significant while most other subtests are insignificant. Our results are insensitive to using state or zipcode fixed effects or

¹⁵ Numerical operations had been included in the 1980 metric of the AFQT before it was replaced with math knowledge.

limiting the sample to only whites. Finally, the results are also robust to controls for contract type (loan interacted with LTV category).

4.4 Additional Evidence from the NLSY: Cognitive Ability and Time Preference

In order to better understand the underlying mechanisms behind the link between cognitive ability and optimal financial decision-making we conduct a similar analysis using the 1979 National Longitudinal Survey of Youth (NLSY). The NLSY followed a nationally representative sample of individuals who were between the ages of 14 and 21 as of January 1979 into adulthood. One hypothesis that we can test is whether cognitive skills are associated with lower discount rates reflecting greater patience. In the 2006 survey, respondents were asked an experimental question designed to elicit their implicit personal discount rates. Specifically, the question read as follows: *Suppose you have won a prize of \$1000, which you can claim immediately. However, you can choose to wait one month to claim the prize. If you do wait, you will receive more than \$1000. What is the smallest amount of money in addition to the \$1000 you would have to receive one month from now to convince you to wait rather than claim the prize now?* A response of \$100, for example, would imply an annual discount rate of over 200%. We use a subset of responses that lie within the range of \$1 to \$500.¹⁶

We link responses to this question to respondent test scores as well as a number of other controls. Individuals in the NLSY were given the ASVAB in 1980 and their scores were used to norm the test. The use of the same scores for a nationally representative sample also may help alleviate any lingering concerns that our results on suboptimal financial behavior are driven by unrepresentative samples. Previous work by Warner and Pleater (2001) showed that AFQT scores are associated with lower discount rates as implied by a real world experiment where military personnel were offered a choice of either a lump-sum payment or an annuity during separation. However, their analysis was limited to four broad intervals of the composite AFQT and could not distinguish between specific subtest scores. .

¹⁶ Many respondents provided answers that were clearly unreasonable with implied discount rates of ___% or more. We also have experimented with a parallel question that asks the same thing over a 1 year range.

In Table 4 we present the results of this analysis. In column (1) we show that a one standard deviation increase in AFQT is associated with 44 dollar decline in the amount an individual would require to be compensated. This implies a decline in the monthly subjective discount rate of 4.4 percent. This estimate controls for several demographic characteristics including gender, race, Hispanic status and education that are all at least marginally significant. As a point of comparison for our AFQT results, even four additional years of schooling would only lower the discount rate by 0.8 percentage points. In column (2) we include the scores from the other 6 ASVAB subtests not incorporated into the composite AFQT. In column (3) we also add one's own annual earnings in 2005. These have a limited effect on our main estimates. In column (4) we utilize the fact that the NLSY contains many multiple sibling families and include family fixed effects. This raises the standard errors considerably, but we still estimate a significant negative effect of about 55 dollars. In this case we have arguably greatly reduced the potential scope for omitted variables bias since we only utilize differences in cognitive ability between siblings and sweep away all variation that is across families.

In columns (5) through (8) we run the same specifications but now show the effects of the four main math and verbal subtests of the ASVAB on our measure of patience. In all four specifications the effects are highly concentrated in the arithmetic reasoning subtest with coefficients ranging from to -27 to -44. The other main subtests also generally have negative coefficients but are never statistically significant.

A simpler interpretation of this survey question is that it is simply picking up whether respondents are able to calculate an interest rate. Even in this we still think it is an important finding since the ability to calculate interest rates is arguably an important aspect of financial planning.

4.5 Additional Evidence from the HRS

A lingering concern may be that math scores simply capture other unobserved characteristics of individuals who tend to avoid sub-optimal behavior in all realms of their life. In other words maybe people who are good at math also avoid making mistakes in all aspects of life, even those that have nothing to do with financial decision-making. In that case we would be falsely attributing improved financial behavior to mathematical cognitive ability. To demonstrate that this is not the case we use data

from the Health and Retirement Survey (HRS) to estimate the effects of mathematical ability on other forms of suboptimal behavior such as the failure to take medication. McCardle et al (2009) use the HRS to demonstrate the importance of cognitive skills such as numerical ability on stock market participation and wealth accumulation. We begin by trying to replicate their basic findings concerning financial behavior and then extend the analysis to include other forms of non-financial behavior.

The HRS collects information about wealth, income, cognitive abilities, and many other variables of interest bi-annually from over 22,000 Americans older than 50 years old. The measures of cognitive ability include word recall, mental status, number series, retrieval fluency and numeracy.¹⁷ Following McCardle et al, we estimated our outcomes include total wealth, total financial wealth, the percent of stock ownership. We supplement these with outcomes from questions pertaining to Instrumental Activities of Daily Living (IADLs). Specifically, we have information for each individual on whether they have difficulty reading a map, buying groceries, taking medication, making a phone call, preparing a meal and managing money. We restrict the sample to those individuals that indicate that they don't have trouble, do have trouble, or cannot perform the task and create indicators for not having trouble performing said task. These are then multiplied by 100 so that the coefficients can be interpreted as percentage point effects.

We present the results in Table 5. In column (1) we find that each additional math question (out of a total of 3 questions) answered correctly is associated with an increase in total wealth of \$100,000 and

¹⁷ For word recall, the interviewer reads a lists of 10 basic nouns and requests the participant to immediately list as many of the 10 nouns as possible. After five minutes the surveyor asks the participant to list as many of the 10 nouns as possible again. Mental status is derived from five tests. The first asks the respondent to subtract 7 from 100 and then to subtract 7 from the previous result. This is done a total of 5 times and a point is given for each proper subtraction. The second is to count backwards from 20 as quickly as possible. The next three tests asked a series of question: what is today's date, who is the President and Vice-President of the United states, what do you usually cut paper with, and what do you call the kind of prickly plant that grows in the desert. The numeracy score n the number of correct answers to three mathematical questions. Number series are designed to test abstract reasoning through a series of number series puzzles. For retrieval fluency the interviewer gives the respondent a category and asks the respondent to name as many items in that category as possible in 45 seconds. Retrieval Fluency and number series were part of an experimental module that was run on a sub-sample of the survey sample. By construction it is a random sample of the survey population which allows us to assume missing at random.

financial wealth of \$66,000.¹⁸ Similarly for the small subsample who answered the number series questions, there are significant effects on wealth, a one standard deviation increase is associated with about an \$85,000 increase in total wealth. Retrieval fluency is also statistically significant. A one standard deviation increase in retrieval fluency (25 points) is associated with about a \$179,000 increase in total wealth. However, no effects are found for mental status and word recall. Of course, these regressions do not necessarily reflect causal relationships as the authors fully acknowledge. Nonetheless, they are strongly suggestive that improvements in cognitive skill could have substantial payoffs.

In columns (4) through (8) we present results on the new outcomes. We find that for the four outcomes that appear to require the least amount of mathematical aptitude (buy groceries, take medication, make a phone call and prepare a meal) that in no case is numeracy statistically significant and in three cases the point estimates are close to zero or negative. In only one case, prepare a meal, is number series statistically significant. In contrast for these same four outcomes, mental status and word recall, the coefficients are always large and positive and in 7 of 8 cases significant at the one percent level. Recall, that these measures of cognitive skill were never significant for wealth or financial wealth. As an additional check that there is no systematic bias in the IADL questions, we do find that numeracy has a huge effect on the outcome of managing money. We find that numeracy also has a significant effect on reading a map, which arguably does require some quantitative skills.

5. Conclusion

There is a clear desire among policy makers in the wake of the recent financial crisis to improve the quality of household financial decision making. An emerging literature has demonstrated that it is not uncommon for consumers to exhibit suboptimal behavior in various markets. While many papers have attempted to link financial market behavior to measures of cognitive ability, we bring new evidence to bear on this important topic that overcomes many of the limitations in previous studies. Specifically, we

¹⁸ These results are significantly larger than the coefficients reported by McCardle et al. They find an effect of \$20,000 for total wealth and \$7000 for financial wealth. We attempted to construct the identical sample of 18,382 reported by McCardle et al in their results in their Table 1 and came close with a sample of 18,338. The means and standard deviations of our cognitive and demographic variables are virtually identical to their sample though we have some modest differences with some of the financial variables.

analyze two examples of consumer financial decisions where suboptimal behavior is extremely well defined: first, the use of a new credit card for convenience transactions after making a balance transfer to the account, and second, inaccurate estimation of the value of one's home on home equity loan or line of credit application that result in higher APRs. We match individuals from the US military in 1993 for whom we have detailed test scores from the Armed Services Vocational Aptitude Battery test (ASVAB), to administrative datasets of retail credit from a large financial institution covering financial activity over the 2000-2002 period.

Our results show that consumers with higher overall AFQT scores, and specifically those with higher math scores, are substantially less likely to make balance transfer and house price estimation mistakes. Specifically a one standard deviation increase in the AFQT score is associated with a 24 percent increase in the probability that a consumer will utilize the optimal strategy within a 6 month period and a 11 percent reduction in 'rate changing mistakes' in the home equity loan/line of credit market. The fact that these effects are almost entirely due to math ability and largely unrelated to other aspects of cognitive aptitude suggests that omitted variables bias is not of major concern.

Using data from the National Longitudinal Survey of Youth (NLSY79) we further demonstrate that a simple survey based measure of patience is strongly associated with only the math component of the test providing a parallel set of supportive results. Finally, using the HRS we show that mathematical ability is not predictive of suboptimal behavior in other aspects of life such as taking medication but that other forms of cognitive ability are in fact, critical. This suggests that there is correspondence in the kinds of cognitive abilities that are relevant for particular outcomes. This strengthens the notion that there is something inherent in mathematical ability that lessens that likelihood of an individual making poor financial decisions.

While we think our findings significantly improve the quality of empirical evidence linking cognitive abilities to financial decision making we think further research is needed to better elucidate the mechanisms underlying this association. The literature suggests that our measures of cognitive ability, ASVAB scores, are not immutable and do not simply reflect innate intelligence. Instead there is growing

evidence that outside factors can influence cognitive abilities. This suggests that there may be scope for educational policies such as financial literacy initiatives to help improve financial decision making behavior.

Working Paper Series

A series of research studies on regional economic issues relating to the Seventh Federal Reserve District, and on financial and economic topics.

Risk Taking and the Quality of Informal Insurance: Gambling and Remittances in Thailand <i>Douglas L. Miller and Anna L. Paulson</i>	WP-07-01
Fast Micro and Slow Macro: Can Aggregation Explain the Persistence of Inflation? <i>Filippo Altissimo, Benoît Mojon, and Paolo Zaffaroni</i>	WP-07-02
Assessing a Decade of Interstate Bank Branching <i>Christian Johnson and Tara Rice</i>	WP-07-03
Debit Card and Cash Usage: A Cross-Country Analysis <i>Gene Amromin and Sujit Chakravorti</i>	WP-07-04
The Age of Reason: Financial Decisions Over the Lifecycle <i>Sumit Agarwal, John C. Driscoll, Xavier Gabaix, and David Laibson</i>	WP-07-05
Information Acquisition in Financial Markets: a Correction <i>Gadi Barlevy and Pietro Veronesi</i>	WP-07-06
Monetary Policy, Output Composition and the Great Moderation <i>Benoît Mojon</i>	WP-07-07
Estate Taxation, Entrepreneurship, and Wealth <i>Marco Cagetti and Mariacristina De Nardi</i>	WP-07-08
Conflict of Interest and Certification in the U.S. IPO Market <i>Luca Benzoni and Carola Schenone</i>	WP-07-09
The Reaction of Consumer Spending and Debt to Tax Rebates – Evidence from Consumer Credit Data <i>Sumit Agarwal, Chunlin Liu, and Nicholas S. Souleles</i>	WP-07-10
Portfolio Choice over the Life-Cycle when the Stock and Labor Markets are Cointegrated <i>Luca Benzoni, Pierre Collin-Dufresne, and Robert S. Goldstein</i>	WP-07-11
Nonparametric Analysis of Intergenerational Income Mobility with Application to the United States <i>Debopam Bhattacharya and Bhashkar Mazumder</i>	WP-07-12
How the Credit Channel Works: Differentiating the Bank Lending Channel and the Balance Sheet Channel <i>Lamont K. Black and Richard J. Rosen</i>	WP-07-13
Labor Market Transitions and Self-Employment <i>Ellen R. Rissman</i>	WP-07-14
First-Time Home Buyers and Residential Investment Volatility <i>Jonas D.M. Fisher and Martin Gervais</i>	WP-07-15

Working Paper Series *(continued)*

Establishments Dynamics and Matching Frictions in Classical Competitive Equilibrium <i>Marcelo Veracierto</i>	WP-07-16
Technology's Edge: The Educational Benefits of Computer-Aided Instruction <i>Lisa Barrow, Lisa Markman, and Cecilia Elena Rouse</i>	WP-07-17
The Widow's Offering: Inheritance, Family Structure, and the Charitable Gifts of Women <i>Leslie McGranahan</i>	WP-07-18
Incomplete Information and the Timing to Adjust Labor: Evidence from the Lead-Lag Relationship between Temporary Help Employment and Permanent Employment <i>Sainan Jin, Yukako Ono, and Qinghua Zhang</i>	WP-07-19
A Conversation with 590 Nascent Entrepreneurs <i>Jeffrey R. Campbell and Mariacristina De Nardi</i>	WP-07-20
Cyclical Dumping and US Antidumping Protection: 1980-2001 <i>Meredith A. Crowley</i>	WP-07-21
Health Capital and the Prenatal Environment: The Effect of Maternal Fasting During Pregnancy <i>Douglas Almond and Bhashkar Mazumder</i>	WP-07-22
The Spending and Debt Response to Minimum Wage Hikes <i>Daniel Aaronson, Sumit Agarwal, and Eric French</i>	WP-07-23
The Impact of Mexican Immigrants on U.S. Wage Structure <i>Maude Toussaint-Comeau</i>	WP-07-24
A Leverage-based Model of Speculative Bubbles <i>Gadi Barlevy</i>	WP-08-01
Displacement, Asymmetric Information and Heterogeneous Human Capital <i>LuoJia Hu and Christopher Taber</i>	WP-08-02
BankCaR (Bank Capital-at-Risk): A credit risk model for US commercial bank charge-offs <i>Jon Frye and Eduard Pelz</i>	WP-08-03
Bank Lending, Financing Constraints and SME Investment <i>Santiago Carbó-Valverde, Francisco Rodríguez-Fernández, and Gregory F. Udell</i>	WP-08-04
Global Inflation <i>Matteo Ciccarelli and Benoît Mojon</i>	WP-08-05
Scale and the Origins of Structural Change <i>Francisco J. Buera and Joseph P. Kaboski</i>	WP-08-06
Inventories, Lumpy Trade, and Large Devaluations <i>George Alessandria, Joseph P. Kaboski, and Virgiliu Midrigan</i>	WP-08-07

Working Paper Series *(continued)*

School Vouchers and Student Achievement: Recent Evidence, Remaining Questions <i>Cecilia Elena Rouse and Lisa Barrow</i>	WP-08-08
Does It Pay to Read Your Junk Mail? Evidence of the Effect of Advertising on Home Equity Credit Choices <i>Sumit Agarwal and Brent W. Ambrose</i>	WP-08-09
The Choice between Arm's-Length and Relationship Debt: Evidence from eLoans <i>Sumit Agarwal and Robert Hauswald</i>	WP-08-10
Consumer Choice and Merchant Acceptance of Payment Media <i>Wilko Bolt and Sujit Chakravorti</i>	WP-08-11
Investment Shocks and Business Cycles <i>Alejandro Justiniano, Giorgio E. Primiceri, and Andrea Tambalotti</i>	WP-08-12
New Vehicle Characteristics and the Cost of the Corporate Average Fuel Economy Standard <i>Thomas Klier and Joshua Linn</i>	WP-08-13
Realized Volatility <i>Torben G. Andersen and Luca Benzoni</i>	WP-08-14
Revenue Bubbles and Structural Deficits: What's a state to do? <i>Richard Mattoon and Leslie McGranahan</i>	WP-08-15
The role of lenders in the home price boom <i>Richard J. Rosen</i>	WP-08-16
Bank Crises and Investor Confidence <i>Una Okonkwo Osili and Anna Paulson</i>	WP-08-17
Life Expectancy and Old Age Savings <i>Mariacristina De Nardi, Eric French, and John Bailey Jones</i>	WP-08-18
Remittance Behavior among New U.S. Immigrants <i>Katherine Meckel</i>	WP-08-19
Birth Cohort and the Black-White Achievement Gap: The Roles of Access and Health Soon After Birth <i>Kenneth Y. Chay, Jonathan Guryan, and Bhashkar Mazumder</i>	WP-08-20
Public Investment and Budget Rules for State vs. Local Governments <i>Marco Bassetto</i>	WP-08-21
Why Has Home Ownership Fallen Among the Young? <i>Jonas D.M. Fisher and Martin Gervais</i>	WP-09-01
Why do the Elderly Save? The Role of Medical Expenses <i>Mariacristina De Nardi, Eric French, and John Bailey Jones</i>	WP-09-02

Working Paper Series *(continued)*

Using Stock Returns to Identify Government Spending Shocks <i>Jonas D.M. Fisher and Ryan Peters</i>	WP-09-03
Stochastic Volatility <i>Torben G. Andersen and Luca Benzoni</i>	WP-09-04
The Effect of Disability Insurance Receipt on Labor Supply <i>Eric French and Jae Song</i>	WP-09-05
CEO Overconfidence and Dividend Policy <i>Sanjay Deshmukh, Anand M. Goel, and Keith M. Howe</i>	WP-09-06
Do Financial Counseling Mandates Improve Mortgage Choice and Performance? Evidence from a Legislative Experiment <i>Sumit Agarwal, Gene Amromin, Itzhak Ben-David, Souphala Chomsisengphet, and Douglas D. Evanoff</i>	WP-09-07
Perverse Incentives at the Banks? Evidence from a Natural Experiment <i>Sumit Agarwal and Faye H. Wang</i>	WP-09-08
Pay for Percentile <i>Gadi Barlevy and Derek Neal</i>	WP-09-09
The Life and Times of Nicolas Dutot <i>François R. Velde</i>	WP-09-10
Regulating Two-Sided Markets: An Empirical Investigation <i>Santiago Carbó Valverde, Sujit Chakravorti, and Francisco Rodriguez Fernandez</i>	WP-09-11
The Case of the Undying Debt <i>François R. Velde</i>	WP-09-12
Paying for Performance: The Education Impacts of a Community College Scholarship Program for Low-income Adults <i>Lisa Barrow, Lashawn Richburg-Hayes, Cecilia Elena Rouse, and Thomas Brock</i>	WP-09-13
Establishments Dynamics, Vacancies and Unemployment: A Neoclassical Synthesis <i>Marcelo Veracierto</i>	WP-09-14
The Price of Gasoline and the Demand for Fuel Economy: Evidence from Monthly New Vehicles Sales Data <i>Thomas Klier and Joshua Linn</i>	WP-09-15
Estimation of a Transformation Model with Truncation, Interval Observation and Time-Varying Covariates <i>Bo E. Honoré and Luojia Hu</i>	WP-09-16
Self-Enforcing Trade Agreements: Evidence from Antidumping Policy <i>Chad P. Bown and Meredith A. Crowley</i>	WP-09-17
Too much right can make a wrong: Setting the stage for the financial crisis <i>Richard J. Rosen</i>	WP-09-18

Working Paper Series *(continued)*

Can Structural Small Open Economy Models Account for the Influence of Foreign Disturbances? <i>Alejandro Justiniano and Bruce Preston</i>	WP-09-19
Liquidity Constraints of the Middle Class <i>Jeffrey R. Campbell and Zvi Hercowitz</i>	WP-09-20
Monetary Policy and Uncertainty in an Empirical Small Open Economy Model <i>Alejandro Justiniano and Bruce Preston</i>	WP-09-21
Firm boundaries and buyer-supplier match in market transaction: IT system procurement of U.S. credit unions <i>Yukako Ono and Junichi Suzuki</i>	WP-09-22
Health and the Savings of Insured Versus Uninsured, Working-Age Households in the U.S. <i>Maude Toussaint-Comeau and Jonathan Hartley</i>	WP-09-23
The Economics of “Radiator Springs:” Industry Dynamics, Sunk Costs, and Spatial Demand Shifts <i>Jeffrey R. Campbell and Thomas N. Hubbard</i>	WP-09-24
On the Relationship between Mobility, Population Growth, and Capital Spending in the United States <i>Marco Bassetto and Leslie McGranahan</i>	WP-09-25
The Impact of Rosenwald Schools on Black Achievement <i>Daniel Aaronson and Bhashkar Mazumder</i>	WP-09-26
Comment on “Letting Different Views about Business Cycles Compete” <i>Jonas D.M. Fisher</i>	WP-10-01
Macroeconomic Implications of Agglomeration <i>Morris A. Davis, Jonas D.M. Fisher and Toni M. Whited</i>	WP-10-02
Accounting for non-annuitization <i>Svetlana Pashchenko</i>	WP-10-03
Robustness and Macroeconomic Policy <i>Gadi Barlevy</i>	WP-10-04
Benefits of Relationship Banking: Evidence from Consumer Credit Markets <i>Sumit Agarwal, Souphala Chomsisengphet, Chunlin Liu, and Nicholas S. Souleles</i>	WP-10-05
The Effect of Sales Tax Holidays on Household Consumption Patterns <i>Nathan Marwell and Leslie McGranahan</i>	WP-10-06
Gathering Insights on the Forest from the Trees: A New Metric for Financial Conditions <i>Scott Brave and R. Andrew Butters</i>	WP-10-07
Identification of Models of the Labor Market <i>Eric French and Christopher Taber</i>	WP-10-08

Working Paper Series *(continued)*

Public Pensions and Labor Supply Over the Life Cycle <i>Eric French and John Jones</i>	WP-10-09
Explaining Asset Pricing Puzzles Associated with the 1987 Market Crash <i>Luca Benzoni, Pierre Collin-Dufresne, and Robert S. Goldstein</i>	WP-10-10
Does Prenatal Sex Selection Improve Girls' Well-Being? Evidence from India <i>Luoji Hu and Analía Schlosser</i>	WP-10-11
Mortgage Choices and Housing Speculation <i>Gadi Barlevy and Jonas D.M. Fisher</i>	WP-10-12
Did Adhering to the Gold Standard Reduce the Cost of Capital? <i>Ron Alquist and Benjamin Chabot</i>	WP-10-13
Introduction to the <i>Macroeconomic Dynamics</i> : Special issues on money, credit, and liquidity <i>Ed Nosal, Christopher Waller, and Randall Wright</i>	WP-10-14
Summer Workshop on Money, Banking, Payments and Finance: An Overview <i>Ed Nosal and Randall Wright</i>	WP-10-15
Cognitive Abilities and Household Financial Decision Making <i>Sumit Agarwal and Bhashkar Mazumder</i>	WP-10-16
