# NONSUPERNEUTRALITY OF MONEY IN THE SIDRAUSKI MODEL WITH HETEROGENOUS AGENTS

## Abstract

Superneutrality is demonstrated to no longer hold in the Sidrauski model as soon as agents are heterogenous with regard to their productivity. However, quantitative effects of inflation on the capital stock are found to be rather small.

JEL Code: D31, E50, E52.

Keywords: superneutrality, Sidrauski model, income heterogeneity.

# 1 Introduction

As a well-known result, money is superneutral in the Sidrauski (1967) money-in-the-utility model. If the labor supply is endogenous, money is still superneutral if the utility is separable in utility from consumption and leisure on the one hand and utility from money on the other hand. In the present paper, we extend the analysis of the Sidrauski model and consider heterogenous households rather than one representative household.<sup>1</sup> Heterogeneity is introduced in the form of stochastic idiosyncratic labor productivity. We show that the result of superneutrality of money does not hold any longer in this case.

## 2 The Sidrauski Model with Heterogenous Agents

As the representative-agent Sidrauski model is well-known, we keep the exposition as brief as possible. For an extensive description of the model, the reader is referred to Sidrauski (1967) or Walsh (1998, Ch. 2.3).

### 2.1 Households

The household  $j \in [0, 1]$  lives infinitely and is characterized by her productivity  $\epsilon_t^j$  and her wealth  $a_t^j$  in period  $t$ . Wealth  $a_t^j$  is composed of capital  $k_t^j$  and real money  $m_t^j \equiv \frac{M_t^j}{P_t}$ , where  $M_t^j$  and  $P_t$  denote the nominal money holdings of agent  $j$  and the aggregate price level, respectively. Individual productivity  $\epsilon_t^j$  is assumed to follow a first-order Markov chain with conditional probabilities given by:

$$\Gamma(\epsilon'|\epsilon) = Pr \{ \epsilon_{t+1} = \epsilon' | \epsilon_t = \epsilon \}, \quad (1)$$

where  $\epsilon, \epsilon' \in \mathcal{E} = \{\epsilon_1, \dots, \epsilon_n\}$ .

---

<sup>1</sup>The study of heterogenous-agent economies has received increasing attention in the recent literature. A survey of computable general equilibrium studies that analyze the distribution of income and wealth is provided by Quadrini and Ríos-Rull (1997).

The household faces a budget constraint. She receives income from labor  $l_t^j$ , capital  $k_t^j$ , and lump-sum transfers  $tr_t$  which she either consumes at the amount of  $c_t^j$  or accumulates in the form of capital or money:

$$k_{t+1}^j + (1 + \pi_{t+1})m_{t+1} = (1 + r)k_t^j + m_t + w_t \epsilon_t^j l_t^j + tr_t - c_t^j, \quad (2)$$

where  $\pi_t \equiv \frac{P_t - P_{t-1}}{P_{t-1}}$ ,  $r_t$ , and  $w_t$  denote the inflation rate, the real interest rate, and the wage rate in period  $t$ .

The household  $j$  maximizes life-time utility:

$$W = \sum_{t=0}^{\infty} \beta^t u(c_t^j, m_t^j, 1 - l_t^j) \quad (3)$$

subject to (2). The functional form of instantaneous utility  $u(\cdot)$  is chosen from the following three cases:

$$u(c, m, 1 - l) = \begin{cases} \gamma \ln c + (1 - \gamma) \ln m & \text{case I} \\ \frac{(c^\gamma m^{1-\gamma})^{1-\sigma}}{1-\sigma} & \text{case II} \\ \gamma \ln c + (1 - \gamma) \ln m + \eta_0 \frac{(1-l)^{1-\eta_1}}{1-\eta_1} & \text{case III} \end{cases} \quad (4)$$

In cases I and II, the labor supply is exogenous,  $l = \bar{l}$ . In all three cases, money is superneutral in the representative-agent Sidrauski model.

## 2.2 Production

Firms are of measure one and produce output with effective labor  $N$  and capital  $K$ . Let  $l(k, m, \epsilon)$  and  $\phi_t(k, m, \epsilon)$  denote the labor supply and the period- $t$  measure of the household with wealth  $a = k + m$  and idiosyncratic productivity  $\epsilon$ , respectively. Effective labor  $N_t$  is given by:

$$N_t = \sum_{\epsilon \in \mathcal{E}} \int_k \int_m l(k, m, \epsilon) \cdot \epsilon \cdot \phi_t(k, m, \epsilon) dm dk. \quad (5)$$

Effective labor  $N$  is paid the wage  $w$ . Capital  $K$  is hired at rate  $r$  and depreciates at rate  $\delta$ . Production  $Y$  is characterized by constant returns to scale and assumed to be Cobb-Douglas:

$$Y_t = F(K_t, N_t) = K_t^\alpha N_t^{1-\alpha}. \quad (6)$$

In a factor market equilibrium, factors are rewarded with their marginal product:

$$w_t = (1 - \alpha)K_t^\alpha N_t^{-\alpha}, \quad (7)$$

$$r_t = \alpha K_t^{\alpha-1} N_t^{1-\alpha} - \delta. \quad (8)$$

### 2.3 Monetary Authority

Nominal money grows at the exogenous rate  $\theta_t$ :

$$\frac{M_t - M_{t-1}}{M_{t-1}} = \theta_t. \quad (9)$$

The seignorage is transferred lump-sum to the households:

$$tr_t = \frac{M_t - M_{t-1}}{P_t}. \quad (10)$$

### 2.4 Stationary Equilibrium

We will concentrate on the analysis of a stationary equilibrium with constant money growth  $\theta_t = \theta$  that is characterized by a stationary distribution of wealth and constant aggregate capital stock and effective labor. As a consequence, factor prices and inflation are also constant. A detailed description of the stationary equilibrium is available upon request from the author.

### 2.5 Calibration

In order to compute the quantitative effect of a change in the steady-state money growth rate on real variables, the model has to be calibrated. The model parameters are cho-

sen with respect to the characteristics of the German economy during 1995-96.<sup>2</sup> Periods correspond to years. The number of productivities is set to  $n = 5$  with  $\mathcal{E} = \{0.2327, 0.4476, 0.7851, 1.0544, 1.7129\}$ . The transition matrix is given by:

$$\pi(\epsilon'|\epsilon) = \begin{pmatrix} 0.3500 & 0.6500 & 0.0000 & 0.0000 & 0.0000 \\ 0.0800 & 0.6751 & 0.1702 & 0.0364 & 0.0383 \\ 0.0800 & 0.1651 & 0.5162 & 0.2003 & 0.0384 \\ 0.0800 & 0.0422 & 0.1995 & 0.5224 & 0.1559 \\ 0.0800 & 0.0371 & 0.0345 & 0.1606 & 0.6879 \end{pmatrix} \quad (11)$$

The parameters  $\gamma$ ,  $\eta_0$ , and  $\eta_1$  presented in table 1 are chosen in order to imply i) an average working time  $\bar{l}$  equal to approximately 1/3, ii) a coefficient of variation of workers' labor supply equal to the empirical value of 0.385 in Germany during 1995-96 (in case III), and iii) a velocity of money  $M1$  equal to the average value during 1995-96,  $PY/M = 4.55$ . The remaining parameters are set equal to  $\sigma \in \{1, 2\}$ ,  $\beta = 0.96$ ,  $\alpha = 0.36$ , and  $\delta = 0.04$ . Furthermore, we set the inelastic labor supply  $\bar{l}$  equal to 0.33 in cases I and II.

### 3 Results and Conclusion

Table 1 reports our results for a change of the money growth rate from 0% to 10% in the three cases considered. Notice that in all cases, money is no longer superneutral. For higher inflation, the capital stock increases. The reason is straightforward: Seignorage is transferred lump-sum to the households. The richer households hold higher real money balances than the poorer households and, therefore, pay a higher inflation tax, even though they all receive equal amounts of seignorage. As a consequence, the income of the wealth-rich households declines relative to the one of the poor households. As the former, however, have a lower propensity to save out of income (for precautionary reasons) than the latter, total savings increase. For  $\sigma = 1$ , aggregate capital  $K$  and output  $Y$  rise by 0.45% and 0.16% for a 10 percentage point increase of the inflation rate, respectively. This effect is even more pronounced for a higher curvature of the utility curve (case II with  $\sigma = 2$ ), even though still quantitatively small. In addition, endogenous labor supply, at least if utility

---

<sup>2</sup>If not stated otherwise, the parameters are taken from Heer/Trede (2003).

Table 1: The money growth rate and real variables

$\theta$	case	Calibration	$K$	$M/P$	$Y$	$N$	$\bar{l}$
0%	I	$\{\sigma, \gamma\} = \{1, 0.990\}$	2.902	0.1354	0.6200	0.2603	0.330
10%	I		2.915	0.0357	0.6210	0.2603	0.330
0%	II	$\{\sigma, \gamma\} = \{2, 0.9912\}$	3.245	0.1430	0.6455	0.2603	0.330
10%	II		3.263	0.0336	0.6468	0.2603	0.330
0%	III	$\{\sigma, \gamma, \eta_0, \eta_1\} = \{1, 0.991, 0.57, 2.70\}$	3.786	0.168	0.758	0.307	0.333
10%	III		3.810	0.0400	0.760	0.308	0.334

is additively separable in consumption, leisure, and money, does not have an economically significant effect (see case III).

In summary, money is no longer superneutral in the presence of idiosyncratic productivity heterogeneity. However, quantitative effects are small.

## 4 Appendix

### 4.1 Stationary Equilibrium

The concept of equilibrium applied in this paper uses a recursive representation of the consumer's problem following Stokey et al. (1989). In the following, we concentrate on the study of a stationary equilibrium and drop time subscripts. The household's state variable is denoted by  $x = (k, m, \epsilon) \in \mathcal{X}$ . Let  $V(k, m, \epsilon)$  be the value of the objective function of a household characterized by wealth  $a = k + m$  and productivity  $\epsilon$ .  $V(k, m, \epsilon)$  is defined as the solution to the dynamic program:

$$V(k, m, \epsilon) = \max_{c, l, k', m'} [u(c, m, 1 - l) + \beta E \{V(k', m', \epsilon')\}], \quad (12)$$

subject to the budget constraint (2), the monetary policy  $\theta$  and the transition matrix  $\Gamma(\epsilon'|\epsilon)$ .  $k'$ ,  $m'$ , and  $\epsilon'$  denote next-period capital stock, money, and productivity, respectively.

Let  $(\mathcal{X}, \mathcal{B}, \psi)$  be a probability space where  $\mathcal{B}$  is a suitable  $\sigma$ -algebra on  $\mathcal{X}$  and  $\phi$  a probability measure. We will define a stationary equilibrium for given government monetary policy  $\theta$  and stationary measure  $\phi$ .

#### *Definition*

A stationary equilibrium for a given set of government policy parameters is a value function  $V(k, m, \epsilon)$ , individual policy rules  $c(k, m, \epsilon)$ ,  $l(k, m, \epsilon)$ ,  $k'(k, m, \epsilon)$ , and  $m'(k, m, \epsilon)$  for consumption, labor supply, and next-period capital and real money balances, respectively, a time-invariant distribution  $\phi$  of the state variable  $x = (k, m, \epsilon) \in \mathcal{X}$ , time-invariant relative prices of labor and capital  $\{w, r\}$ , and a vector of aggregates  $K, N$  such that:

1. Factor inputs, aggregate consumption  $C$ , and real money  $M/P$  are obtained aggregating over households:

$$K = \sum_{\epsilon \in \mathcal{E}} \int_k \int_m k \cdot \phi(k, m, \epsilon) dm dk, \quad (13)$$

$$N = \sum_{\epsilon \in \mathcal{E}} \int_k \int_m l(k, m, \epsilon) \cdot \epsilon \cdot \phi(k, m, \epsilon) dm dk, \quad (14)$$

$$C = \sum_{\epsilon \in \mathcal{E}} \int_k \int_m c(k, m, \epsilon) \cdot \phi(k, m, \epsilon) dm dk, \quad (15)$$

$$\frac{M}{P} = \sum_{\epsilon \in \mathcal{E}} \int_k \int_m m \cdot \phi(k, m, \epsilon) dm dk. \quad (16)$$

2.  $c(k, m, \epsilon)$ ,  $l(k, m, \epsilon)$ ,  $k'(k, m, \epsilon)$ , and  $m'(k, m, \epsilon)$  are optimal decision rules and solve the household decision problem described in (12).
3. Factor prices (7) and (8) are equal to the factors' marginal productivities, respectively.
4. The goods market clears:

$$F(K, N) + (1 - \delta)K = C + K' = C + K. \quad (17)$$

5. Seignorage  $tr$  is transferred lump-sum to households.
6. The measure of households is stationary:

$$\phi(B) = \sum_{\epsilon \in \mathcal{E}} \int_k \int_m 1_{(k'(k, m, \epsilon), m'(k, m, \epsilon), \epsilon') \in B} \cdot \Gamma(\epsilon' | \epsilon) \cdot \phi(k, m, \epsilon) dm dk \quad (18)$$

for all  $B \in \mathcal{B}$ .  $1_x$  is an index function that takes the value one if  $x$  is true and zero otherwise.

Since the household's decision problem is a finite-state, discounted dynamic program, an optimal stationary Markov solution to this problem always exists.

## 4.2 Computation

The solution algorithm is described by the following steps:

1. Make initial guesses of the aggregate capital stock  $K$ , aggregate effective labor  $N$ , and aggregate real money  $M/P$ .
2. Compute the values of  $w$  and  $r$  that solve the firm's Euler equations. Compute the transfers  $tr$ .
3. Compute the household's decision functions.

4. Compute the steady-state distribution of the state variable  $\{k, m, \epsilon\}$ .
5. Update  $K$ ,  $N$ , and  $M/P$ , and return to step 1 until convergence.

In step 3, an optimization problem is to be solved. One possible solution method consists in the computation of the individual policy function as functions of the individual state space  $\{\epsilon_t, k_t, m_t\}$ . A much easier way to solve this problem, however, consists in a consideration of a different state space, as has been proposed by Krusell and Smith (1998) and as has also recently been applied by Erosa and Ventura (2002). For this reason, we reformulate the individual optimization problem. Let  $\omega_t = k_t + (1 + \pi)m_t$  denote current wealth. The optimization problem of the household can be separated into two individual optimization problems: i) the choice of next-period wealth  $\omega_{t+1}$  and ii) the portfolio allocation problem, i.e. the allocation of  $\omega_t$  on  $k_t$  and  $m_t$ , respectively.

Accordingly, the dynamic program problem (12) can also be stated in the individual state space  $\{\omega_t, \epsilon_t, \epsilon_{t-1}\}$ :

$$V(\omega_t, \epsilon_t, \epsilon_{t-1}) = \max_{c_t, \omega_{t+1}} [u(c_t, m_t, 1 - l_t) + \beta E_t \{V(\omega_{t+1}, \epsilon_{t+1}, \epsilon_t)\}], \quad (19)$$

subject to the budget constraint:

$$(1 + r)k_t + m_t + w_t \epsilon_t l_t = c_t + \omega_{t+1}. \quad (20)$$

The capital stock  $k_t$  and the real money balances  $m_t$  are functions of  $\omega_t$  and  $\epsilon_{t-1}$  ( $\epsilon_t$  is not known when the households decides upon  $k_t$  and  $m_t$  in period  $t - 1$ ). The solution is a function  $\omega_{t+1} = g_\omega(\omega_t, \epsilon_t, \epsilon_{t-1})$ .

The optimal portfolio of capital  $k_t = g_k(\omega_t, \epsilon_{t-1})$  and money  $m_t = g_m(\omega_t, \epsilon_{t-1})$  is obtained from the following problem:

$$(g_k(\omega_t, \epsilon_{t-1}), g_m(\omega_t, \epsilon_{t-1})) = \operatorname{argmax}_{k, m} \beta E_{t-1} u(c_t, m_t, 1 - l_t), \quad (21)$$

subject to  $\omega_t = k_t + (1 + \pi)m_t$  and  $\omega_{t+1} = g_\omega(\omega_t, \epsilon_t, \epsilon_{t-1})$ .

In our algorithm, we started with an initial guess for  $\omega_{t+1} = g_\omega(\omega_t, \epsilon_t, \epsilon_{t-1})$ . We then computed the portfolio allocation. In particular, for given  $\epsilon_{t-1}$  and  $\omega_t$ , the optimal capital stock  $k_t$  solves the Euler equation:

$$E_{t-1} \{(1+r)u_c(c_t, m_t, 1-l_t)\} = E_{t-1} \left\{ \frac{u_c(c_t, m_t, 1-l_t) + u_m(c_t, m_t, 1-l_t)}{1+\pi} \right\}, \quad (22)$$

subject to  $m_t = (\omega_t - k_t)/(1+\pi)$  and the first-order condition of the household with respect to leisure in period  $t$ :

$$u_l(c_t, m_t, 1-l_t) = u_c(c_t, m_t, 1-l_t)w\epsilon_t. \quad (23)$$

The optimal  $k_t$  was computed with a nonlinear-equations solver.

Given the optimal portfolio allocation functions  $g_k$  and  $g_m$  as well as the labor supply  $l(\omega_t, \epsilon_t)$ , we solved the intertemporal optimization problem of the household. In particular, for every  $\{\omega_t, \epsilon_t, \epsilon_{t-1}\}$ , we solved:

$$u_c(c_t, m_t, 1-l_t) = \beta E_t \{(1+r)u_c(c_{t+1}, m_{t+1}, 1-l_{t+1})\}, \quad (24)$$

subject to  $k_t = g_k(\omega_t, \epsilon_{t-1})$ ,  $k_{t+1} = g_k(\omega_{t+1}, \epsilon_t)$ ,  $m_t = g_m(\omega_t, \epsilon_{t-1})$ , and  $m_{t+1} = g_m(\omega_{t+1}, \epsilon_t)$ . The solution is given by  $\omega_{t+1} = g_\omega(\omega_t, \epsilon_t, \epsilon_{t-1})$ . We then updated  $g_\omega$  and continued to compute  $g_\omega$ ,  $g_k$ , and  $g_m$  until they converged.

Finally, in step 4, the stationary distribution is computed as described in Huggett (1993).

### 4.3 Accuracy of the Computation

The basic criterion applied in the CGE literature in order to check for accuracy of the computation is the violation of the Euler equations:<sup>3</sup>

---

<sup>3</sup>See, e.g., Judd (1998) or Heer/Maussner (2004).

$$R_1(k, m, \epsilon) = 1 - \frac{u_c(c_t, m_t, 1 - l_t)w\epsilon}{u_{1-l}(c_t, m_t, 1 - l_t)}, \quad (25)$$

$$R_2(k, m, \epsilon) = 1 - \beta E_t \left\{ \frac{u_c(c_{t+1}, m_{t+1}, 1 - l_{t+1})(1 + r)}{u_c(c_t, m_t, 1 - l_t)} \right\}, \quad (26)$$

$$R_3(k, m, \epsilon) = 1 - \frac{\beta}{u_c(c_t, m_t, 1 - l_t)} E_t \left\{ \frac{u_c(c_{t+1}, m_{t+1}, 1 - l_{t+1}) + u_m(c_{t+1}, m_{t+1}, 1 - l_{t+1})}{(1 + \pi)} \right\} \quad (27)$$

As our algorithm, however, is designed to solve these equations, the accuracy, of course, depends on the accuracy of our non-linear equations solver, which is equal to  $10^{-8}$ .

#### 4.4 Accuracy of the Calibration

In case I-III, the velocity of money  $PY/M$  is equal to 4.58, 4.51, and 4.51, respectively. In case III, the variational coefficient of labor supply amounts to 0.381.
