On The Economic Value of Repeated Interactions Under Adverse Selection

Summary

The paper studies, in a repeated interaction setting, how the presence of cooperative agents in a heterogeneous community organized in groups affects efficiency and group stability. The paper expands on existing literature by assuming that each type can profitably mimic other types. It is shown that such enlargement of profitable options prevents group stabilization in the single group case. Stabilization can be obtained with many groups, but its driver is not the efficiency gain due to the presence of cooperative individuals. Rather, stabilization is the result of free riding opportunities.

1 Introduction

This paper studies how the degree of cooperativeness affects efficiency in a community organized in groups, when individual type is private information and group stability is endogenous. In this regard our interest is akin to Ghosh and Ray's (1996). They consider a population composed by patient and impatient individuals. Initially, individuals are randomly matched in pairs to play a prisoner dilemma in continuous strategies. At the end of each period partners may opt between continuing their current relationship or separating and trying another random matching. In the case of break off, information about partners' types is not disclosed to the rest of the population (local information). It is shown that the presence of the impatient type gives a value to being matched with the patient type, which can support cooperation among patient players. Equilibrium strategies contemplate an initial round in which patient players test their partners by setting a moderate level of cooperation. If the partner is patient, he does the same and an

ever-lasting relationship starts, where cooperation is at its highest possible level. If the partner is impatient, he does not cooperate and the relationship breaks down. Therefore, equilibrium permanent relationships emerge with a positive effect on social surplus. Similar results can be found in Kranton (1996) – for later contributions see Rauch and Watson (2002) and Watson (2002) – and in the reputation building literature following the seminal paper of Milgrom and Roberts (1982).

At first sight, Ghosh and Ray’s results are somewhat surprising, since one might expect that the incentive costs of exploiting information, elicited in the early phase of a relationship, exceed the benefit from exploitation itself, due to the “ratchet” effect. However, a careful examination shows that such exploitation costs never arise in their framework. On the one hand, “bad” (impatient) agents do not face any temptation to mimic patient players - they always find it advantageous to defect at the first opportunity. On the other hand, “good” agents can only accede to the benefits of a stable relationship by being considered patient. So, in the absence of any incentive to misreport, the ratchet effect is excluded by definition.

In the model we present below, in which we stick to the assumption that information is local, the bad type may mimic the good type in the first interaction and then, if stabilization occurs, exploit their partners.

Let us briefly describe our setting. We consider a two-period model in which members of a large population of risk-neutral individuals interact in groups. Initially, groups are formed randomly. After completing the first round of interaction, each group can either continue interaction or dissolve. In the case of dissolution, former group members are randomly assigned to newly formed “fresh” groups. In both periods group members bargain over sharing the cost of provision of an indivisible local public good. Bargaining is modelled as a direct revelation mechanism in which a benevolent principal maximizes expected group surplus over the rest of the game¹. Individual type is bi-dimensional. The first dimension is the degree of alignment of the objective function of the agent with that of the principal (we refer to this feature as altruism towards partner group members). This is a time-invariant characteristic, which is privately learned at the beginning of the whole game. The second dimension, which is privately learned at the beginning of each period, is the agent’s own “material” benefit deriving from the consumption of the public good. Types are independently and identically distributed both among individuals and also over time. Type distribution is common knowledge. Moreover, the two components

¹Group payoff thus obtained is to be viewed as an upper bound to the expected group surplus that can be obtained through any bargaining procedure.

of an individual's type are stochastically independent. We also assume that no intertemporal and intergroup transfers are possible and that information revealed within a group does not leak outside.

Decisions concerning continuation/stabilization of a group are taken by the first-period principal. In the case of continuation he transmits information about group composition to group members and to his second-stage successor, whose task is reduced to operating a mechanism for the revelation of the agents' second-period levels of material benefit from the public good. We analyze the adverse incentive effects that prevent group members from taking full advantage of the information about group composition that emerges in the first stage of the game. We show that stable relationships can emerge in equilibrium; this has positive value for group members, but hurts society, in the sense that social surplus is lower than in a situation in which stable relationships are forbidden.

The rest of the paper is organized as follows. Section 2 presents the model, Section 3 contains the main results, Section 4 discusses the robustness of our findings and suggests possible extensions, Section 5 concludes. Minor technical proofs are collected in two appendices.

2 The model

At date $t = 1$, nature randomly forms N groups, each one composed of n members. Next in each group a benevolent principal announces the probabilities of provision of the public good and the payments due by each individual. Both probabilities and payments are functions of all members' reported types. The principal also announces the probability that the group is stabilized, that is, all members remain together, in which case he informs the second-period principal and all members about individuals' permanent types, as a function of reported types. The principal of a group maximizes the sum of expected surpluses, over the two periods, of the agents he currently supervises. Observing the menu of proposed allocations and probabilities of group stabilization, each group member confidentially reports his type to his principal. At date $t = 2$, non-stabilized groups dissolve and their members are randomly matched into fresh groups, where they play again the direct revelation mechanism faced at date 1, under the rule of a new principal – of course, the decision about a group's stabilization is irrelevant in the second period since the game ends. Rather, the members of stabilized groups play a direct mechanism for the revelation of their material benefit under the supervision of a new principal and common knowledge of members' permanent types. For the sake of simplicity, in our analysis agents do not learn about

their partners' types by observing realized payments. To this end, we assume that goods are produced and consumed, and transfers are paid only at the end of the second period.

The sake of simplicity also motivates the assumption that the first-period and the second-period principals do not coincide. This allows us to avoid consideration of intertemporal strategies, and also of the tricky issue of what information the principal should communicate to the agents².

Agents' preferences are modelled as follows. Type-*e* agents maximize their own present and future expected material benefits; type-*a* agents are more aligned with the principal: they also assign a positive weight to the material benefit (present and future) of the current partners. Furthermore, we limit the possibility of redistribution by assuming that an agent's utility is infinitely negative if his *ex post* material benefit is negative.

Therefore type-*a* agents do not take into account the benefit that will accrue to the new partners they will interact with in the case that the group is dissolved³. However, if dissolution occurs, when taking their second period decisions, they will be concerned with the welfare of their partners at that time. Furthermore, from the outset, they rationally anticipate the consequences of such concern on their own future material benefits. This kind of concern characterizes the attitude of an agent who, when interacting with a group of people, takes his partners' welfare into account. However, their welfare is not for him a source of utility to be included in his own intertemporal maximand (on this see Sen 1985).

To further limit the possibility of redistribution, we posit that individual payments cannot be negative and the budget must balance within each group in each period.

To further simplify, we will only consider the cases in which members of a first-period group meet again in fresh groups with probability one and with probability zero, respectively – so we disregard the case in which this probability is fractional. This corresponds to $N = 1$ (one group only), and to $N = \infty$ (a very large number of groups), respectively.

Given that individuals are ex-ante identical, we can limit our attention to anonymous mechanisms; moreover, we focus on truth-telling, symmetric, perfect Bayes-Nash equilibria.

Now, we can state a list of objects.

The individual type in period i is $\mathbf{t}^i = (t_1, t_2^i) \in T = \{a, e\} \times \{h, l\}$ where t_1 is the alignment parameter, assumed to be time invariant, and t_2^i is the private benefit from the public good, a

²The timing of production and payment can be the usual one – that is, public goods are produced and transfers are paid at the end of each period – when the number of active groups is very large, since in such a case the realized state in a first period group does not convey any additional information on the population distribution.

³Instead, in his first-period decisions a type-*a* agent assigns a positive weight to the future welfare of his first-period partners even if in the second period they will be dispersed.

time-varying parameter.

The cost of the public good is $c > 0$.

At date 1, it is common knowledge that $\Pr(t_1 = a) = \theta \in (0, 1)$, $\Pr(t_1 = e) = 1 - \theta$, $\Pr(t_2^i = h) = p \in (0, 1)$, $\Pr(t_2^i = l) = 1 - p$, $\Pr(\mathbf{t}^i) = \Pr(t_1) \Pr(t_2^i)$, all i .

A realization of the agents' type profile, i.e. a state, at date i is denoted \mathbf{v}^i . A state is completely described by the number of agents of each type, $v_{\mathbf{t}^i}^i$, all \mathbf{t}^i , so \mathbf{v}^i is defined as $\mathbf{v}^i = (v_{ah}^i, v_{al}^i, v_{eh}^i, v_{el}^i)$. Henceforth we will omit the zeros and – for the reader's comfort – we write, for example, $\mathbf{v}^i = (nah)$ in place of $\mathbf{v}^i = (n, 0, 0, 0)$, $\mathbf{v}^i = (kah.(n - k)eh)$ in place of $\mathbf{v}^i = (k, 0, n - k, 0)$, and so on.

When considering the possibility of agents deviating from truth-telling, we need to consider only one deviator at a time. So we express the reported state as a function of the true state and the deviation in the following way.

Let $j \in J = \{1, 2, s_k, k = 0, 1, \dots, n\}$ denote, respectively, a period-one group, a period-two fresh group, a period-two stabilized group, with k type- a members. Let $\mathbf{d}^j \in T$ denote the type reported in group j by the agent under consideration; then $\widehat{\mathbf{v}}(\mathbf{v}^i, \mathbf{t}^i, \mathbf{d}^j)$ is the reported state in group j when the true state is \mathbf{v}^i (recall that states and types are time-dependent), the reporter is of type \mathbf{t}^i and declares \mathbf{d}^j while all the other individuals truthfully report their types. Hereafter, for simplicity we omit all the arguments of $\widehat{\mathbf{v}}$ and refer to the kind of group under examination by adding the apex j : i.e. $\widehat{\mathbf{v}}^j$ denotes the reported state in group j . If $\mathbf{t}^i = \mathbf{d}^j$, obviously $\widehat{\mathbf{v}}^j = \mathbf{v}^i$; if instead $\mathbf{d}^j \neq \mathbf{t}^i$, it is $\widehat{\mathbf{v}}^j = \{\widehat{v}_\tau^j : \widehat{v}_\tau^j = v_\tau^i \text{ for } \tau \notin \{\mathbf{t}^i, \mathbf{d}^j\}; \widehat{v}_\tau^j = v_\tau^i - 1 \text{ for } \tau = \mathbf{t}^i, \widehat{v}_\tau^j = v_\tau^i + 1 \text{ for } \tau = \mathbf{d}^j\}$. We write $\mathbf{d}^j = (d_1^j, d_2^j)$, $j = s_k, k = 0, 1, \dots, n$, to emphasize that in stabilized groups the permanent type is common knowledge since it has already been revealed at time 1.

The payment, if any, due by an individual who reports \mathbf{d}^j in a group j when the reported state is $\widehat{\mathbf{v}}^j$ is denoted $g_j(\widehat{\mathbf{v}}^j, \mathbf{d}^j)$. The probability of provision of the public good when the reported state is $\widehat{\mathbf{v}}^j$ is denoted $r_j(\widehat{\mathbf{v}}^j) \in [0, 1]$. Moreover, $\sigma(\widehat{v}_{ah}^1 + \widehat{v}_{al}^1)$ is the probability that a first-period principal opts for stabilization and informs the second-period principal about individual types: it is a function of the reported number of type- a members.

We define $\Psi_j = \{g_j(\widehat{\mathbf{v}}^j), r_j(\widehat{\mathbf{v}}^j), \text{ all } \widehat{\mathbf{v}}^j, k = 0, 1, \dots, n\}$, all j . Now, $\Psi_j, j \neq 1$, is the strategy of a j -group principal while the strategy of the first-period principal is $\{\Psi_1, \sigma(k), k = 0, 1, \dots, n\}$.

In order to gain an overall picture of the game, we now write the problem of each principal in a very general form. Suppose that $N = \infty$ and the stabilization policies of first-period principals are identical and denoted by $\bar{\sigma}$. By knowing $\bar{\sigma}$ and in turn the proportion of type- a agents in their groups, all second-period principals each solve a static direct revelation problem.

Denoting $\Phi_j(\Psi_j, \bar{\sigma})$ the expected surplus of a j -group, $j \neq 1$,⁴ the corresponding value function is $V_j(\bar{\sigma}) = \max_{\Psi_j} \Phi_j(\Psi_j, \bar{\sigma})$ where Ψ_j satisfies the ex-post budget-balance constraint, the non-negative payment constraint, the participation and incentive compatibility constraints for all types.

Proceeding backwardly, the each first-period principal solves a more complex direct revelation problem. Denote $\Phi = \Phi_1(\Psi_1, \sigma, \bar{\sigma}) + \Phi_c(\{\Psi_j^*\}, \bar{\sigma})$ the overall expected surplus of the members of his group, where Φ_1 is the current expected surplus, Φ_c is the expected surplus in the second period, and Ψ_j^* is the optimal strategy of j -group principals. The value of his problem is $V(\bar{\sigma}) = \max_{\Psi_1, \sigma} \Phi$ where $\{\Psi_1, \sigma\}$ satisfies ex post budget-balance, the non-negative payment constraint, and the intertemporal participation and incentive compatibility constraints for all types. In a symmetric equilibrium, when there are $N = \infty$ first-period principals, it is $\sigma^*(\bar{\sigma}) = \bar{\sigma}$, where σ^* is the optimal stabilization policy of a first-period principal — recall that his stabilization decision does not influence the composition of the fresh population in the second period. In the case $N = 1$, of course, there is no strategic interaction among first-period principals; $\bar{\sigma}$ is directly determined by the unique first-period principal, who solves a linear programming problem after having computed the optimal strategies of second-period principals (recall that if a fresh group occurs, its composition will be the same as the first-period group). The following pictures illustrate the structure of the game.

[FIGURE 1 AND FIGURE 2 HERE]

After this overview, let us precisely describe our game. Preliminarily, a list of more complex objects has to be defined. In doing that, to simplify notation, we do not make anymore explicit the dependence on $\bar{\sigma}$.

The material surplus, if any, accruing in group j to an individual of type t^i who reports d^j when $\hat{\mathbf{v}}^j$ is the reported state is $s_j(t^i, \hat{\mathbf{v}}^j, d^j)$. We define

$$s_j(\mathbf{t}^i, \hat{\mathbf{v}}^j, \mathbf{d}^j) = d_2^j - g_j(\hat{\mathbf{v}}^j, \mathbf{d}^j) \quad (1)$$

The unconditional probability of state v^i is $\Pr(\mathbf{v}^i)$ while $\Pr_j(\mathbf{v}^i)$ denotes the probability of state v^i as seen by a j -group principal. To illustrate the latter, let $n = 2$. Then, for instance, $\Pr_{s1}(ah.eh) = p^2$; $\Pr_1(ah.eh) = 2\theta p(1 - \theta)p$; $\Pr_2(ah.eh) = 2\Theta p(1 - \Theta)p$, where Θ is obtained by applying Bayes' rule using the strategies of first-period principals. Moreover, $\Pr(k)$ denotes

⁴Inclusion of $\bar{\sigma}$ among the arguments of Φ_j is redundant for $j \neq 2$.

the probability a first-period principal assigns to the event that the number of type- a members in his group is k .

Under truth-telling, the principal of a j -group computes current expected surplus as

$$\Phi_j = \sum_{\mathbf{v}^i \in V} \Pr_j(\mathbf{v}^i) r_j(\mathbf{v}^i) \sum_{\tau \in T: v_\tau > 0} v_\tau^i s_j(\tau, \mathbf{v}^i, \tau) \quad (2)$$

(Notice that $i = 1$ when $j = 1$ and $i = 2$ otherwise.)

From the perspective of a type- \mathbf{t}^1 member who reports \mathbf{d}^1 , his first-period expected material surplus is

$$z_1(\mathbf{t}^1, \mathbf{d}^1) = \sum_{\mathbf{v}^1 \in V} \Pr_1(\mathbf{v}^1 | \mathbf{t}^1) r_1(\widehat{\mathbf{v}}^1) s_1(\mathbf{t}^1, \widehat{\mathbf{v}}^1, \mathbf{d}^1) \quad (3)$$

Similarly, the expected surplus in a j -group, $j \neq 1$, of an agent of type \mathbf{t}^2 who reported d_1^1 in the first period and reports \mathbf{d}^j in the second period is

$$z_j(\mathbf{t}^2, d_1^1, \mathbf{d}^j) = \sum_{\mathbf{v}^2 \in V} \Pr_j(\mathbf{v}^2 | \mathbf{t}^2, d_1^1) r_j(\widehat{\mathbf{v}}^j) s_j(\mathbf{t}^2, \widehat{\mathbf{v}}^j, \mathbf{d}^j) \quad (4)$$

Moreover, an individual who is of type τ^2 and reports \mathbf{d}^2 in the second period after having reported d_1^1 in the first period, will compute the surplus in a fresh group to a type \mathbf{t}^2 individual as follows

$$z_2^{\tau^2}(\tau^2, d_1^1, \mathbf{d}^2) = \sum_{\mathbf{v}^2 \in V} \Pr_2(\mathbf{v}^2 | \tau^2, d_1^1) r_2(\widehat{\mathbf{v}}^2) s_2(\mathbf{t}^2, \widehat{\mathbf{v}}^2, \mathbf{d}^2) \quad (5)$$

In the first period, a type \mathbf{t}^1 individual who reports \mathbf{d}^1 expects that the total first period surplus to his partners is

$$\phi_1(\mathbf{t}^1, \mathbf{d}^1) = \sum_{\mathbf{v}^1 \in V} \Pr_1(\mathbf{v}^1 | \mathbf{t}^1) r_1(\widehat{\mathbf{v}}^1) \left[(\widehat{v}_{\mathbf{d}^1}^1 - 1) s_1(\mathbf{d}^1, \widehat{\mathbf{v}}^1, \mathbf{d}^1) + \sum_{\tau^1 \in T, \tau^1 \neq \mathbf{d}^1} \widehat{v}_{\tau^1}^1 s(\tau^1, \widehat{\mathbf{v}}^1, \tau^1) \right] \quad (6)$$

Similarly, for $j \neq 1$, in a j -group, a type \mathbf{t}^2 individual who reports \mathbf{d}^j , after having reported d_1^1 in the first period expects that the total surplus accruing to his current partners is

$$\phi_j(\mathbf{t}^2, d_1^1, \mathbf{d}^j) = \sum_{\mathbf{v}^2 \in V} \Pr_j(\mathbf{v}^2 | \mathbf{t}^2, d_1^1) r_j(\widehat{\mathbf{v}}^j) \left[(\widehat{v}_{\mathbf{d}^j}^j - 1) s_j(\mathbf{d}^j, \widehat{\mathbf{v}}^j, \mathbf{d}^j) + \sum_{\tau^2 \in T, \tau^2 \neq \mathbf{d}^j} \widehat{v}_{\tau^2}^j s(\tau^2, \widehat{\mathbf{v}}^j, \tau^2) \right] \quad (7)$$

Let $\widehat{k}(k, t_1, d_1^1)$ denote the number of agents who report to be of type- a in a first-period group, when the actual number of type- a agents is k and an agent of type t_1 reports d_1^1 while his partners tell the truth.

A type τ^2 agent who reports \mathbf{d}^2 in the second period after having reported d_1^1 in the first period expects, conditionally on the number of reported altruists \widehat{k} , that the total surplus accruing to his former partners in fresh groups is

$$\begin{aligned} \Omega_2(\tau^2, d_1^1, \mathbf{d}^2, \widehat{k}) &= \left(\widehat{k} - 1_{[d_1^1=a]}\right) E_{t_2^2} z_2^{(a, t_2^2)}(\tau^2, d_1^1, \mathbf{d}^2) + \\ &\quad + (n - \widehat{k} - 1 + 1_{[d_1^1=a]}) E_{t_2^2} z_2^{(e, t_2^2)}(\tau^2, d_1^1, \mathbf{d}^2) \end{aligned} \quad (8)$$

where $1_{[d_1^1=a]}$ is a dummy which takes 1 if $d_1^1 = a$ and zero otherwise. Notice that this definition covers the cases $N = 1$ and $N = \infty$ only.

In order to define the objective function of the agents, let $z_j^\star(\cdot) = z_j(\cdot)$ if none of the addends that sum up to $z_j(\cdot)$ is negative, and $z_j^\star(\cdot) = -\infty$ otherwise, for all j . Then, the objective function of an agent in group $j \neq 1$ is

$$U_j(\mathbf{t}^2, d_1^1, \mathbf{d}^j) = z_j^\star(\mathbf{t}^2, d_1^1, \mathbf{d}^j) + t_1 \phi_j(\mathbf{t}^2, d_1^1, \mathbf{d}^j) \quad (9)$$

i.e. the sum of an individual's material surplus and of his partners' surplus weighted by his alignment parameter. With this formulation there is a material surplus threshold below which even a fully altruistic agent is not willing to sacrifice himself for the benefit of his partners. Notice that, were it not so, a low benefit agent might deviate and declare high benefit.

For $j = 1$, the agent's objective function is the sum of two components: $U_1(\mathbf{t}^1, \mathbf{d}^1) + C(\mathbf{t}^1, \mathbf{d}^1)$, where

$$U_1(\mathbf{t}^1, \mathbf{d}^1) = z_1^\star(\mathbf{t}^1, \mathbf{d}^1) + t_1 \phi_1(\mathbf{t}^1, \mathbf{d}^1) \quad (10)$$

and

$$\begin{aligned} C(\mathbf{t}^1, \mathbf{d}^1) &= \sum_{k=0}^n \Pr(k | t_1) \sigma(\widehat{k}) E_{t_2^2} \left[z_{s_{\widehat{k}}}^*((t_1, t_2^2), d_1^1, \mathbf{d}^{*s_{\widehat{k}}}(\mathbf{t}^2, d_1^1)) + t_1 \phi_{s_{\widehat{k}}}^*(\mathbf{t}^1, d_1^1, \mathbf{d}^{*s_{\widehat{k}}}(\mathbf{t}^2, d_1^1)) \right] + \\ &+ \sum_{k=0}^n \Pr(k | t_1) (1 - \sigma(\widehat{k})) E_{t_2^2} \left[z_2^*((t_1, t_2^2), d_1^1, \mathbf{d}^{*2}(\mathbf{t}^2, d_1^1)) + t_1 \Omega_2^*((t_2^2, t_1), d_1^1, \mathbf{d}^{*j}(\mathbf{t}^2, d_1^1), \widehat{k}) \right] \end{aligned} \quad (11)$$

where $\mathbf{d}^{*j}(\mathbf{t}^2, d_1^1)$, $j \neq 1$, is the the optimal report of a type \mathbf{t}^2 individual who reported d_1^1 in the first period, when the j -group principal plays his equilibrium strategy Ψ_j^* — that is, $\mathbf{d}^{*j}(\mathbf{t}^2, d_1^1) = \arg \max_{\mathbf{d}^j} U_j(\mathbf{t}^2, d_1^1, \mathbf{d}^j; \Psi_j^*)$. The other symbols with an asterisk are similarly defined. Equation (11) defines the expected continuation payoff throughout period 2 and takes into account both the possibility of stabilization and the uncertainty on individual future evaluation of the public good.

Finally, we make the following additional assumptions:

Assumption a1 $h = 1, l = 0$

This is an innocuous normalization.

Assumption a2 $c < n - 1$

Only under a2 might high benefit individuals profit from reporting low benefit.

Assumption a3 $a = 1, e = 0$

To simplify, we consider only the case in which type- a agents assign the same weight to their own material benefit and to their partners', and type- e agents are indifferent to the fate of their partners. This allows us to label type- a agents altruists and type- e ones egoists.

Assumption a4 The parameters are such that in an isolated interaction inefficiency is obtained at equilibrium.

Asymmetric information is an interesting problem to study only if efficiency cannot be obtained at equilibrium. Below inefficiency is guaranteed at equilibrium by assumption a4' together with assumption a7 (see p. 10 and Appendix A).

Assumption a5 $\left(\sum_{\hat{\mathbf{v}}_{\mathbf{d}}^j \in \hat{\mathbf{v}}^j} \hat{v}_{\mathbf{d}}^j g_j(\hat{\mathbf{v}}^j, \mathbf{d}^j) - c \right) r_j(\hat{\mathbf{v}}^j) = 0$

As mentioned, we require ex-post budget balance.

Assumption a6 $g_j(\mathbf{v}^j, \mathbf{t}^j) \geq 0$.

This assumption excludes pure redistribution.

3 Analysis

Let us state the problem. The principal of a j -group, $j \neq 1$, having observed $\bar{\sigma}$, if $j = 2$, or having learned the number of type- a individuals in his group if $j = s_k$, $k = 0, \dots, n$, solves the following program, assuming that truth-telling is obtained in the first period.

$$\text{Program } j : \max_{\Psi_j} \Phi_j \tag{12}$$

s. t.

$$\left(\sum_{\mathbf{t}^2 \in \mathbf{T}} v_{\mathbf{t}^2}^2 g_j(\mathbf{v}^2, \mathbf{t}^2) - c \right) r_j(\mathbf{v}^2) = 0, \quad \forall \mathbf{v}^2 \in V \quad (13)$$

$$0 \leq g_j(\mathbf{v}^2, \mathbf{t}^2) \quad \forall \mathbf{v}^2 \in V, \forall \mathbf{t}^2 \in T \quad (14)$$

$$0 \leq r_j(\mathbf{v}^2) \leq 1, \quad \forall \mathbf{v}^2 \in V \quad (15)$$

$$U_j(\mathbf{t}^2, \mathbf{t}^2) \geq 0, \quad \forall \mathbf{t}^2 \in T \quad (16)$$

$$U_j(\mathbf{t}^2, \mathbf{t}^2) \geq U_j(\mathbf{t}^2, \mathbf{d}^j), \quad \forall (\mathbf{t}^2, \mathbf{d}^j) \in T \times T \quad (17)$$

Conditions (13)-(15) simply require feasibility within our framework. Inequality (16) imposes individual rationality and inequality (17) requires that truth-telling is incentive compatible.

Consider now the principal's problem at $j = 1$ (in the following an asterisk denotes an object evaluated at the equilibrium values of program j). Let

$$\begin{aligned} & \Phi_c(\{\Psi_j^*\}, \bar{\sigma}) = \\ & = \sum_{k=0}^n \Pr(k) \left\{ \sigma(k) \Phi_{s_k}^* + (1 - \sigma(k)) E_{t_2^2} [k z_2^*((a, t_2^2), a, (a, t_2^2)) + (n - k) z_2^*((e, t_2^2), e, (e, t_2^2))] \right\} \end{aligned} \quad (18)$$

be the expected surplus in the second period.

The first-period principal solves the following program, assuming that the other first-period principals, if any, are playing the strategy $\bar{\sigma}$:

$$\text{Program 1 : } \max_{\Psi_1, \sigma} [\Phi_1(\Psi_1, \sigma, \bar{\sigma}) + \Phi_c(\{\Psi_j^*\}, \bar{\sigma})]$$

s. t.

$$\left(\sum_{\mathbf{t}^1 \in \mathbf{T}} v_{\mathbf{t}^1} g_1(\mathbf{v}^1, \mathbf{t}^1) - c \right) r_1(\mathbf{v}^1) = 0, \quad \forall \mathbf{v}^1 \in V \quad (19)$$

$$0 \leq g_1(\mathbf{v}^1, \mathbf{t}^1), \quad \forall \mathbf{v}^1 \in V, \forall \mathbf{t}^1 \in T \quad (20)$$

$$0 \leq r_1(\mathbf{v}^1) \leq 1, \quad \forall \mathbf{v}^1 \in V \quad (21)$$

$$U_1(\mathbf{t}^1, \mathbf{t}^1) + C(\mathbf{t}^1, \mathbf{t}^1) \geq 0, \quad \forall \mathbf{t}^1 \in T \quad (22)$$

$$U_1(\mathbf{t}^1, \mathbf{t}^1) + C(\mathbf{t}^1, \mathbf{t}^1) \geq U_1(\mathbf{t}^1, \mathbf{d}^1) + C(\mathbf{t}^1, \mathbf{d}^1), \quad \forall (\mathbf{t}^1, \mathbf{d}^1) \in T \times T \quad (23)$$

Similar to program j definition, conditions (19)-(21) impose feasibility, inequality (22) is the intertemporal participation constraint and inequality (23) is the intertemporal incentive compatibility constraint. Of course at a symmetric Nash equilibrium it will be $\sigma = \bar{\sigma}$. In appendix C we prove that a symmetric equilibrium always exists.

To further simplify the analysis we make the following assumption.

Assumption a7 Groups size is $n = 2$.

As a result, the number of possible type profiles (states) is greatly reduced. We will comment on the generalization to the case of groups of any size in section 4.

When $n = 2$, assumption a4 simplifies to:

Assumption a4' The probability p that an agent is of type h is such that $p > \frac{2-2c}{2-c(1+\theta)}$.

Now we have all the tools to develop our analysis. The first question we study is whether a first-period principal may find it profitable to stabilize the group and communicate his information to the second-period principal. Preliminarily, let us state a simple fact.

Fact 1 *In an isolated interaction, the group expected surplus is larger when the permanent type of each member is common knowledge than when it is private information.*

Proof. See Appendix, part A. ■

It follows from Fact 1 that if eliciting information on permanent types were not costly, then group stabilization would certainly benefit society, because in the second period common knowledge would induce higher surplus. However, notice that from a first-period principal's perspective, when a group is composed of two type- e agents, group surplus would be larger when the group is dissolved and members go to fresh groups, but this would be detrimental for society. Therefore the values of information for a group and for society as a whole do not coincide.

Nevertheless, knowledge of group composition would be an asset that one would like to exploit, choosing whether to stabilize or dissolve the group. In a context of asymmetric information, extracting private information from the agents is costly. Does this cost exceed the benefits of common knowledge? We shall provide an answer in the next subsections.

3.1 Only one active group

The analysis of the whole game is rather complex, so it is illuminating to study first the problem under the hypothesis that only one group exists.

We summarize our findings in the following.

Proposition 1 *When only one group exists, the knowledge of group composition acquired through the first interaction cannot be exploited to increase per-period surplus with respect to the case of an isolated interaction. Formally, the first-period principal never stabilizes the group, i.e.*

$\sigma(k) = 0$, $k = 0, \dots, 2$. Such a result is due to the fact that when group stabilization is possible, the cost of inducing truthful reporting exceeds the efficiency gain.

The same holds when many groups are supervised by a unique principal who aims at maximizing the overall surplus.

Proof. The equilibrium allocations in stabilized groups coincide with those we characterized in proving Fact 1 under common knowledge of the individuals' permanent type (see Appendix A). As far as fresh groups are concerned, the second-period principal computes the probability, Θ , that a member is of type- a by means of the Bayes' rule, under the assumption that at date 1 all agents reported their type truthfully, that is $\Theta = \frac{\theta^2(1-\sigma(2))+2\theta(1-\theta)(1/2)(1-\sigma(1))}{\theta^2(1-\sigma(2))+2\theta(1-\theta)(1-\sigma(1))+(1-\theta)^2(1-\sigma(0))}$. Now, suppose $\sigma(k) = 0$, $k = 0, \dots, 2$ at equilibrium. Then, it follows that $\Theta = \theta$, and hence the equilibrium allocation coincides with that we found in proving Fact 1 under asymmetric information. To prove that $\sigma(k) = 0$, all k is not immediate. Indeed, the stratagem used in the proof of the ratchet effect in Fudenberg and Tirole, 1991, of constructing an equivalent static strategy through an appropriate averaging of the candidate optimal dynamic strategy, does not apply in our game: no averaging can simultaneously conserve both the surplus of the group and that of each agent. So, we proceed in two steps. In the first step we consider a modified mechanism in which the above mentioned stratagem applies. In the second step we show that the optimal solution of the modified mechanism also maximizes the original mechanism.

Step 1

Consider a new mechanism, which differs from the one considered above only in the timing of reporting: each agent firstly reports his permanent type to the principal, then learns his own benefit from the public good and reports it without knowing the permanent type of his partners — except, of course, in stabilized groups in which no reporting of the permanent type is needed and members' permanent reported types are common knowledge. Let $\Psi^e = \{r_j^e(\widehat{\mathbf{v}}^j), g_j^e(\widehat{\mathbf{v}}^j, \mathbf{d}^j), j = 1, 2, s_0, s_1, s_2, \text{all } \widehat{\mathbf{v}}^j, \text{all } \mathbf{d}^j\}$ denote an equilibrium choice of probabilities of provision and transfers in this modified game, and let lotteries $\gamma_j(\mathbf{t}^i, \mathbf{d}^j, \widehat{\mathbf{v}}^j) = \{r_j^e(\widehat{\mathbf{v}}^j), 1 - r_j^e(\widehat{\mathbf{v}}^j); t_2^i - g_j^e(\widehat{\mathbf{v}}^j, \mathbf{d}^j), 0\}$ denote the surplus allocation for a j -group to an individual of type \mathbf{t}^i , $i = 1, 2$, who declares \mathbf{d}^j , when the reported state is $\widehat{\mathbf{v}}^j$, $j = 1, 2, s_0, s_1, s_2$.

The equilibrium surplus allocation in the whole game that a type- e individual expects before

learning his private benefit is

$$\begin{aligned}
S(e; e, \{\gamma_j\}) &= p\theta [p\gamma_1(eh, eh, eh.ah) + (1-p)\gamma_1(eh, eh, eh.al)] + \\
&\quad + \theta p^2 [\sigma(1)\gamma_{s1}(eh, eh, eh.ah) + (1-\sigma(1))\gamma_2(eh, eh, eh.ah)] + \\
&\quad + \theta p(1-p) [\sigma(1)\gamma_{s1}(eh, eh, eh.al) + (1-\sigma(1))\gamma_2(eh, eh, eh.al)] + \\
&\quad + (1-\theta)p [p\gamma_1(eh, eh, 2eh) + (1-p)\gamma_1(eh, eh, eh.el)] + \\
&\quad + (1-\theta)p^2 [\sigma(0)\gamma_{s0}(eh, eh, 2eh) + (1-\sigma(0))\gamma_2(eh, eh, 2eh)] + \\
&\quad + (1-\theta)p(1-p) [\sigma(0)\gamma_{s0}(eh, eh, eh.el) + (1-\sigma(1))\gamma_2(eh, eh, eh.el)] \quad (24)
\end{aligned}$$

Now let us consider the class of strategies for the first-period principal such that $\sigma(k) = 0$, $k = 0, \dots, 2$. Observe that if a strategy in this class results as being optimal, the second-period principal will also be using it at equilibrium — we are assuming uniqueness for simplicity; of course, choosing a value for $\sigma(k)$'s is not essential in the second period. We name a strategy with $\sigma(k) = 0$, $k = 0, \dots, 2$, a static strategy.

We will show that, whatever the equilibrium allocation set $\{\gamma_j\}$, we can always attain the principal's problem value by restricting attention to static strategies. This means that using information extracted in the first period is worthless.

Let $\gamma(\mathbf{t}^1, \mathbf{d}^1, \hat{\mathbf{v}}^1)$ be the allocation, induced by an optimal strategy in the class of static strategies, to an individual of type \mathbf{t}^1 who reports \mathbf{d}^1 in state $\hat{\mathbf{v}}^1$.

Next, consider an individual who is of type \mathbf{t}^1 in the first period and rewrite his surplus allocation for the whole game, let it be denoted by $S(t_1, t_1; \{\gamma\})$, when $\gamma()$ and not $\gamma_j()$, for all j , is adopted. Notice that the expected value of $S(t_1, t_1; \{\gamma\})$ (expectation is computed with respect to the probabilities of provision) equals $E_{t_2^1} [U_1(\mathbf{t}^1, \mathbf{t}^1) + C(\mathbf{t}^1, \mathbf{t}^1)]$. As an example, the equilibrium expected surplus of a type e individual is

$$\begin{aligned}
S(e, e; \{\gamma\}) &= p\theta [p\gamma(eh, eh, eh.ah) + (1-p)\gamma(eh, eh, eh.al)] + \\
&\quad + \theta p^2 \gamma(eh, eh, eh.ah) + \theta p(1-p)\gamma(eh, eh, eh.al) + \\
&\quad + (1-\theta)p [p\gamma(eh, eh, 2eh) + (1-p)\gamma(eh, eh, eh.el)] + \\
&\quad + (1-\theta)p^2 \gamma(eh, eh, 2eh) + (1-\theta)p(1-p)\gamma(eh, eh, eh.el) \quad (25)
\end{aligned}$$

Notice that $S(e, e; \{\gamma\})$ can be obtained from $S(e, e; \{\gamma_j\})$ by writing $\gamma()$ instead of γ_j in all states, and then simplifying.

It will be $S(e, e; \{\gamma\}) = S(e, e; \{\gamma_j\})$ if the following set of elementary conditions on $\{\gamma\}$ is satisfied:

$$\begin{aligned} \gamma(eh, eh, eh.\tau) &= \frac{\gamma_1(eh, eh, eh.\tau)}{2} + \\ &+ \frac{1}{2} \sum_{k=0}^2 \Pr(k | e.\tau) \{ \sigma(k) \gamma_{s_k}(eh, eh, eh.\tau) + (1 - \sigma(k)) \gamma_2(eh, eh, eh.\tau) \} \quad \forall \tau. \end{aligned} \quad (26)$$

In the same way we get:

$$\begin{aligned} \gamma(ah, ah, 2ah) &= \frac{\gamma_1(ah, ah, 2ah)}{2} + \\ &+ \frac{1}{2} [\sigma(2) \gamma_{s_2}(ah, ah, 2ah) + (1 - \sigma(2)) \gamma_2(ah, ah, 2ah)] \end{aligned} \quad (27)$$

$$\begin{aligned} \gamma(ah, ah, ah.eh) &= \frac{\gamma_1(ah, ah, ah.eh)}{2} + \\ &+ \frac{1}{2} [\sigma(1) \gamma_{s_1}(ah, ah, ah.eh) + (1 - \sigma(1)) \gamma_2(ah, ah, ah.eh)] \end{aligned} \quad (28)$$

$$\begin{aligned} \gamma(ah, ah, ah.el) &= \frac{\gamma_1(ah, ah, ah.el)}{2} + \\ &+ \frac{1}{2} [\sigma(1) \gamma_{s_1}(ah, ah, ah.el) + (1 - \sigma(1)) \gamma_2(ah, ah, ah.el)] \end{aligned} \quad (29)$$

$$\begin{aligned} \gamma(ah, ah, ah.al) &= \frac{\gamma_1(ah, ah, ah.al)}{2} + \\ &+ \frac{1}{2} [\sigma(2) \gamma_{s_2}(ah, ah, ah.al) + (1 - \sigma(2)) \gamma_2(ah, ah, ah.al)] \end{aligned} \quad (30)$$

$$\gamma(\cdot l, \cdot l, \cdot l.\tau) = \{\cdot, \cdot; 0, 0\} \quad (31)$$

These conditions are such that the strategy that implements $\{\gamma\}$ is well defined: that is, both

its $r(\mathbf{v})$'s and $g(\mathbf{v}, \mathbf{t})$'s are defined in terms of all the equilibrium probabilities $r_j(\mathbf{v})$ and all the payments $g_j(\mathbf{v}, \mathbf{t})$ in such a way that the allocation for a given type in a given state uses the same probabilities of providing the good as the other types' allocations in the same state. Moreover each of these allocations is feasible, because it is a convex linear combination of feasible allocations contingent on the same state – so all constraints on payments and ex-post budget balance constraints are satisfied.

Now let us prove that the strategy that implements $\{\gamma\}$ is incentive compatible. Unilateral deviations from truthful reporting to be considered are (indicating the true type on the left side and the false type on the right side): $e \rightarrow a, a \rightarrow e, eh \rightarrow el, ah \rightarrow al$.

Since by construction, each type's expected payoff from truthful reporting is the same under $\{\gamma\}$ and $\{\gamma_j\}$, the strategy that implements $\{\gamma\}$ is incentive compatible if the expected value of lottery $S(t_1, d_1; \{\gamma\})$ is lower than the expected value of lottery $S(t_1, d_1; \{\gamma_j\})$ for each possible t_1, d_1 . Now, notice that the strategy that implements $\{\gamma\}$ must induce an individual of type \mathbf{t}^1 at date 1 to report \mathbf{t}^1 . Instead the strategy that implements $\{\gamma_j\}, j = 1, 2, s_k, k = 0, 1, 2$ must induce an individual that is of type \mathbf{t}^1 at date 1 not only to report his true type in group 1 but also to report his true types in all the possible second period groups. Therefore the strategy which implements $\{\gamma\}$ offers less opportunities for lying than the strategy that implements $\{\gamma_j\}$. Thus we conclude that the expected value of lottery $S(t_1, d_1; \{\gamma\})$ is lower than the expected value of lottery $S(t_1, d_1; \{\gamma_j\})$.

Finally, noting that the first-period principal gets the same group surplus as with $\{\gamma_j\}$, we conclude that $(\{\gamma\}, \{\gamma\})$ is no worse than $\{\gamma_j\}, j = 1, \dots, 2$. Actually, the first-period principal's surplus coincides with the altruist's expected payoff if at least one altruist belongs to the group and with twice the egoist's expected payoff if only egoist agents compose the group. Given that our construction conserves total individual payoff for all types in any state, it also conserves first-period principal surplus⁵.

Step 2.

Let us come back to our original game, in which each agent learns and reports both dimensions of his type simultaneously. Note that the incentive constraints in the first-period mechanism are more restrictive than those considered in the modified mechanism of step 1, since the deviations to be considered are $eh \rightarrow al, eh \rightarrow el, eh \rightarrow ah, el \rightarrow al, ah \rightarrow eh, ah \rightarrow al, ah \rightarrow el, al \rightarrow el$. Notice that our assumption that material surplus must be nonnegative implies that no low type will ever report high type.

⁵Recall that a high benefit altruist's material surplus is one half of his surplus.

It follows that in the class of the strategies that use the information elicited in the first period, no strategy can exist that does better than the best strategy in the modified game above.

Let us consider the class of those strategies that do not use the information elicited in the first period. We will show that the system of incentive compatibility constraints in our game is equivalent to that in the modified game. In what follows we directly replace in the *ICs* the optimal payments, which are described in Appendix A. Note the following three facts.

1) Incentive compatibility constraint $IC(e, a)$ in the modified game is equivalent to the two constraints $IC(eh, al)$, $IC(eh, ah)$ in the original game – a low-type egoist does not have any incentive to lie. In fact in both games $r(\cdot h, \cdot h) = 1$, $r(\cdot l, \cdot l) = 0$ at equilibrium and hence $IC(e, a)$ is

$$\begin{aligned}
& p\theta(p + (1-p)(1-c)r(eh.al)) + p(1-\theta)\left(p\left(1 - \frac{c}{2}\right) + (1-p)(1-c)r(eh.el)\right) \geq \\
& p \max \left\{ \theta p \left(1 - \frac{c}{2}\right) + (1-p)(1-c)r(ah.al) + (1-\theta)\left(p(1-c) + (1-p)(1-c)r(ah.el)\right), \right. \\
& \qquad \qquad \qquad \left. \theta pr(ah.al) + (1-\theta)pr(eh.al) \right\} \quad (32)
\end{aligned}$$

The *IC* above reads as follows. Take an egoist (addressed also as first player). The left-hand-side represents the payoff he obtains by truthfully reporting his permanent type. Suppose he is high benefit, an event with probability p . He will obtain a positive surplus, the amount of which depends on the bi-dimensional type of his partner. Conversely, an egoist with low benefit (an event with probability $1-p$) will obtain no surplus independently of his partner's type. Let us discuss now how the positive expected surplus is formed. If the partner has type (a, h) , whose probability is θp , the public good will be certainly provided. The egoist under scrutiny will get 1 at no cost. The entire cost of provision is paid by his partner. When the partner has type (a, l) the good is provided with probability $r(eh.al)$, but now the full cost is borne by the first player. Moreover, the partner can also be of type- e . With probability p he will be of type (e, h) . In this case the good is certainly provided and the cost is equally shared. With probability $1-p$ the partner is of type (e, l) : now the good is provided with probability $r(eh.el)$ and the entire cost is born by the first player.

The right-hand-side represents agent's surplus when he lies about his permanent type. Once more he gets a positive surplus only when his own contingent type is h . Note that he has two possible lies: saying he is of type (a, h) or of type (a, l) . He will clearly opt for the one that secures more surplus for himself. Consider the possible cases. First, the egoist declares (a, h) . When his partner is of type (a, h) , the public good will be certainly provided and the cost is

equally shared, because both individuals appear to have the same type. When the partner is of type (a, l) the good is provided with probability $r(ah.al)$ and all the cost is paid by the first player. Again, when the partner is of type (e, h) the good is certainly provided and the cost is paid by the first player because he has declared to be altruist. Finally, when the partner is of type (e, l) , the good is provided with probability $r(ah.el)$ and the cost is born by the first player. Now, suppose the egoist declares to be of type (a, l) . If the partner is of type (a, h) the good is provided with probability $r(ah.al)$ at the partner's expenses. When the partner is of type (e, h) the good is provided with probability $r(eh.al)$ again at the partner's expenses. Finally, note that when the partner is of low benefit the good will not be provided.

This incentive constraint is equivalent to the system of constraints $IC(eh, al)$ and $IC(eh, ah)$, that is

$$\begin{aligned} & \theta(p + (1-p)(1-c)r(eh.al)) + \\ & + (1-\theta)\left(p\left(1 - \frac{c}{2}\right) + (1-p)(1-c)r(eh.el)\right) \geq \theta pr(ah.al) + (1-\theta)pr(eh.al) \end{aligned} \quad (33)$$

$$\begin{aligned} & \theta(p + (1-p)(1-c)r(eh.al)) + (1-\theta)\left(p\left(1 - \frac{c}{2}\right) + (1-p)(1-c)r(eh.el)\right) \geq \\ & \theta\left(p\left(1 - \frac{c}{2}\right) + (1-p)(1-c)r(ah.al)\right) + (1-\theta)\left(p(1-c) + (1-p)(1-c)r(ah.el)\right) \end{aligned} \quad (34)$$

2) The system of incentive compatibility constraints $IC(a, e)$ and $IC(eh, el)$ in the modified game is equivalent to the system of constraints $IC(eh, el)$ and $IC(ah, eh)$ in the original game. In fact since in both games $r(\cdot h, \cdot h) = 1, r(\cdot l, \cdot l) = 0$ at equilibrium, and a high altruist will certainly report h in both games, $IC(a, e)$ is

$$\begin{aligned} & (1-c)(1-p)p(\theta r(ah.al) + (1-\theta)r(eh.al) - \theta r(ah.el) - (1-\theta)r(eh.el)) + \\ & + p\theta\left(p(2-c)(1-1) + (1-p)(1-c)(r(ah.al) - r(eh.al))\right) + \\ & p(1-\theta)\left(p(2-c)(1-1) + (1-p)(1-c)(r(ah.el) - r(eh.el))\right) \geq 0 \end{aligned} \quad (35)$$

which simplifies to

$$\begin{aligned} & \theta(r(ah.al) - r(ah.el)) + (1-\theta)(r(eh.al) - r(eh.el)) + \\ & + \theta(r(ah.al) - r(eh.al)) + (1-\theta)(r(ah.el) - r(eh.el)) \geq 0 \end{aligned} \quad (36)$$

On the other hand $IC(eh, el)$ is

$$\theta r(eh.al) + (1 - \theta)r(eh.el) - \theta r(ah.el) - (1 - \theta)r(eh.el) \geq 0 \quad (37)$$

and $IC(ah, eh)$ is

$$\theta r(ah.al) + (1 - \theta)r(ah.el) - \theta r(eh.al) - (1 - \theta)r(eh.el) \geq 0 \quad (38)$$

and hence adding these two constraints we get

$$\begin{aligned} & \theta r(ah.al) + (1 - \theta)r(eh.al) - \theta r(ah.el) - (1 - \theta)r(eh.el) + \theta r(ah.al) + \\ & \quad + (1 - \theta)r(ah.el) - \theta r(eh.al) - (1 - \theta)r(eh.el) = \\ & \quad \theta (r(ah.al) - r(ah.el)) + (1 - \theta)(r(eh.al) - r(eh.el)) + \\ & \quad + \theta(r(ah.al) - r(eh.al)) + (1 - \theta)(r(ah.el) - r(eh.el)) \geq 0 \quad (39) \end{aligned}$$

3) $IC(al, el)$, $IC(el, al)$ and $IC(eh, ah)$ are not binding at equilibrium. (see Appendix part A) Therefore we have proved that the system of IC constraints in the modified mechanism is equivalent to that of the original mechanism. This allows us to conclude that the class of strategies for the modified mechanism that do not use the information elicited in the first period is large enough to include the optimal strategy for our original game. ■

A careful examination of the proof above shows that dissolving the group is an equilibrium strategy no matter what the number of altruists and the number of existing groups are, provided that the equilibrium strategy used in fresh groups and in first-period groups is the same.

It is immediately seen that the logic of proof also applies to the case where one first-period principal supervises all first-period groups with the purpose of maximizing the overall surplus, adopting the same strategy in all of them.

The result just obtained is due to a complex sort of ratchet effect. In the standard framework, the ratchet effect consists in the agent anticipating that in future rounds of interaction the principal will exploit the information elicited in the current round, so there is an incentive for the agent to lie on his type; restoring the incentive to telling the truth entails an additional cost to the principal that overcomes the benefit of exploiting the information. In our framework the

story is more complicated, since the expectation that the principal will intertemporally exploit information triggers three distinct perverse incentive effects.

The first - that we call “plain ratchet effect” - corresponds to the situation described above: good-type agents are reluctant to declare truthfully their permanent type, fearing that the principal will use it to their disadvantage in the current and in the following rounds. However, setting $a = 1$ and $e = 0$ as we did for simplicity causes this effect to vanish; in fact, perfectly altruist agents do not care about possible reductions of their own surplus, as they look at the whole group surplus. This allows us to focus on the remaining two effects, which are much less straightforward.

The second effect - that we call “chain of lies effect” consists in an agent misreporting his permanent type in the first period in order to get the chance of advantageously lying on his temporary type in the second period. This effect only regards an egoist: he can falsely declare himself to be altruist in the first period to increase the probability of group stabilization; if the group is indeed stabilized, he will report low benefit in the case that he discovers himself to be a high benefit individual. Specifically, as a consequence of the first lie he will face an incentive constraint designed for an altruist, and therefore inappropriate for inducing an egoist to tell the truth. An obvious case in which this effect does prevent the exploitation of the information elicited during the first period arises when the principal sets $\sigma(k) = 1$, for all k ; recall that Fact 1 ensures that in this case the group’s expected surplus in the second period is greater than in the case $\sigma(k) = 0$ for all k . For simplicity, let us consider the case of a single group. An altruist has no reason to lie: in fact, by telling the truth he can only end up in groups s_1 and s_2 and in both such groups efficiency results; on the other hand, by lying he risks being part of group s_0 where inefficiency prevails. Conversely, egoists find it profitable to lie. This is an immediate implication of Proposition 1 — still, we offer an independent proof in Appendix B. Crucially, note that it is the possibility of a second lie that makes the incentive constraint of egoists especially hard to satisfy. In fact, once the egoist has declared himself to be altruist, he profits from declaring low benefit even when he is of high benefit⁶, so the perspective of the second lie increases the attractiveness of the first⁷.

⁶Once in an s_1 -group a false altruist who happens to be high benefits obtains p by lying and $1 - c$ by telling the truth. We know that $p > 1 - c$, as this inequality is implied by the inefficiency condition, that can be rewritten as $p > (1 - c) \frac{2}{2 - (1 + \theta)c}$.

In an s_2 -group the corresponding condition is $p - [p(1 - c/2) + (1 - p)(1 - c)] = -\frac{1}{2}pc - 1 + c + p > 0$, which is satisfied for $p > \frac{2 - 2c}{2 - c}$. This inequality also follows from the inefficiency condition, since $\frac{2 - 2c}{2 - (1 + \theta)c} > \frac{2 - 2c}{2 - c}$.

⁷For some triplets of parameters, absent the possibility of the second lie, the egoist would not find it advantageous to tell the first lie in front of the announcement $\sigma_0 = \sigma_1 = \sigma_2 = 1$. In fact the payoff of truthtelling is $p \left[\theta (p + (1 - p)(1 - c)) + (1 - \theta) \left[p(1 - c/2) + (1 - p)(1 - c) \frac{1}{2} p \frac{-2 + c}{1 - c - 2p + pc} \right] \right]$, while that of the single lie would

The third effect - probably the most surprising at first sight - concerns altruists: even a perfect altruist, who does aim at maximizing group surplus, may be tempted to declare himself to be an egoist to modify the probabilities of public good provision, in order to enforce what he myopically sees as an improvement in group welfare. We label this effect the “white lie effect”. The point is that the principal is assumed to have a commitment to implement - in a time consistent way - the strategy initially announced; agents, on the other hand, are by definition followers, who maximize ex-post, taking the principal’s announcement as given. So, in his reporting decision an agent whose objective function is aligned with the principal’s does not realize - qua agent - that the latter is subjecting himself to a costly constraint for the purpose of disciplining the egoists, and tries to improve upon the resulting outcome. The consequence is the opposite since, in order to prevent such behavior, the principal is forced to subject himself to further constraints, and therefore to shift to a less preferred strategy.

Consider the following example, in which only one principal controls all N first-period groups and N is infinitely large - so the change in the expected composition of fresh groups due to an agent’s deviation is negligible - and maximizes the overall surplus. Let $c = p = \theta = 3/4$. When $\sigma(k) = 0$, for all k , efficiency can never be obtained⁸. However, setting $\sigma(0) = 0$, $\sigma(1) = 1$, $\sigma(2) = 0$ would ensure full efficiency in the second period. In fact, not surprisingly, efficiency is warranted in group s_1 and, furthermore, thanks to the fact that the proposed selective group stabilization leads to a Θ sufficiently greater than θ , efficiency would also be obtained in a fresh group⁹. It can easily be shown that this move does not deteriorate the incentive for an egoist to declare truthfully her permanent type in the first period - indeed, an egoist who happens to be high benefits and has declared his permanent type truthfully, obtains nearly the maximum conceivable surplus¹⁰ in the second period. Conversely, it is only the altruists who now have a clear incentive to lie: whoever an altruist’s partner, group surplus is greater if the altruist declares himself egoist. To better see the point, let us consider the two possible cases. First

be $p[\theta p(1 - c/2) + \theta(1 - p)(1 - c) + (1 - \theta)(1 - c)]$. In fact, for $p = 3/4, c = 3/4, \theta = 3/4$ the two expressions amount to 0.3457 and 0.5529, respectively.

⁸The efficiency condition $p < \frac{2-2c}{2-c(1+\theta)}$ is not satisfied, as $.75 > .72727$.

⁹Since N is large, $\Theta = \frac{\theta^2}{\theta^2 + (1-\theta)^2} = 0.9$ and therefore the threshold for p would become $p < \frac{2-2c}{2-c(1+\Theta)} = 0.86957$, so the efficiency condition would be satisfied - recall that it is $p = .75$.

¹⁰More precisely - remember that her payoff is only nonzero when she happens to be high - it can be shown that she has only to lose by lying. In fact, if her mate is an altruist, she would obtain the payoff of an egoist in the fresh group, rather than the payoff of an egoist in a s_1 group, which is greater (there she is sure of being matched with an altruist); if instead her mate is an egoist, the group would be stabilized, so the best payoff she can get is by declaring low (again the chain of lies) and is equal to p (in fact by declaring high, as a supposed altruist, she would be asked to pay all the cost of the good, and thus obtain $1 - c$, which is less than p since assumption $a4'$ implies $p > 1 - c$) while by declaring truthfully, she would obtain the payoff of an egoist in the fresh mechanism, which in this case is greater (indeed for $p = c = 3/4$ and $\Theta = 9/10$ it can easily be checked that it is $\Theta p + (1 - \Theta)p(1 - c/2) + (1 - p)(1 - c) > p$).

case: the altruist has an altruist partner. The group will be stabilized thanks to the former altruist's lie, and thus he obtains the efficient surplus. On the other hand, by telling the truth, both partners would be reallocated to fresh groups, where they would each get less than half of the efficient pie. Second case: the altruist has an egoist partner. The lie will cause reallocation to fresh groups, which is preferable to stabilization (stabilization would only ensure the efficient group surplus, while reallocation to fresh groups allows one altruist and one egoist to obtain more because efficiency still results and the ratio of altruists to egoists exceeds 1:1).

3.2 An infinite number of active groups

We now turn to the case in which N groups exist and, according to the initial description of the game, each first-period principal aims at maximizing the surplus obtained over the whole game by the group he supervises. Since his first-period choices concur in determining the composition of second-period fresh groups, a strategic interaction between first-period principals arises. In this context Proposition 1 cannot be assumed to hold, since no game among first-period principals is considered there. So, group stabilization cannot be excluded. Of course, Proposition 1 implies that stabilization can only result in deterioration social surplus.

In the following, the number of groups is so large that each first-period principal can neglect the impact of his own stabilization decisions on the composition of fresh groups.

Before presenting our results, let us explain, on intuitive grounds, why the strategy of never stabilizing groups may not be Nash. If all the other first-period principals dissolved their groups, one principal might find it advantageous to selectively stabilize his group: in particular, when both members are of type- e , letting them go is attractive, since they will gain surplus in fresh groups at the expense of type- a agents coming from other groups; conversely, stabilizing the group when this is composed of two type- a individuals ensures more surplus than reallocation into fresh groups. So, a free riding problem characterizes the interaction between first-period principals. Nevertheless, group stabilization does not necessarily occur in equilibrium, since eliciting and exploiting private information on members' permanent types is still made costly by the ratchet effect.

As regards the computation of Nash equilibria, thanks to N being infinitely large we can easily verify whether a given strategy for first-period principals is Nash by solving a simple linear programming problem — actually, a first-period principal knows that the composition of fresh groups is independent of his own decision. Below we present an example in which group stabilization is obtained at equilibrium, and an example in which stabilization does not obtain.

Let be $\theta = 1/2$, $c = 3/4$, $p = 3/4$, $n = 2$, N infinitely large. The strategy of always dissolving the group is not Nash since the best reply of a first-period principal to such a strategy is $\sigma(0) = 0$, $\sigma(1) = 1$, $\sigma(2) = \frac{11}{15}$, which would get him an expected surplus of 1.610 — notice that he will set $r_1(eh.al) = .7416$, $r_1(ah.al) = .9841$, $r_1(eh.el) = .4674$, $r_1(ah.el) = 1$, $r_1(\cdot h \cdot h) = 1$, $r_1(\cdot l \cdot l) = 0$; instead the strategy of always dissolving the group brings him $2(.786222) = 1.572$ only. Therefore unilateral deviation is profitable.

Then, consider stabilizing the group with probability $\sigma(0) = 0$, $\sigma(1) = 1$, $\sigma(2) = .4720$. A first-period principal knows that, independently of his move, the probability that a member of a fresh group is of type a is $\Theta = \frac{\theta^2(1-\sigma(2))+2\theta(1-\theta)(1/2)(1-\sigma(1))}{\theta^2(1-\sigma(2))+(1-\sigma(1))2\theta(1-\theta)+(1-\sigma(0))(1-\theta)^2}$, that is $\Theta = .34627$. If we compute a first-period principal's optimal reply we find $\sigma(0) = 0$, $\sigma(1) = 1$, $\sigma(2) = .4720$, and so a Nash equilibrium occurs — he will set $r_1(ah.al) = 1$, $r_1(eh.el) = .1386$, $r_1(eh.al) = .6944$, $r_1(ah.el) = 1$. Group expected surplus at equilibrium is $.7799 + .7803 = 1.5602$. Notice that, as we anticipated, expected group surplus at equilibrium is less than would be secured by all principals adopting the strategy of always dissolving their group.

Now consider the parameter constellation $\theta = \frac{1}{4}$, $p = \frac{3}{4}$, $c = \frac{3}{4}$. The strategy of stabilizing the group with probability $\sigma(0) = 0$, $\sigma(1) = 0$, $\sigma(2) = 0$ is Nash when N is infinitely large. Indeed a first-period principal's optimal reply is $\sigma(2) = 0$, $\sigma(1) = 0$, $\sigma(0) = 0$ ¹¹.

We summarize our results in the following:

Proposition 2 *When a very large number of groups exists, group stabilization can be obtained in a Nash equilibrium. Therefore the knowledge of group composition acquired in the first interaction has a positive economic value for the group.*

However, expected group surplus per period cannot be greater than in a single isolated interaction.

4 Discussion and extensions

First of all, notice that removing the assumption that the levels of benefit which type- h and type- l players derive from the public good are the same across periods does not invalidate Proposition 1. Moreover Proposition 1 still holds if a discount factor different from 1 is introduced, and also if a greater (even infinite) number of periods is considered. Notice, in this regard, that no stable groups can dissolve after the second interaction since the share of altruists in fresh groups may only decrease over time. Also, the assumption that group size is $n = 2$ can be easily generalized.

¹¹The probability that a member is of type a in a fresh group is $\Theta = \frac{1}{4}$. The probabilities of provision are $r_i(\cdot h \cdot h) = 1$, $r_i(\cdot l \cdot l) = 0$, $r_i(eh.al) = .712$, $r_i(ah.el) = .712$, $r_i(eh.el) = .808$, $r_i(ah.al) = 1$ $i = 1, 2$.

We conjecture that at Nash equilibrium only groups in which the share of altruists lies between a lower and an upper limit might be stabilized.

It is of greater interest to reconsider the assumptions concerning: a) the principal's powers; b) the definition of altruism

4.1 The principal's powers

Several alternatives to our assumptions can be considered. Below, we confine ourselves to examining one situation in which the principal has more powers and one in which he has less powers than we have assumed until now.

i) More powers. Recall that in what proceeds, first-period principals do not choose allocations in stabilized groups and second-period principals hold no more information about permanent types than group members.

The first assumption is made only for simplicity and is not essential for the results above. In fact, mechanism coordination across periods can improve the value of the best dynamic strategy, but Proposition 1 continues to apply (the proof above holds, whatever the candidate optimum strategy). On the other hand when first-period principals play Nash giving them greater powers in the case of group stabilization could only enlarge the set of parameter triplets for which group stabilization is obtained.

The second assumption rules out the possibility of an informed second-period principal who might prefer not to reveal information to agents. Further research is needed to analyze this possibility.

ii) Less powers. The principal might not be endowed with the power of stabilizing groups, since this decision might be thought to be in the hands of group members. Of course, this requires that group composition is common knowledge after the first period. The effects of this alternative power distribution are easily understood in our framework. After the first round, agents will unanimously choose to terminate their relationship when no altruist is present, and to continue it when there are either one or two altruists¹². So – irrespectively of whether one

¹²It can be immediately inferred why two altruists prefer to stay together (so they split the efficient surplus, instead of receiving each less than half of it in fresh groups) and two egoists have nothing to gain from staying together (that is the worst group composition from their point of view). When only one of them is an altruist, the egoist prefers continuation, since it ensures him the best possible payoff. As to the altruist, he must compare the efficient group surplus secured by the s_1 -group with the sum of the expected material payoff of one altruist and one egoist in a fresh group. It is clear that this sum is less than the efficient group surplus as soon as $\Theta < 1/2$ (in that case one altruist and one egoist together receive less than the expected group surplus, which is at most the efficient surplus). The last step is to observe that when $\sigma(2) = 1$ and $\sigma(0) = 0$ it is: $\Theta = \frac{\theta(1-\theta)(1-\sigma_1)}{2\theta(1-\theta)(1-\sigma_1)+(1-\theta)^2}$, which is certainly less than $1/2$ irrespectively of the value of σ_1 .

principal controls all groups, or instead N principals play Nash – in equilibrium no altruist will be present in fresh groups.

Therefore, we are *de facto* in the situation in which $\sigma(k) = 1$, for all k . In this case, as we proved when illustrating the chain of lies effect, egoists cannot be prevented from lying in the first period. Notice that the first-period principal has no instruments at his disposal for countering the incentive of a low benefit egoist to declare himself altruist since, whatever the first period allocation, he is indifferent as to reporting his permanent type. So separation of altruists from egoists becomes impossible. This means that altruism is completely ineffective in the first period — or, more generally, in all periods except the last.

4.2 Altruism

According to the definition of altruism we have adopted, in the first period altruists are concerned with the future fate of their first-period partners. Indeed, a different variety of altruism is conceivable: as far as future periods are concerned, in today's decisions an altruist cares about the future surplus not of today's but of tomorrow's partners. This apparently small change has significant effects. Going back to the example presented above to describe the white lie effect, it is straightforward to check whether the strategy we examined there would now become feasible. In fact, now the shift from $\sigma(1) = 0$ to $\sigma(1) = 1$ provides no incentive for an altruist to declare himself egoist: his objective function is satisfied exactly at the same level irrespective of whether the group is stabilized or not, since in both cases group surplus takes on the efficiency level. Observe that in this example selective group stabilization is socially beneficial. Commenting on this result, one could notice that the initial definition of altruism is more “particularistic” in nature, so it is not surprising if such altruists exert greater resistance to the principal's attempts at maximizing social surplus. Still, the “particularistic” definition seems to us more realistic as a description of concern for group welfare.

5 Conclusions

The model we have presented helps clarify that, in hidden information contexts, the value of repeated interactions is not necessarily embodied in long-lasting fruitful relationships themselves, but rather in the possibility of eliciting information on group composition in the first stage of interaction and using it for selectively stabilizing or terminating relationships. Suppose for instance that all the principals but one adopt the strategy of never stabilizing groups. Then the remaining principal may find it advantageous to stabilize groups with a relatively high share of

altruists, and discontinue the others. This possibility is limited, but not necessarily excluded, by the agent's reluctance to reveal their degree of cooperativeness. In fact we find Nash equilibria with stabilization. The difference between the two statements above is not apparent in Ghosh and Ray's model, since their bad agents (i.e. the impatient) have "non cooperation" as the dominant strategy, so they have nothing to gain from cheating on their type. So all productive relationships (those with 2 patient players in their setting) persist in equilibrium. Conversely, in our model, given that both types have good reasons for cheating, exploiting information requires that certain fruitful relationships be discontinued (in particular those with two altruists). Furthermore, the decision of one principal on group termination exerts externalities on the other principals, via the expected composition of fresh groups. Thus, whilst social surplus and group surplus coincide in Ghosh and Ray's model, in our model maximization of group surplus may entail stabilization of some groups even though social surplus is certainly less with stabilization than without it.

Our model also sheds some light on the effects of altruism in social relationships. On the one hand, due to adverse intertemporal incentives connected with private information, the presence of even perfect altruists can be ineffective at improving social surplus when mobility decisions are left to individual discretion. On the other hand, the notion of altruism that appears natural in the context of a single group, appears particularistic when it is applied to an intertemporal context with mobility, so altruism may result less beneficial to society than it is in a sequence of one-time interactions.

Appendix A

Proof of Fact 1.

When members' permanent types are common knowledge three cases are possible.

Case 1: both agents are of type a .

It is immediately seen that efficiency is obtained at equilibrium. This means that $r(2ah) = r(ah.al) = 1, r(2al) = 0$. Moreover, the payments are as follows: $g(2ah, ah) = c/2, g(ah.al, ah) = c, g(ah.al, al) = 0, g(2al, al) = 0$.

Case 2: one agent is of type a and one of type e .

It is immediately seen that again efficiency is obtained at equilibrium. This means that $r(ah.eh) = r(ah.el) = r(eh.al) = 1, r(al.el) = 0$. Moreover the payments are as follows: $g(ah.eh, ah) = g(ah.el, ah) = g(eh.el, eh) = c, g(eh.al, al) = g(2al, al) = 0$.

Case 3: both agents are of type e .

As, of course, at equilibrium it is $r(2eh) = 1, r(2el) = 0, g(2eh, eh) = c/2, g(eh.el, eh) = c$, and $g(eh.el, el) = 0$, in order for the incentive compatibility constraint for type eh to be satisfied, it must be

$$(1 - c/2)p + (1 - c)(1 - p)r(eh.el) \geq pr(eh.el) \quad (40)$$

Notice that from $p > 2\frac{1-c}{2-c(1+\theta)}$ (assumption a4'), it follows that: $1 - 2p - c + cp < 0$ and $-\frac{1}{2}(2 - c)\frac{p}{1-2p-c+cp} < 1$. Hence from (40) we get $r(eh.el) \leq -\frac{1}{2}(2 - c)\frac{p}{1-2p-c+cp} < 1$.

Next, let us consider the case in which individual permanent types are private information.

Equilibrium individual payments are easily characterized. When a member is of high benefit and his partner is of low benefit, the former pays all the cost of provision. When both members have high benefit the cost is equally shared, except when one member is altruist and his partner is egoist in which case the former pays the entire cost (this is for incentive purposes, as an altruist is indifferent as to who pays the cost, whereas an egoist is tempted to lie to avoid any payment). As regards the probabilities of provision, suppose that at equilibrium the binding incentive compatibility constraints are $IC(eh, el), IC(eh, al), IC(ah, eh)$ – we will verify this later. Therefore we have the following three equations:

$$\begin{aligned} \theta(p + (1 - p)(1 - c)r(eh.al)) + (1 - \theta)p\left(1 - \frac{1}{2}c\right) + \\ + (1 - \theta)(1 - p)(1 - c)r(eh.el) - \theta pr(ah.el) - (1 - \theta)pr(eh.el) = 0 \end{aligned} \quad (41)$$

$$\begin{aligned} & \theta(p + (1-p)(1-c)r(eh.al)) + (1-\theta)p\left(1 - \frac{1}{2}c\right) + \\ & + (1-\theta)(1-p)(1-c)r(eh.el) - \theta pr(ah.al) - (1-\theta)pr(eh.al) = 0 \end{aligned} \quad (42)$$

$$(1-p)(1-c)((1-\theta)r(ah.el) + \theta r(ah.al)) - (1-p)(1-c)((1-\theta)r(eh.el) + \theta r(eh.al)) = 0 \quad (43)$$

The solution to this system has one degree of freedom. So let us write $r(eh.al)$, $r(ah.el)$, $r(ah.al)$ as a function of $r(eh.el)$. This gives:

$$r(eh.al) = r(ah.el) = \frac{2r(eh.el)(\theta + c - 1 - c\theta + 2p - 2p\theta - pc + pc\theta) - 2p + pc - pc\theta}{2\theta(-2p + 1 - c + pc)} \quad (44)$$

and

$$\begin{aligned} r(ah.al) &= \frac{2p - pc + 3pc\theta - 2pc\theta^2}{2\theta^2(-2p + 1 - c + pc)} + \\ &+ \frac{2r(eh.el)(1 + 4p\theta + 2c\theta + pc - 2\theta - c - 2p - 2pc\theta + \theta^2 - 4\theta p - c\theta^2 - 2p\theta^2 + pc\theta^2)}{2\theta^2(-2p + 1 - c + pc)} \end{aligned} \quad (45)$$

Now let us verify that $IC(eh, ah)$

$$\begin{aligned} & \theta(p + (1-p)(1-c)r(eh.al)) + (1-\theta)p\left(1 - \frac{1}{2}c\right) + (1-\theta)(1-p)(1-c)r(eh.el) \geq \\ & \theta p(1 - c/2) + (1-\theta)p(1-c) + \theta(1-p)(1-c)r(ah.al) + (1-\theta)(1-p)(1-c)r(ah.el) \end{aligned} \quad (46)$$

is not binding. By substituting (44) and (45) into (46), the left side becomes $-\frac{1}{2}p^2 \frac{c\theta - c + 2}{pc - 2p + 1 - c}$ which is greater than the right side (which amounts to $-\frac{1}{2}p \frac{c - 3pc - c^2 + pc^2 + 2p + p\theta c}{pc - 2p + 1 - c}$).

Next we show that $IC(al, el)$ is satisfied as an equality when $IC(eh, el)$ and $IC(eh, al)$ are binding. In fact, from

$$\begin{aligned} & \theta(p + (1-p)(1-c)r(eh.al)) + (1-\theta)p\left(1 - \frac{1}{2}c\right) + (1-\theta)(1-p)(1-c)r(eh.el) + \\ & - \theta pr(ah.el) - (1-\theta)pr(eh.el) = 0 \end{aligned} \quad (47)$$

and

$$\begin{aligned} & \theta(p + (1-p)(1-c)r(eh.al)) + (1-\theta)p\left(1 - \frac{1}{2}c\right) + (1-\theta)(1-p)(1-c)r(eh.el) + \\ & - \theta pr(ah.al) - (1-\theta)pr(eh.al) = 0 \end{aligned} \quad (48)$$

it follows that $\theta r(ah.al) + (1 - \theta) r(eh.al) - (\theta r(ah.el) + (1 - \theta) r(eh.el)) = 0$, which is $IC(al, el)$ written as an equality.

What remains to prove is our hypothesis that constraints (41) to (43) are binding. Let us add three slack variables u_1 , u_2 , and u_3 , required to obtain equality. Then, compute again the system solutions which are now expressed as (cumbersome) functions of $r(eh.el)$ and of all the slacks. Finally, substitute them into the principal objective function and take first derivatives with respect to u_1 , u_2 , u_3 . It results:

$$\frac{\partial S}{\partial u_1} = 2p^2 (1 - p) (1 - c) \frac{1 - \theta}{1 + pc - c - 2p} < 0 \quad (49)$$

$$\frac{\partial S}{\partial u_2} = 2p (1 - p) (1 - c) \theta \frac{(1 - c) (1 - p)}{1 + pc - c - 2p} < 0 \quad (50)$$

$$\frac{\partial S}{\partial u_3} = 2 (1 - p) (1 - c) \frac{p}{1 + pc - c - 2p} < 0 \quad (51)$$

– recall that $1 + pc - c - 2p$ is negative by assumption a4'.

This proves that our hypothesis is true: at equilibrium $IC(eh, el)$, $IC(eh, al)$, $IC(ah, eh)$ are binding.

When the probabilities take the values defined in (44) and (45), it is $\frac{dS}{dr(eh.el)} = 0$, thus $r(eh.el)$ can really be set at discretion.

So let us set it to its equilibrium value in a group where it is common knowledge that there are no altruists, that is $r(eh.el) = p \frac{1 - c/2}{p - (1 - p)(1 - c)}$. Then it is immediately verified that $r(eh.al) = r(ah.el) = \frac{p}{2p - 1 + c - pc} < 1$ for $p < 1$, $r(ah.al) = \frac{1}{2} \frac{-c + c\theta + 2\theta}{\theta} r(ah.el) < 1$ since it is both $r(ah.el) < 1$ and $\frac{-c + c\theta + 2\theta}{\theta} = (2 + c) - c/\theta < 2$.

Therefore, we conclude that expected group surplus is lower when individual permanent types are private information than when they are common knowledge.

Appendix B

This appendix proves that when $N = 1$, $\sigma(0) = \sigma(1) = \sigma(2) = 1$ cannot occur at a Nash equilibrium.

When $\sigma(0) = \sigma(1) = \sigma(2) = 1$, the second-period expected surplus of an egoist if he reports a (and then he optimally declares l) is p^2 , while if he truthfully reports e it is:

$$p \{ \theta (p + (1 - p)(1 - c)) + (1 - \theta) [p(1 - c/2) + (1 - p)(1 - c)\nu] \} \quad (52)$$

where $\nu = r(eh.el)$ is the probability of providing the good when there are two egoists with opposite evaluations in the s_0 -mechanism. Let $\bar{\nu}$ denote the highest value of ν such that lying is preferable for an egoist, so $\bar{\nu}$ solves $p\theta(p + (1-p)(1-c)) + p(1-\theta)[p(1-c/2) + (1-p)(1-c)\bar{\nu}] - p^2 = 0$. Hence this threshold amounts to

$$\bar{\nu} = \frac{1}{2} \frac{2\theta(c-1) - 3\theta pc + pc + 2\theta p}{(1-c)(1-p)(1-\theta)} \quad (53)$$

On the other hand, we know from Appendix A that in the equilibrium of the s_0 -mechanism we have $\nu = \frac{1}{2} p \frac{-2+c}{1-c-2p+pc}$ ¹³.

So, if $\bar{\nu} - \nu > 0$ we know that the intertemporal incentive constraint of a type- e is violated. Let us check this point. We have

$$\bar{\nu} - \nu = -\frac{1}{2} \frac{p^2(2-c)(1+\theta-2\theta c) - 2p(1-c)(1+2\theta-2\theta c) + 2\theta(1-c)^2}{(1-\theta)(1-p)(1-c)(1-c-2p+pc)} \quad (54)$$

The denominator is obviously negative. The numerator is a U-shaped parabola in p . Since the first and the last coefficients are positive while the middle is negative, then if there are two intersections with the p -axis, these are positive. The largest is $\bar{p} = (1-c) \frac{(1+2\theta-2\theta c) + \sqrt{(1-2\theta c+2\theta^2 c)}}{(2-c)(1+\theta-2\theta c)}$. If $p > \bar{p}$ then $\bar{\nu} - \nu > 0$. Now we show that \bar{p} is smaller than the threshold stated by assumption a4', i.e. $\bar{p} \leq \frac{2-2c}{2-c(1+\theta)}$.

$$\begin{aligned} \bar{p} - \frac{2-2c}{2-c(1+\theta)} &= (1-c) \left[\frac{(1+2\theta-2\theta c) + \sqrt{(1-2\theta c+2\theta^2 c)}}{[2-c(1+\theta)] + 2\theta(1-c)^2} - \frac{2}{2-c(1+\theta)} \right] < \\ &= (1-c) \left[\frac{(1+2\theta-2\theta c) + (1-\theta c + \theta^2 c)}{(2-c)(1+\theta-2\theta c)} - \frac{2}{2-c(1+\theta)} \right] = \\ &= - (1-c)\theta c^2 \frac{(1-\theta)^2}{(2-c)(1+\theta-2\theta c)[2-c(1+\theta)]} < 0 \quad (55) \end{aligned}$$

where the first inequality derives from the fact that $\sqrt{(1-2\theta c+2\theta^2 c)} < 1-\theta c + \theta^2 c$.¹⁴

So we can conclude that, in the relevant range of p , we have $\bar{\nu} - \nu > 0$, i.e. the incentive constraint of egoists is always violated.

¹³In the equilibrium of the s_0 -mechanism it is $p(1-c/2) + (1-p)(1-c)\nu = \nu p$, whence: $\nu = \frac{1}{2} p \frac{-2+c}{1-c-2p+pc}$. Notice that the denominator is negative, since $p > 1-c$, as implied by the condition for inefficiency.

¹⁴Notice that $1 > \sqrt{(1-2\theta c+2\theta^2 c)} > (1-2\theta c+2\theta^2 c) > 0$

In fact $1 > 1-2\theta c+2\theta^2 c$ since $\theta < 1$ and $1-2\theta c(1-\theta) > 0$, since $\theta(1-\theta) < 1/2$. We know that for $0 < q < 1$, $\sqrt{q} < (1+q)/2$ (this is implied by $(1-\sqrt{q})^2 > 0$). So $\sqrt{(1-2\theta c+2\theta^2 c)} < \frac{2-2\theta c+2\theta^2 c}{2} = 1-\theta c + \theta^2 c$.

Appendix C

This appendix proves that a symmetric equilibrium exists in the game among first-period principals.

Consider the stabilization outcome when infinitely many groups exist. Let us limit ourselves to symmetric equilibria. First, notice that all first-period principals each share the same utility function, the same strategy space $\{\Psi_1, \sigma\}$, and the same constraint set. As far as the interaction among first-period principals is concerned, their strategy profiles can be summarized by the proportion $\Theta(\bar{\sigma}) = \frac{\theta^2(1-\bar{\sigma}(2))+2\theta(1-\theta)(1/2)(1-\bar{\sigma}(1))}{\theta^2(1-\bar{\sigma}(2))+2\theta(1-\theta)(1-\bar{\sigma}(1))+(1-\theta)^2(1-\bar{\sigma}(0))}$ of altruists in fresh groups. This is because our setting is anonymous and atomless. Then, each first-period principal's best reply function is:

$$\{\Psi_1^*(\Theta(\bar{\sigma})), \sigma^*(\Theta(\bar{\sigma}))\} = \arg \max_{\{\Psi_1, \sigma\} \in G(\Theta(\bar{\sigma}))} \Phi_1(\Psi_1, \sigma, \bar{\sigma}) + \Phi_c(\{\Psi_j^*\}, \bar{\sigma}) \quad (56)$$

where $G(\Theta(\bar{\sigma}))$ denotes the constraint set.

Since the principal faces a linear programming problem that has at least a solution for each Θ — $\sigma(k) = 0$ all k , $r_1(v) = 0$, $g_1(v) \in [0, c]$, all v , is always feasible —, the constraint set is compact (closed, bounded) for each Θ , and the function $\Phi_1(\cdot) + \Phi_c(\cdot)$ is continuous and linear in $(\sigma, \Theta(\bar{\sigma}))$, then, thanks to the maximum theorem, $\sigma^*(\Theta(\bar{\sigma}))$ will be nonempty, convex-valued and upper-hemicontinuous. Hence, there exists a fixed point of σ^* such that $\bar{\sigma} \in \sigma^*(\Theta(\bar{\sigma}))$. This fixed point is a symmetric Nash Equilibrium as all players share the same best reply function.
