Founded in 1963 by two prominent Austrians living in exile – the sociologist Paul F. Lazarsfeld and the economist Oskar Morgenstern – with the financial support from the Ford Foundation, the Austrian Federal Ministry of Education and the City of Vienna, the Institute for Advanced Studies (IHS) is the first institution for postgraduate education and research in economics and the social sciences in Austria. The **Economics Series** presents research done at the Department of Economics and Finance and aims to share “work in progress” in a timely way before formal publication. As usual, authors bear full responsibility for the content of their contributions.

Das Institut für Höhere Studien (IHS) wurde im Jahr 1963 von zwei prominenten Exilösterreichern – dem Soziologen Paul F. Lazarsfeld und dem Ökonomen Oskar Morgenstern – mit Hilfe der Ford-Stiftung, des Österreichischen Bundesministeriums für Unterricht und der Stadt Wien gegründet und ist somit die erste nachuniversitäre Lehr- und Forschungsstätte für die Sozial- und Wirtschaftswissenschaften in Österreich. Die **Reihe Ökonomie** bietet Einblick in die Forschungsarbeit der Abteilung für Ökonomie und Finanzwirtschaft und verfolgt das Ziel, abteilungsinterne Diskussionsbeiträge einer breiteren fachinternen Öffentlichkeit zugänglich zu machen. Die inhaltliche Verantwortung für die veröffentlichten Beiträge liegt bei den Autoren und Autorinnen.

Abstract

This paper investigates the effects of transaction taxes on depth and bid-ask spread under asymmetric information. The paper uses a static model where a monopolistic market maker faces liquidity and informed traders. Introducing transaction taxes could, surprisingly, lead to increase in depth. Under some distributional assumptions, when market conditions are favorable to the dealer, the spread responds less than proportionally to an increase in the transaction tax while the depth actually increases. In contrast, when market conditions are unfavorable to the dealer, the spread widens more than proportionally and the depth decreases, potentially to zero, in response to an increase in the transaction tax. Our model sheds light on the disagreement in the empirical literature on the relative magnitude of transaction costs on trading volume.

1. Introduction

This paper investigates the effects of securities transaction taxes (STT) on the liquidity of a quote-driven market under asymmetric information. Academics and financial market regulators (e.g. Dow and Rahi (2000), OECD (2002), and Hakkio (1994)) have studied the potential effects of imposing securities transaction taxes (akin to the Tobin tax) as an instrument to curb speculation and excess volatility without impairing market liquidity. Kyle (1985) states that liquidity can be measured by bid-ask spread, depth and resiliency.¹ Past research, however, uses an aggregate measure of liquidity, trading volume, in analysing the relationship between transaction costs and liquidity. In this paper, we examine the effects of taxation on a disaggregate level using bid-ask spread and depth.² Consequently, our results can accommodate some of the disagreements in the empirical literature on the relative magnitude of transaction taxes on trading volume (Kandel and Marx (1998) and Brennan, Chordia and Subrahmanyam (1998)).

Our model builds on Glosten and Milgrom (1985), who study the pricing strategy of an uninformed market maker facing potentially better informed traders. Our approach, however, differs from Glosten and Milgrom (1985) in the following way. First, they assume the existence of an equilibrium whereas we characterize the conditions for the existence of an equilibrium in our framework. Moreover, as in Dupont (2000), we incorporate both spread and depth into a model that allows the theoretical dealer to adjust the depth differently than the bid-ask spread in response to changes in the degree of information asymmetry. In this setting, we analyze the effects of transaction tax on market liquidity across different levels of information asymmetry.

¹Resiliency is the speed with which price fluctuations resulting from trades are dissipated, and depth is the maximum amount the dealer stands ready to sell or buy at the posted prices. See Kyle (1985) for details.

²Previous research on the relationship between transaction costs and trading volume can be used to study the effects of transaction taxes on liquidity (see among many, Constantinides (1986), Barclay, Kandel and Marx (1998), Vayanos (1998), and Vayanos and Vila (1999)).

Our analysis uses a one-period model where a monopolistic market maker posts firm prices (including tax) and depths on the bid and ask sides, while facing a risk-neutral informed trader and a liquidity trader. The informed trader observes a private signal correlated with the true value of the asset. The demand of the liquidity trader is price sensitive and subject to the liquidity shock.

Our results can be summarized as follows. First, introducing a transaction tax could lead to either increase or decrease in depth, depending on the degree of information asymmetry and liquidity demand. Secondly, the spread could respond disproportionately to increase in tax. Subsequently, our results seem to point to two regimes as far as transaction tax is concerned. First, when information asymmetry is weak or liquidity demand is strong (i.e., when market conditions are favorable to the market maker), the market maker pays part of the transaction tax himself by increasing the spread less than the tax. Moreover, he quotes a larger depth to attract order flow in order to make up for the loss in demand due to the transaction tax. On the other hand, when market conditions are unfavorable, increasing the transaction tax leads to a drastic reduction in the liquidity provided by the market maker, enticing him to exit the market. In turn, the paper suggests that lowering transaction tax may not necessarily lead to increase in quoted depth.

Our paper is structured as follows. The next section introduces the model. To numerically analyze our model under various distributional assumptions, we study two cases. Section 3 analyses the equilibrium conditions under a discrete distribution: the asset value, the informed trader's signal and the liquidity shock each take two values. Section 4 looks at the equilibrium conditions under continuous distributions where the asset value is lognormally distributed with mean 1. Both the private signal and the liquidity shock are, however, normally distributed.

Section 5 concludes the paper.

2. Model

A monopolistic dealer posts firm prices and depths on the bid and ask sides. He faces a price-sensitive liquidity trader and a trader possessing private information about the value of the asset. The liquidity trader's demand is price sensitive and stochastic. The informed trader, who observes a signal correlated with the true value of the asset, buys the asset if the ask is below (or sells if the bid is above) his valuation. For simplicity, we assume no limit-order book or floor brokers compete with the dealer (or specialist). The model focuses on asymmetric information and excludes other factors such as misdiversification and order-processing costs.

To simplify computations, we assume that the informed trader is risk neutral. His demand is satisfied before that of the liquidity trader. This assumption simplifies the informed trader's demand but excludes some strategies potentially available to actual traders, such as conditioning orders on the volume of liquidity trade. Informed and liquidity traders' buy or sell orders are lumped together and passed on to the dealer so that the quantity limit becomes binding if the sum of all orders is greater than the posted depth.

We study only the ask side of the dealer's activity as the bid side is symmetrical. Let x be the true value of the asset, c the transaction tax, a the ask price inclusive of tax, z the quantity limit, G the informed trader's private signal, $v = E[x|G]$ his valuation of the traded asset, η the liquidity shock (η and G are independently distributed), and $d(a)$ the liquidity trader's demand.

The orders of the liquidity trader and of the informed trader are pooled together and passed on to the dealer. By convention, the dealer pays the transaction tax but, *ceteris paribus*, the

transaction tax could be levied on the customers. To acquire one unit of the traded asset, informed and liquidity traders pay a but the dealer receives only $(a - c)$ if the transaction tax is a fixed amount per transaction (fixed transaction tax), or $(\frac{a}{1+c})$ if it is a fixed percentage of the price (proportional transaction tax).

The effective demand, $S(a, z, v, \eta)$, depends on the realization of liquidity shocks and the valuation of informed trader. If $v > a$, then a risk neutral informed trader will demand the maximum amount.³ On the other hand, if $v \leq a$ then the informed trader does not participate and hence the transaction volume on the ask side depends on the liquidity demand. The following equation represents the effective demand:

$$S(a, z, v, \eta) = I(v \leq a) I(d(a) \geq 0) \min(d(a), z) + I(v > a) z \quad (2.1)$$

where I the indicator function. Consequently, the dealer's net and expected profit are

$$\Pi = \left\{ \begin{array}{l} S(a, z, v, \eta) (a - c - x) \text{ for linear tax} \\ S(a, z, v, \eta) \left(a - \frac{c}{1+c} - x \right) \text{ for proportional tax} \end{array} \right\} \quad (2.2)$$

$$E[\pi] = \left\{ \begin{array}{l} E[I[v \leq a](a - c - v)] E[I[d(a) \geq 0] \min(d(a), z)] \\ \quad + E[I[v > a](a - c - v)] z \text{ for linear tax} \\ E[I[v \leq a](a/(1+c) - v)] E[I[d(a) \geq 0] \min(d(a), z)] \\ \quad + E[I[v > a](a/(1+c) - v)] z \text{ for proportional tax} \end{array} \right\} \quad (2.3)$$

³If the informed trader is risk averse then his demand remains finite.

3. Equilibrium with discrete distributions

Let x and G take the values 1 or -1 and η take the values $\bar{\eta}$ or $-\bar{\eta}$ with probability $\frac{1}{2}$. With the discrete distribution, the demand is $d(a) = -a + \eta$. The informed trader's valuation v takes values $\bar{v} = E[x|G = 1]$ and $\underline{v} = E[x|G = -1] = -\bar{v}$ with probability $\frac{1}{2}$. The tax is linear. The market maker can take the following strategies: Table 3.1 summarizes the results.

1. The market maker can exclude the informed trader by setting the selling price above the latter's maximum valuation; $a \geq \bar{v}$. By having no informed trader, the dealer imposes no quantity limit, z . In this case, the market maker is a monopolist facing a downward sloping curve and his expected profit is

$$E[\pi] = E \left[I[d(a) \geq 0] d(a) \right] (a - c) = E \left[I[\eta \geq a] (\eta - a) \right] (a - c) = \frac{1}{2} (\bar{\eta} - a) (a - c).$$

The profit-maximizing price, $(c + \bar{\eta})/2$ is the listed price provided this price is above \bar{v} and the maximum value for the profit is $\frac{1}{8}(\bar{\eta} - c)^2$. To summarize when $a \geq \bar{v}$: the optimal price that excludes the informed trader is $\max[\bar{v}, (c + \bar{\eta})/2]$; there is no quantity limit; the maximum expected profit is $\frac{1}{8}(\bar{\eta} - c)^2$; and the maximum amount of tax is $\bar{\eta}$.

2. Alternatively, the market maker can set his selling price below \bar{v} in the hope of attracting more demand; $0 < a < \bar{v}$.⁴ Naturally, he then runs the risk of being picked by the informed trader. Given a selling price a , $\bar{\eta} - a$ is the highest possible liquidity demand.⁵ If the dealer set the depth strictly above this level, he would incur extra losses when transacting with

⁴If $0 < a < \bar{v}$ then $I[v \leq a] = I[v = -\bar{v}]$, $I[v > a] = I[v = \bar{v}]$.

⁵We impose $a \leq \bar{\eta}$ since setting a above $\bar{\eta}$ would make the liquidity demand always negative, and hence the liquidity trader would not trade in this case.

the informed without generating extra liquidity trade. Hence, $z \leq \bar{\eta} - a$. When the liquidity demand is positive, it is equal to the quantity limit. Consequently, the expected profit is:

$$\begin{aligned}
E[\pi] &= E[I[v \leq a](a - c - v)] E[I[d(a) \geq 0] z] + E[I[v > a](a - c - v)] z \\
&= \left(E[I[v \leq a](a - c - v)] p(d(a) \geq 0) + E[I[v > a](a - c - v)] \right) z \\
&= \left(\frac{1}{4}(a + \bar{v} - c) + \frac{1}{2}(a - \bar{v} - c) \right) z \\
&= \frac{3}{4}z(a - c - \frac{1}{3}\bar{v})
\end{aligned} \tag{3.1}$$

If $a < c + \bar{v}/3$, the optimal z is 0; if $a > c + \bar{v}/3$, the optimal z is the maximum quantity limit $\bar{\eta} - a$; if $a = c + \bar{v}/3$, z can be set arbitrarily, for example, to zero.

With $z = \bar{\eta} - a$, the expected profit function becomes:

$$E[\pi] = \frac{3}{4}(\bar{\eta} - a)(a - c - \frac{1}{3}\bar{v}). \tag{3.2}$$

The dealer maximizes the function defined in Equation (3.2) under the constraint that $0 < a < \bar{v}$. If $\bar{v} > 3(\bar{\eta} - c)$, this function is negative for $a < \bar{\eta}$ and the dealer exits the market. If $\bar{v} \leq 3(\bar{\eta} - c)$, the price that maximizes $E[\pi]$ without the constraint $a < \bar{v}$, $\frac{1}{2}(c + \bar{\eta}) + \frac{1}{6}\bar{v}$, is smaller than \bar{v} if $\bar{v} > \frac{3}{5}(\bar{\eta} + c)$. Hence, if $\frac{3}{5}(c + \bar{\eta}) < \bar{v} \leq 3(\bar{\eta} - c)$, the optimal price is $\frac{1}{2}(\bar{\eta} + c) + \frac{1}{6}\bar{v}$ and the maximum profit is $\frac{1}{48}(3\bar{\eta} - 3c - \bar{v})^2$; if $\bar{v} \leq \frac{3}{5}(c + \bar{\eta})$, the constraint $a < \bar{v}$ is binding; in the limit, the dealer wants to set $a = \bar{v}$.

The final step is to compare the maximum expected profit when $a > \bar{v}$ and when $a \leq \bar{v}$. When $\frac{3}{5}(\bar{\eta} + c) < \bar{v} < 3(\bar{\eta} - c)$, maximizing expected profit setting $a \geq \bar{v}$ would yield a lower

Table 3.1: Equilibrium price and quantity limit with risk-neutral informed trader and discrete distributions.

\bar{v}	$\bar{v} \leq \frac{1}{2}(\bar{\eta} + c)$	$\frac{1}{2}(\bar{\eta} + c) < \bar{v} \leq \frac{3}{5}(\bar{\eta} + c)$	$\frac{3}{5}(\bar{\eta} + c) < \bar{v} \leq 3(\bar{\eta} - c)$	$\bar{v} > 3(\bar{\eta} - c)$
optimal a	$\frac{1}{2}(\bar{\eta} + c)$	\bar{v}	$\frac{1}{2}\bar{\eta} + \frac{1}{2}c + \frac{1}{6}\bar{v}$	n.a.
optimal z	n.a.	n.a.	$\frac{1}{2}\bar{\eta} - \frac{1}{2}c - \frac{1}{6}\bar{v}$	0
$\max(E[\pi])$	$\frac{1}{8}(\bar{\eta} - c)^2$	$\frac{1}{2}(\bar{v} - c)(\bar{\eta} - \bar{v})$	$\frac{1}{48}(3\bar{\eta} - 3c - \bar{v})^2$	0
maximum c	$\bar{\eta}$	$\frac{2}{3}\bar{\eta}$	$\frac{1}{4}\bar{\eta}$	0

When $a \geq \bar{v}$, imposing a quantity limit is not necessary; the optimal z is undefined and “n.a.” is entered in the corresponding cell. When $\bar{v} > 3(\bar{\eta} - c)$, the expected profit is never positive and the dealer exits the market by setting z to 0; the optimal a is undefined and “n.a.” is entered in the corresponding cell.

maximum than letting $a < \bar{v}$. The optimal price and depth in this case are $a^* = \frac{1}{2}(\bar{\eta} + c) + \frac{1}{6}\bar{v}$ and $z^* = \bar{\eta} - a^*$. When $\frac{1}{2}(\bar{\eta} + c) < \bar{v} \leq \frac{3}{5}(\bar{\eta} + c)$, the optimal price is ν and no quantity limit need be imposed. When $\bar{v} \geq 3(\bar{\eta} - c)$, the depth is set to zero and no price need be quoted.

For expositional purpose, Figure 3.1 maps the results in Table 3.1. Figure 3.1 plots the half spread, a , and the depth, z , against the informed trader’s valuation, \bar{v} . The main message from Figure 3.1 is that the introducing of a transaction cost has non-linear effects on the spread and the depth. When the random variables follow discrete distributions, imposing a finite depth is not necessary if the asymmetry in information is low enough. For example, in the region where $\bar{v} \in (0, \frac{3}{5})$, a small increase in the transaction cost pushes up the spread but does not affect

the depth⁶, while a larger change may result in the imposition of a finite quantity limit but may not translate into a spread increase of equal magnitude. In contrast, when the information asymmetry is more severe, $\bar{v} \in (\frac{3}{5}, 3)$, and the quantity limits are imposed, an increase in the transaction cost has a proportional effect on the spread.

4. Equilibrium with continuous distributions

In the following section, we take the asset value, x , to be lognormally distributed. With the lognormal distribution, the demand is $d(a) = -\log(a) + \eta$ and $y = \log(x)$. We also assume that the distribution of (x, η, G) is common knowledge with η and G are normally distributed.

4.1. Marginal condition

Although no equilibrium closed-form solution exists, the marginal conditions for the price and the quantity limit shed light on the trade-offs governing the dealer's profit maximization.

The first derivative of the specialist's expected profit with respect to the quantity limit is given in Equation (4.1); the one with respect to the ask price is given in Equation (4.2), where $d'(a)$ denotes the slope of the liquidity demand at price a .⁷

$$\frac{\partial}{\partial z} E[\pi] = p(d(a) > z) E\left[I[v \leq a] (a - c - v)\right] + E\left[I[v > a] (a - c - v)\right], \quad (4.1)$$

$$\begin{aligned} \frac{\partial}{\partial a} E[\pi] &= p(v > a) z + p(v \leq a) E\left[I[d(a) \geq 0] \min(d(a), z)\right] \\ &+ d'(a) p(0 \leq d(a) \leq z) E\left[I[v \leq a] (a - c - v)\right]. \end{aligned} \quad (4.2)$$

⁶In fact, the depth in this region is "undefined".

⁷The derivation of equations (4.1) and (4.2) can be provided upon request.

Figure 3.1: Half-spread and depth when the informed trader's valuation and the liquidity shock each take two values with probability 1/2. The positive value of the liquidity shock is 1, that of the informed trader's valuation is \bar{v} and is displayed on the horizontal axis. This figure represents the market conditions facing the dealer.

Equation (4.1) has an intuitive interpretation. Increasing the quantity limit by an infinitesimal amount brings the market maker a profit equal to $E\left[I[v \leq a] (a - c - v)\right]$ if the limit is hit by a liquidity trader, or a loss equal to $E\left[I[v > a] (a - c - v)\right]$ if it is hit by an informed trader. Equation (4.2) is similar to the standard monopolistic case in which increasing the price by \$1 makes the monopolist earn another \$1 on the total volume but reduces the overall demand. The first two terms on the right-hand side of Equation (4.2) represent the expected sales when the informed trader wants to trade, $p(v > a) z$, and when he does not, $p(v \leq a) E\left[I[d(a) \geq 0] \min(d(a), z)\right]$. The last term represents the impact on profits resulting from the reduction in overall demand. A price increase depresses demand if the quantity limit is not binding, that is, if the liquidity trader's demand is positive but lower than z and the informed trader's evaluation is below a . In this event, the effect on overall demand is proportional to the slope of the liquidity trader's demand.

4.2. Expected dealer's profit

We assume that the informed trader is endowed with a negative exponential utility function with risk aversion γ . Equivalently, the informed trader maximizes $E[\pi^i | G] - \gamma \text{var}(\pi^i | G)/2$, where π^i is the informed trader's profit and $\text{var}(\pi^i | G)$ is the conditional variance of his profit given G . We assume that his initial wealth is conditionally independent of the value of the asset and the liquidity shock. The informed trader chooses the quantity q to maximize

$$q (E[x|G] - a - c) - \frac{1}{2} q^2 \gamma \text{var}(x|G), \quad (4.3)$$

where $\text{var}(x|G)$ is the conditional variance of x given G . As the informed trader's orders are filled before those of the liquidity trader, the informed trader's demand function is

$$q(a) = \max\left[0, \left(\gamma \text{var}(x|G)\right)^{-1} (v - a - c)\right], \quad (4.4)$$

with $\text{var}(x|G) = \sigma_x^2(1 - \rho^2)$. When x is lognormally distributed, this is not linear in v because the conditional variance of x given G depends on the realization of G : $\text{var}(x|G) = [\exp((1 - \rho^2)\sigma_y^2) - 1]v^2$, where σ_y is the standard deviation of $y = \log(x)$ and $\rho = \text{corr}(G, y)$.⁸

Thus, the informed trader's demand is defined by

$$q(a, c, v) = \frac{1}{\theta} \max\left[0, \frac{1}{v} - \frac{a + c}{v^2}\right],$$

where $\theta = \gamma [\exp((1 - \rho^2)\sigma_y^2) - 1]$.

4.3. Numerical Results

When x is lognormally distributed, we search for the optimal price (or spread) and for the optimal depth numerically. The dealer's profit maximization simplifies to a one-dimensional problem when the informed trader is risk neutral because the optimal depth in this case can be written as a function of the spread.

Figure 4.1 graphs the half-spread and depth, both divided by σ_η , against $\rho\sigma_y/\sigma_\eta$ when x is lognormally distributed and $\sigma_\eta = 0.1$.⁹ Figure 4.1 uses a logarithmic scale for the

⁸To compute the conditional variance in the lognormal case, use $\text{var}(x|G) = E[x^2|G] - E[x|G]^2$ together with the fact that $\log(x)$, $\log(x^2)$, and G are jointly normally distributed.

⁹Note that note that $\bar{v} = \rho\sigma_y$ and $\bar{\eta} = \sigma_\eta$. Consequently, an increase in $\rho\sigma_y/\sigma_\eta$ represents an increase in the degree of asymmetric information: the valuation of informed trader increase, which translates into an unfavorable market condition for the dealer.

vertical axis. As in the discrete case, introducing a transaction cost has non-linear effects on the spread and the depth and the effect depends on whether market conditions are favorable or unfavorable to the dealer.

The spread increases and the depth decreases with $\rho\sigma_y/\sigma_\eta$. When market conditions are very favorable - that is, the informed trader is poorly informed - the depth grows without bound while the spread remains finite because of the dealer's market power. When market conditions become very unfavorable, the dealer exits the market by setting the depth to 0 while maintaining a finite spread. When x is lognormally distributed, half-spread and depth are approximately proportional to σ_η . For example, for $\rho\sigma_y/\sigma_\eta = 0.5$, the half-spread equals about 0.8 percent when $\sigma_\eta = 0.01$ and 9 percent when $\sigma_\eta = 0.1$.¹⁰

When market conditions are favorable to the dealer (e.g. $\rho\sigma_y/\sigma_\eta \in (0.2, 0.4)$), introducing a transaction cost increases the spread by less than the amount of the transaction cost and creates a larger depth. On the other hand, when market conditions are unfavorable to the dealer (e.g. $\rho\sigma_y/\sigma_\eta \in (0.8, 1.0)$), introducing a transaction cost pushes the price up by more than the transaction cost and narrows the depth.

Furthermore, for both the discrete and continuous cases, the strength of the liquidity demand plays a central role in determining the equilibrium spread and depth. When studying the market making process, one can focus on the liquidity conditions the dealer faces rather than on information asymmetry. This is particularly suited to the U.S. government bond market. For example, spreads are typically narrower and depth larger for securities that are the most recent issues in their maturity class (the on-the-run Treasuries) than for similar securities issued

¹⁰Making the informed trader risk averse and choosing different volatilities for the asset and the liquidity shock do not qualitatively affect the results.

Figure 4.1: Half-spread (in percentage) and depth with a proportional transaction cost of 1 percent (solid line) and without transaction cost (short-dashed line). The asset value, x , is lognormally distributed and $y = \log(x)$. In the top panel, the long-dashed line is the sum of the price without transaction cost and the transaction cost. Half-spread and depth are divided by σ_η .

just before (the off-the-run Treasuries). Bid-ask spreads on coupon Treasury securities have traditionally been about twice as high for off-the-run issues than for comparable on-the-run issues, while quoted depth is lower. Moreover, during the recent bouts of market volatility, bid-ask spreads have widened and depth has contracted proportionally more for off-the-run than for on-the-run coupon securities. The asymmetric information argument cannot easily account for this fact since the quality of private information should be equal across the two market segments. However, agents trading bonds prefer to trade in the on-the-run securities, therefore creating a stronger liquidity demand in that market. The more fundamental question as to why agents prefer to trade in the on-the-run segment is not addressed here, although self-fulfilling expectation arguments could be made.

The paper seems to point to two regimes as far as transaction cost is concerned. When market conditions are favorable, the dealer pays part of the transaction cost himself (by increasing the spread less than the cost) and quotes a larger depth to attract order flow in order to make up for the loss in demand due to the transaction cost. The increase in the depth offsets, albeit partially, the effect on trading volume of the wider spread. When market conditions are unfavorable, increasing the transaction cost leads to a drastic reduction in the liquidity provided by the market maker, enticing him to exit the market.

Although, the implications of the model have been introduced by presenting the effect on the spread and the depth of an increase in the transaction cost, symmetric conclusions hold for a reduction in this cost. As a consequence, a decision to lower taxes on transactions in the hope of improving market liquidity might actually lead to smaller depths and a less-than-proportional reduction in the spreads. This is because, when market conditions are rather favorable to the dealer, a tax—insofar as it is at least partially reflected in the bid and ask prices—reduces the

probability of the informed trader's buying at the ask or selling at the bid. This additional protection entices the market maker to quote a larger depth than he would without tax.

5. Conclusion

The model shows that introducing a transaction tax could affect market liquidity differently depending on the market conditions facing the dealer. If the asset value, the informed trader's signal, and the liquidity shock each take two values, there is an interval for the precision of the private signal for which increasing the transaction tax has no or little effect on the spread (no quantity limit is necessary then). If the asset value is lognormally distributed, the market maker widens the spread by less than the transaction tax and actually increases the depth when the degree of information asymmetry is subdued or liquidity demand is strong. In contrast, when market conditions are unfavorable to the dealer, he increases the spread by more than the transaction tax and reduces the depth. For all distributions, introducing a transaction tax may induce the dealer to exit the market before he would have done so in the absence of a transaction tax. This suggests that a transaction tax could aggravate liquidity loss in periods of market stress.
