## Employment Adjustment in German ${\rm Firms}^*$

### Sven Jung<sup>a</sup>

Abstract: Using a representative establishment data set for Germany, we show that, in line with the existing literature for several countries, firms' adjustment costs for employment are characterized by a fixed and convex functional form. Furthermore, they are asymmetric with dismissal costs exceeding hiring costs. An analysis of firms' adjustment in the period 1996–2010 also indicates that adjustment behavior has changed over time. Comparing the employment adjustment in the two observed business cycles comprising the years 1996–2003 and 2004–2010, we find that the adjustment speed was higher in the second business cycle indicating that adjustment costs have fallen in recent years.

Zusammenfassung: Anhand von repräsentativen Daten des IAB-Betriebspanels wird gezeigt, dass die Kosten der betrieblichen Beschäftigungsanpassung in Deutschland eine funktionale Form mit fixer und konvexer Komponente aufweisen, wie es auch frühere Studien für andere Länder feststellen. Des Weiteren ist die Struktur der Anpassungskosten asymmetrisch, wobei die Entlassungskosten größer als die Einstellungskosten sind. Bei der Analyse des betrieblichen Anpassungsverhalten für den Zeitraum 1996–2010 wird zudem deutlich, dass sich das Verhalten über die Zeit geändert hat. Ein Vergleich der betrieblichen Beschäftigungsanpassung in den zwei beobachteten Konjunkturzyklen 1996–2003 und 2004–2010 zeigt eine schnellere Anpassung im zweiten Konjunkturzyklus, was auf gesunkene Anpassungskosten hinweist.

Keywords: adjustment costs, dynamic labor demand, employment adjustment, Germany

New JEL-Classifications: C24, D22, E24, J23

### 1 Introduction

Following the 2008/2009 economic crisis, the adjustment of firms' labor volume has again moved into the focus of economic analysis. Across countries, firms have shown different reactions to this crisis, but also within countries firms' behavior has differed from previous reactions. For example, German firms predominantly adjusted working hours, while less adjustment of the number of employees was visible (see Burda and Hunt, 2011). This points to a fundamental change in firms' adjustment processes. Several studies for Germany indicate that firms' employment adjustment has indeed changed over time (see, e.g., Gartner and Klinger, 2010; Herzog-Stein and Seifert, 2010). However, these studies are mostly based on descriptive analyses of aggregated data. In contrast, the present study provides a more detailed econometric analysis based on data at the establishment level. Using a representative panel data set on German establishments, we estimate a dynamic labor demand model for the period 1996 to 2010. This allows us to compare employment adjustment in the two business cycles occurring between 1996 and 2010 and to investigate econometrically whether firms' adjustment behavior has changed over time. Moreover, we analyze labor demand separately for Western and Eastern Germany, thus extending the sparse empirical evidence on dynamic labor demand in Eastern Germany.

We also provide new insights concerning the functional form of firms' adjustment costs. Adjustment costs are an important component of dynamic labor demand theory. Firms' adjustment behavior depends on the functional form of the adjustment costs they face. Although empirical evidence so far indicates a fixed and convex specification (see Vermeulen, 2006, p. 11), this has not been established for Germany yet. In the only studies for (Western) Germany which contain an intensive analysis of the functional form, Kölling (1998) prefers a convex and Yaman (2011) a linear functional form of adjustment costs, making the empirical evidence for Germany ambiguous. We will use a different switching regression approach than Kölling (1998) and will show that for Germany in addition to the convex specification a fixed component of adjustment costs is also relevant. Thus, we establish the assumption of fixed and convex adjustment costs also for Germany. Furthermore, the existing studies do not contain separate results for Western and Eastern Germany, which we provide.

The paper proceeds as follows: Section 2 sketches the main aspects of adjustment costs and presents the relevant empirical evidence on the functional form of adjustment costs. Section 3 provides a description of our data. Section 4 shows the empirical model, while Section 5 presents and discusses the results of a basic dynamic labor demand model. We investigate the change of firms' adjustment behavior over time in Section 6, and Section 7 concludes.

# 2 Adjustment Costs: Theoretical Considerations and Empirical Evidence

The underlying theory for our analysis is the dynamic labor demand theory. While the static labor demand theory focuses on firms' optimal employment level, the dynamic counterpart analyzes firms' adjustment toward the optimum and the time it takes to reach the optimal employment level which is not possible within the static theory (see Cahuc and Zylberberg, 2004, p. 212). Adjustment costs are an essential component of dynamic labor demand theory because they play an important role in firms' adjustment behavior. These costs are the reason that a plant does not dismiss all employees before the weekend and re-hire them on Monday (see Franz, 2009, p. 142; Nickell, 1986, p. 473). Labor is not a completely variable production factor because adjustment costs form a fixed component of total labor costs. Therefore Oi (1962) calls labor a 'quasi-fix' factor. Adjustment costs arise from an employment change and consist of hiring costs (e.g., search, selection, first training, administrative expenses of the Human Resources Department) and costs of dismissals (e.g., severance pay, consideration of dismissal protection, administrative expenses of the Human Resources Department). Ehrenberg and Smith (2012, p. 145) consider hiring costs as investments and so they point out the 'sunk' character of these costs.

Several criteria can be used for distinguishing adjustment costs (see, e.g., Hamermesh, 1993, p. 207; Kölling, 1998, p. 8; Nickell, 1986, p. 475). With regard to the place where the costs incur, one can differentiate between internal and external adjustment costs . If costs incur within the firm (e.g., costs for first training), they are internal. Expenses for job advertisements or external recruiting companies, which accrue outside the firm, are external. The internal costs can further be divided into an explicit and an implicit category. Explicit costs are expenses that are unambiguously quantifiable in monetary terms (e.g., expenses for job advertisements, severance pay) whereas the other expenses are implicit costs (e.g., temporary losses of productivity in the first days of the new employee at work).<sup>1</sup> Furthermore, one can distinguish between a gross and a net perspective in the analysis of adjustment costs. Net adjustment costs incur if the number of employees changes. In contrast, each hiring and dismissal decision affects gross adjustment costs, even if the employment level does not change. In this study, we use a net approach due to the underlying empirical model (see Section 4). Furthermore, as labor is assumed to be homogenous, there

<sup>&</sup>lt;sup>1</sup> Although there are some studies which quantify adjustment costs, measurement is not easy. Existing studies arrive at very different results that can be explained by different concepts and categories for the adjustment costs (see Freyens, 2010, p. 291; Hamermesh, 1993, p. 208). In particular, lack of a clear definition makes it very difficult to accurately measure adjustment costs.

should be no difference between gross and net perspectives, as it would make no sense that a firm dismisses and hires the same type of labor (see Yaman, 2011, p. 5).

The basic theory of dynamic labor demand assumes labor to be a homogeneous production factor, which is a restrictive assumption in the context of adjustment costs (see Kölling, 1998, p. 61). Different kinds of jobs and different qualification levels of employees can lead to different sizes of adjustment cost meaning that the firm would not adjust separate groups of employees in the same manner. Yet, following earlier studies, we assume labor to be homogeneous for the sake of analytical simplicity. Nevertheless, this allows us to draw some interesting conclusions about the adjustment procedures of labor demand (see Kölling, 1998, p. 61).

Another simplifying assumption concerns the two dimensions of labor demand. Firms can adjust their total labor volume by changing the number of employees and by changing working hours. Adjustment of working time gives more flexibility compared to an adjustment of just the number of employees. It can be done faster (see Sargent, 1978, p. 1015) and cheaper (see Shapiro, 1986, p. 516) than the adjustment of the number of employees. Therefore, in periods when the adjustment of the number of employees is no longer optimal, a firm can still get closer to the optimal labor volume by changing the number of hours worked (see, e.g., Nickell, 1978, p. 332–335; Santamäki, 1988, p. 101–102). Yet, the consideration of both dimensions leads to complex adjustment models. In order to simplify the model, working hours are ignored in the following analysis. The data set used (see Section 3), which does not provide clear information about working hours, is another reason for disregarding the working time. However, basic conclusions about adjustment procedures of labor demand are still possible (see Hamermesh, 1993, p. 209).

Furthermore, adjustment costs differ in functional form. One can classify fixed, linear, and convex adjustment costs. Fixed adjustment costs incur from firms' decision to adjust employment independently of the amount of employment adjustment.<sup>2</sup> An example is a job advertisement for two or four employees, which costs the same in both cases (see Hamermesh, 1989, p. 675; Kölling, 1998, p. 44). If the firm faces a new optimal employment level due to a shock or a changing economic situation, it must make a decision about an adjustment to the new optimum. Fixed adjustment costs and their relative magnitude to the profits resulting from an employment level closer to the optimal one are essential for this decision. If profits exceed costs, the firm will adjust employment. Because of the fixed specification, firms' adjustment is then done instantly and completely towards the new optimal

 $<sup>2^{2}</sup>$  For details about fix adjustment costs we refer to Hamermesh (1989; 1990).

employment level (see Hamermesh, 1993, p. 214).<sup>3</sup>

Linear adjustment costs, which increase proportionally in the amount of adjustment, result in a different adjustment behavior. Again, firms adjust instantly while taking into account the costs-profits relation. But with a linear structure, the employment level is not adjusted completely towards the optimal level (see, e.g., Kölling, 1998, p. 30; Nickell, 1986, p. 491). Instead, firms keep employment constant near the optimum because of costs exceeding profits (see, e.g., Anderson, 1993, p. 1018; Kölling, 1998, p. 30; Nickell, 1978, p. 332; Nickell, 1986, p. 495). Examples for a linear cost structure, such as hiring from an agency (see Nickell, 1986, p. 477) or severance pay, show that linear adjustment costs are not unrealistic.

Convex adjustment costs, mostly used in a quadratic specification, are the third functional form. This specification was the one first used in the literature and goes back to Holt et al. (1960). Convex costs increase disproportionately with the amount of adjustment. Although a convex specification might be suitable for a specific part of adjustment (see Nickell, 1986, p. 477), it should not be considered as the only existing functional form (see, e.g., Bentolila and Bertola, 1990, p. 382; Hamermesh, 1989, p. 475; Nickell, 1986, p. 477; Rothschild, 1971, p. 605). A convex cost structure is a very restrictive assumption and difficult to justify. The reason for the common use of convex adjustment costs in the literature was the simple analytical handling in the models (see, e.g., Kölling, 1998, p. 9; Pfann and Verspagen, 1989, p. 365). But already Holt et al. (1960, p. 52) mentioned that the quadratic form is just a "...suitable first approximation." Adjustment costs can have different forms in reality (see Nickell, 1986, p. 519). Assuming convex adjustment costs rather than fixed or linear costs, firms spread adjustment of employment over several periods (see, e.g., Cahuc and Zylberberg, 2004, p. 218; Hamermesh, 1993, p. 211; Nickell, 1986, p. 483). Because of the convexity, marginal costs increase with the amount of employment adjustment. Therefore, it is optimal to spread the adjustment over several periods. Furthermore, the optimal employment level will not be reached in finite time (see, e.g., Kölling, 1998, p. 21; Nickell, 1986, p. 483), although there is long-run convergence to the optimum (see Kölling, 1998, p. 60).

Considering the functional form also raises the question whether adjustment costs are symmetric or asymmetric, thus whether hiring costs and firing costs are equal. A symmetric cost structure simplifies the econometric model but there is no reason to expect an upward employment adjustment to generate the same costs as a downward employment adjustment (see Schiantarelli and Sembenelli, 1993, p. 149). Therefore, asymmetric adjustment costs are a much less restrictive assumption. The costs of hiring and firing result from different sources so that asymmetry is a reasonable

<sup>&</sup>lt;sup>3</sup> The result of fixed adjustment costs are periods with adjustment and periods with no adjustment. Therefore Hamermesh (1990, p. 96) calls this behavior 'bang-bang adjustment'.

assumption.

In case of a fixed specification, increasing adjustment costs lead to a longer period with no adjustment and a greater amount of employment change if an adjustment is optimal (see Gorter et al., 2003, p. 100). Assuming a linear structure instead, higher adjustment costs also cause a longer period of inaction. Furthermore, the difference between the optimal employment level and the actual level when the firm stops adjustment is larger (see, e.g., Anderson, 1993, p. 1018; Nickell, 1978, p. 337; Nickell, 1986, p. 495). Finally, the result of higher convex adjustment costs is a slower adjustment which is spread over many more periods (see, e.g., Cahuc and Zylberberg, 2004, p. 218; Sargent, 1978, p. 1018).

There is a large body of empirical evidence on the significant role of firms' adjustment costs (see, e.g., Burgess, 1988; Dolfin, 2006, p. 870; Gavosto and Sestito, 1993, p. 447; Nissim, 1984, p. 433; Oi, 1962; Rosen, 1968, p. 337; Rota, 2004, p. 43) showing that these costs actually have an effect on adjustment behavior. In contrast, Hall (2004) as well as Pindyck and Rotemberg (1983*a*; 1983*b*) find that adjustment costs are just marginal. Regarding the functional form, the studies by Holt et al. (1960) and Nickell (1984, p. 546) show that a convex structure is appropriate.<sup>4</sup> However, their evidence it not entirely persuasive as they assume pure convexity in their empirical models and make no comparison with other functional forms in these analyses. In addition, given the not convincing theoretical justification it is not surprising that there are many empirical objections to pure convex costs.

Hamermesh (1989, p. 687) presents first evidence against a pure convex structure. He shows that a fixed cost specification suits the data better than convex adjustment costs. The results of Anderson (1993), Caballero et al. (1997), Cooper and Willis (2009), Gavosto and Sestito (1993), Holtz-Eakin and Rosen (1991), Rota (2004), and Varejão and Portugal (2007) are also inconsistent with the assumption of pure convex adjustment costs. Instead, they find that firms' adjustment behavior is better represented by an assumption of a combination of various functional forms, for example, a fixed and convex specification (see, e.g., Abowd and Kramarz, 2003; Cooper et al., 2004; Hamermesh, 1992; Kramarz and Michaud, 2010; Lapatinas, 2009; Nilsen et al., 2007; Pfann and Verspagen, 1989).<sup>5</sup> For Germany, however, the studies by Kölling (1998) and Yaman (2011), which are the only two analyses investigating intensively the functional form of the adjustment costs we are aware of, find that a model with combined fixed and convex adjustment costs components provides no further insights compared with a pure convex specification (see Kölling, 1998, p. 153) or respectively that a model with linear adjustment costs

<sup>&</sup>lt;sup>4</sup> Nickell (1984, p. 546) finds that the adjustment has a lag, which is just the case in the presence of convex adjustment costs.

<sup>&</sup>lt;sup>5</sup> Vermeulen (2006, p. 11) confirms the dominance of a combination structure for adjustment costs in the existing literature.

fits better the data (see Yaman, 2011, p. 25). Therefore, the predominance of the combination structure for adjustment cost has not been shown to extend to Germany yet.

Regarding the symmetry or rather asymmetry of adjustment costs the empirical evidence clearly favors asymmetry. However, there is no clarity concerning the relation of hiring costs to dismissal costs (see Hunt, 2000, p. 181). Based on data from the production sector in Italy, Jaramillo et al. (1993) find higher dismissal costs compared to hiring costs. This relation also has been confirmed for Germany (see Burda, 1991, p. 73; Kölling, 1998, p. 151), for France (see Abowd and Kramarz, 2003; Goux et al., 2001; Kramarz and Michaud, 2010) as well as for Norway (see Nilsen et al., 2007, p. 597). In addition, based upon British and Dutch data, Pfann and Palm (1993) show higher dismissal costs for non-production workers, whereas they find higher hiring costs is described in Pfann and Verspagen (1989) for the Netherlands and in Chang and Stefanou (1988), Hamermesh (1993, p. 208) as well as in Hamermesh and Pfann (1996) for the US.

Our study investigates firms' adjustment behavior of labor in Germany. We assume a combined cost structure and asymmetry with dismissal costs exceeding hiring costs that we will test in the following analysis. Our hypothesis regarding the relation of hiring and dismissal costs is based on the labor market institutions in Germany. Germany, like other countries in continental Europe, has a more regulated labor market with higher dismissal protection than, for instance, the US (see, e.g., Abraham and Houseman, 1994, p. 59; Burda, 1991, p. 62; Emerson, 1988, p. 776). This in turn leads to less flexibility for firms and results in higher adjustment costs, especially higher dismissal costs in Europe compared to the US (see, e.g., Hunt, 2000, p. 177; Merkl and Wesselbaum, 2011, p. 805).

### **3** Data and Descriptive Evidence

The data used for the analysis come from the IAB Establishment Panel, which is a representative annual survey of German establishments.<sup>6</sup> The interviewed establishments are drawn from a stratified sample of plants, which are included in the German employment statistics. The strata are defined over plant sizes and industries; however, sampling within each cell is random. The panel oversamples large establishments, but weighting for representative results is possible. The panel started in 1993 with Western German plants and was extended to Eastern German plants in 1996. Nowadays, almost 16,000 establishments are interviewed

 $<sup>\</sup>overline{}^{6}$  For a detailed description of this data set see Bellmann et al. (2002), Fischer et al. (2009), and Kölling (2000).

each year. Information about, for example, plant characteristics, wages, profitability, management policy and especially about the workforce composition and its development over time is provided by the panel with the reference date June 30th.

We use the waves 1996 until 2010. Although the IAB Establishment Panel contains information about the agreed weekly working time and overtime, this information is not available for all years. An exact calculation of working hours based on the numbers of employees in full-time and part-time jobs is also not viable. Therefore, our empirical investigation can only analyze the adjustment of the number of employees and has to neglect the working time dimension. In particular, we consider the number of employees covered by social security.<sup>7</sup> The group of employees covered by social security is more homogenous regarding adjustment costs than the group of all employees. Therefore, the analysis of firms' adjustment behavior (e.g., adjustment speed) should be more accurate. Furthermore, we only analyze the private sector because of differences in the adjustment behavior between the public and private sector (shown descriptively by Ellguth and Kohaut (2011*a*)). Another reason for this decision is the derivation of the empirical model, which is based on the assumption of profit maximization (see Section 4) that does not hold for the public sector.

Furthermore, we only consider firms' adjustment of the core workforce. In the last years, the use of temporary agency workers has increased, especially after the reform of the Temporary Employment Agencies Act (*Arbeitnehmerüberlassungsgesetz*) in 2003 (see, e.g., Antoni and Jahn, 2009; Spermann, 2011, pp. 5–11). The temporary agency workers can serve as an alternative instrument for employment adjustment. Therefore, one could also consider them in an analysis of firms' adjustment behavior. However, we ignore temporary workers for two reasons. First, the IAB Establishment Panel does not contain the number of temporary agency worker in all years of the sample. Second, we are interested in the adjustment of the core workforce that does not include temporary agency workers. As mentioned before, there are higher regulations in the German labor market than in the U.S. labor market. Dismissal protection plays an important role in Germany. Analyzing the core workforce, we focus on firms' adjustment behavior with regard to employees affected by labor market regulations (e.g., dismissal protection).

Figure 1 illustrates the average number of employees covered by social security per plant from 1996 until 2010. The fluctuation over time expresses changing employment levels and thus the employment adjustment of the plants. Furthermore, it shows the phases of the business cycle (except for the first years). The average

 <sup>&</sup>lt;sup>7</sup> Bellmann and Pahnke (2006) also use the number of employees covered by social security only.
 Nevertheless as a robustness check (not reported in the paper) we also carry out the analysis with all employees, which does not change our insights.

Figure 1: Average number of employees per plant
 Notes: Weighted data, private sector only

number of employees per plant is lower during the economic downturn 2002/2003 and increases again in the economic upturn after 2004. Figure 2 provides more detailed information on adjustment behavior. Every year plants increase, decrease or do not change employment, regardless of the business cycle phase.<sup>8</sup> However, there is no clear pattern. Although a bigger share of plants reduced employment in the economic downturn 2002/2003, some plants also increased employment during that time. Another striking result is that more than 50 percent of the plants do not change their employment level over the year. This is a first evidence in favor of non-convex adjustment costs: no employment adjustment is only optimal for a plant in the presence of fixed or linear adjustment costs.<sup>9</sup> Figures 3 and 4 show a slight difference between Western and Eastern Germany. In nearly every year, the share of plants that do not adjust employment is bigger in Western Germany compared with Eastern Germany. Because of this difference and the existing general differences between the labor markets in Western and Eastern Germany we will conduct the econometric analysis separately for the two German regions.

Table 1, which illustrates the varying adjustment decision of the plants from one year to another, further underlines the relevance of non-convexity. With convex adjustment costs plants should optimally spread employment adjustment over several time periods so that adjustment takes place in every period. But Table 1 indicates that many plants which adjust (increase or decrease) employment in one year do not further adjust it in the following year.<sup>10</sup> Of course, we need econometric analysis to identify the functional form of adjustment costs more clearly.

### 4 Econometric Model

As no direct data on firms' adjustment costs is available for Germany, the analysis of the firms' adjustment costs structure is based on a theoretical model of dynamic labor demand. We will compare a pure convex specification for adjustment costs

<sup>&</sup>lt;sup>8</sup> Increase or decrease of the employment means a change of the number of employees covered by social security from the previous to the present year.

<sup>&</sup>lt;sup>9</sup> This evidence may be not completely convincing. One could think that no employment adjustment can also be optimal in the presence of convex adjustment costs if the optimum does not change. However, the optimum will not be reached in finite time. Furthermore, it is plausible that the optimal employment level changes at least within two years. Therefore, no employment adjustment two years in a row should not be observed in the presence of pure convex adjustment costs. Yet, Table 1 shows the opposite.

<sup>&</sup>lt;sup>10</sup> One could argue that results coming from annual data do not show permanent adjustment and thus cannot serve as evidence for pure convex costs because employment adjustment towards the optimum is already achieved within a year. However, the economic environment and thus the optimal employment level changes at least annually. Therefore, a plant might switch from increasing employment to decreasing, but should not stop adjustment.

with a combination of a fixed and a convex structure.<sup>11</sup> First we derive the empirical model with convex adjustment costs which we will then compare to the empirical model with fixed and convex adjustment costs. For the model with pure convex costs, we follow the work of Kölling (1998, pp. 10–22), Nickell (1986), as well as Sargent (1978; 2010) and assume labor  $L_t$ , which is the only existing production factor, to be homogeneous.

The starting point of the model is the following profit equation:<sup>12</sup>

$$\Pi = \sum_{t=0}^{\infty} \rho^t (a_1 L_t - \frac{1}{2} a_2 L_t^2 - L_t w_t - \frac{c}{2} (L_t - L_{t-1})^2) .$$
(1)

II is the present value of future differences between revenues (with output following from a quadratic production function with the positive and constant parameters  $a_1$  und  $a_2$  and prices normalized to unity) and the sum of labor costs and convex adjustment costs (with a constant parameter c).<sup>13</sup>  $\rho$  (0 <  $\rho$  < 1) denotes the firm's discount factor. Assuming rational expectations<sup>14</sup> profit maximization leads to the following law of motion for the firm's employment:

$$L_t = \gamma_1 L_{t-1} + \gamma_2 L_t^* + \nu_t .$$
 (2)

According to equation (2) the number of employees in period t is a function of the optimal employment level  $L^*$  in period t and the employment level in the previous period  $L_{t-1}$ .  $\gamma_1$  represents a measure of the adjustment speed as  $\gamma_1$  indicates how strongly  $L_t$  depends on  $L_{t-1}$  and thus how sluggishly  $L_t$  is adjusted towards  $L_t^*$  (see Kölling, 1998, p. 21). Low adjustment costs cause a high adjustment speed and result in a low value for  $\gamma_1$ . Finally,  $\nu_t$  is the residual term when estimating equation (2).

Following the traditional approach in the literature, equation (2) will be

<sup>&</sup>lt;sup>11</sup> A separate analysis of a linear form is not required because its effect on adjustment behavior is nested in the fixed and convex form (see Gavosto and Sestito, 1993, p. 437).

<sup>&</sup>lt;sup>12</sup> For the profit equation some restrictive assumptions are made regarding the production function: the production function is quadratic and uses homogeneous labor as the only input factor in the short-run. While a wide range of production functions have been used in the literature, a quadratic production function was used, e.g., by Bentolila and Saint-Paul (1994), Hamermesh (1995), Kölling (1998), Sargent (1978). Note that the exact specification of the production function does not play a role for general statements about firms' adjustment behavior (see Kölling, 1998, pp. 11–12). Furthermore, the fact that capital is not considered (see Hamermesh, 1995, p. 624) and that labor is homogeneous (see Kölling, 1998, p. 61) does not bias the results regarding firms' adjustment behavior.

<sup>&</sup>lt;sup>13</sup> The factor  $\frac{1}{2}$  in the formulas for production and adjustment costs simplifies optimization.

<sup>&</sup>lt;sup>14</sup> Equation (1) is maximized for the derivation of equation (2). The result of this profit maximization is an Euler equation, which contains expectations about future labor demand (not shown in this paper). In this context rational expectations are assumed, which is a suitable and often used assumption (see Kölling, 1998, p. 148; Bresson et al., 1992, p. 361).

expressed with employment levels in logarithmic form.<sup>15</sup>

$$l_t = \lambda_1 l_{t-1} + \lambda_2 l_t^* + \nu_t , \qquad (3)$$

where lower-case letters represents logarithms. Yet, we still cannot estimate equation (3) in its current form since the data does not contain information about the optimal employment level. To solve this problem, we follow Kölling (1998, p. 132). Assuming a Cobb-Douglas production function and using the implication that in the long-run optimum the real wage equals the marginal product of labor (see Breitung, 1992, p. 144) one can show that the logarithm of the optimal employment level depends on the logarithm of the output and the logarithm of the real wage rate. After another transformation, which is obligatory because the IAB Establishment Panel does not contain information about output and real wage rate,  $l_t^*$  can be expressed as a linear function of the logarithm of the turnover and the logarithm of the nominal wage bill per employee (see Breitung, 1992, p. 170).<sup>16</sup> In addition, further controls are included in the empirical model which is given by:

$$l_t = \alpha_1 l_{t-1} + \beta_1 \log. \text{turnover} + \beta_2 \log. \text{wage} + \beta \boldsymbol{x}_t + \nu_t .$$
(4)

The vector of controls  $\boldsymbol{x}_t$ , which are assumed to be strictly exogenous, includes several variables for employment structure like: the share of female employees in the workforce, the share of qualified employees, the share of part-time employees, the share of fixed-term employees and the share of employees covered by social security in the regression (see Bellmann and Pahnke, 2006, p. 207; Kölling, 1998, p. 134). Additionally, we consider a dummy variable whether the managers regarded the profit situation in the previous year as very good or good, a dummy reflecting modern production technology, a dummy reflecting the existence of a works council (lagged by one year to avoid endogeneity problems), a dummy reflecting the existence of a collective agreement (lagged by one year to avoid endogeneity problems), two dummies indicating whether the managers expect an increasing or decreasing turnover and a set of dummy variables for the industry and the year.

Regarding the share of female employees, two effects in the labor demand equation are possible. On the one hand, women in stereotyped occupations (e.g., secretary) are overrepresented in small plants, which would lead to a negative coefficient. On the other hand, women are rather concentrated in the production of

<sup>&</sup>lt;sup>15</sup> Clearly, equation (3) does not follow directly from equation (2). We use the logarithmic expression in the tradition of the previous studies, e.g., Arellano and Bond (1991), Bellmann and Pahnke (2006), Bohachova et al. (2011), Breitung (1992; 1994), Buch and Lipponer (2010), Cooper and Willis (2009), FitzRoy and Funke (1998), Funke et al. (1998), Kölling (1998), Lapatinas (2009) and Rottmann and Ruschinski (1998).

<sup>&</sup>lt;sup>16</sup> For details about the algebraic transformation we refer to Kölling (1998, pp. 132–134).

bulk commodities or in simple services which are carried out in bigger plants. This in turn implies a positive coefficient. There are also ambiguous expectations regarding the sign of the share of qualified employees. As they are more productive than other employees, the plant is able to produce the same output with less workers (negative coefficient). However, the higher productivity can result in higher economic success and so in more labor demand (positive coefficient). The sign of the share of part-time employees is expected to be positive, as a plant needs more employees to produce same output. The share of fixed-term employees should also has a positive effect because for fixed-term employees adjustment costs are lower, especially dismissal costs (see Goux et al., 2001, p. 548; Varejão and Portugal, 2007, p. 159). Thus, labor demand can be higher without adjustment costs increasing too much. Both signs are possible for the share of employees covered by social security. On the one hand, these employees show higher adjustment costs compared to marginal employees. If adjustment is mainly achieved by changing the number of employees covered by social security, a higher labor demand increases costs in case of adjustment (negative coefficient). On the other hand, the employees covered by social security could have higher productivity compared to other employees and so the same effects occur as with qualified employees (positive/negative coefficient).

The dummy variable whether the managers regarded the profit situation in the previous year as very good or good is expected to have a positive sign, as plants in a good economic situation are likely to show a higher labor demand (see Bellmann and Kölling, 1997, p. 98). The same should hold for the dummy variable reflecting modern production technology. Modern technology leads to higher productivity and thus to more labor demand. But it is ambiguous as with modern, more productive technology a plant is able to produce the same output with less workers (negative coefficient). No clear effect can also be predicted for the dummy variable reflecting the existence of a works council. Following the exit-voice-approach, a works council results in a better economic situation for the plant with less fluctuation and, hence, less adjustment (see, e.g., Freeman and Medoff, 1984; Hirsch et al., 2010; Jirjahn, 2010). Thus, more labor demand and a positive coefficient can be expected. However, the works council with its codetermination rights (e.g., in case of dismissal or social plans) and rentseeking activities may increases labor costs, especially adjustment costs (see, e.g., Addison and Teixeira, 2006; Hirsch et al., 2010; Jirjahn, 2010; Müller-Jentsch, 1997, pp. 265–272). The result would be a lower labor demand and a negative coefficient. The dummy variable reflecting the existence of a collective agreement should have similar effects. The regulations in the collective agreement, especially regarding the dismissals (e.g., severance pay, social plans), raise adjustment costs. Further, as a collective agreement indicates higher union power, it may also lead to higher adjustment costs (see Jaramillo et al., 1993).

If the plant expects a higher turnover in the future connected with a higher labor demand, it will start the upward employment adjustment in the present period because of the convex cost structure (see Bellmann and Pahnke, 2006, p. 207). The result is a positive coefficient for the dummy variable indicating whether the managers expect increasing turnover and a negative coefficient in the decreasing case.

For the analysis of the asymmetry we estimate the following model including interaction terms<sup>17</sup> based on Jaramillo et al. (1993) as well as Schiantarelli and Sembenelli (1993):

$$l_{t} = \alpha_{1}l_{t-1} + \Delta\alpha_{1}\delta l_{t-1} + \beta_{1}\text{log.turnover} + \Delta\beta_{1}\delta\text{log.turnover} + \beta_{2}\text{log.wage} + \Delta\beta_{2}\delta\text{log.wage} + \beta \boldsymbol{x_{t}} + \Delta\beta\delta\boldsymbol{x_{t}} + \nu_{t}$$
(5)

with

$$\delta = \begin{cases} 1, & \text{if } L_t > L_{t-1} \\ 0, & \text{else.} \end{cases}$$

Different costs for upward and downward adjustment and thus different adjustment speeds are reflected in different values for  $\alpha_1$ . A negative  $\Delta \alpha_1$  indicates a faster adjustment in the case of upward adjustment and so higher dismissal costs compared to the costs of hiring.

As equation (4) is a dynamic panel model, we use an system GMM estimator (GMM-SYS / Arellano-Bover estimator) (see Arellano and Bover, 1995).<sup>18</sup> This estimator is an extension of the difference GMM estimator (GMM-DIFF / Arellano-Bond estimator) (see Arellano and Bond, 1991). The GMM-SYS estimator uses previous levels  $l_{t-2}, ..., l_1$  as instruments for the first differences  $\Delta l_{t-1}$  like the GMM-DIFF estimator and additionally lagged first differences  $\Delta l_{t-1}, ..., \Delta l_2$  as instruments for the levels. Comparing the two estimators, the GMM-SYS estimator is more efficient and yields better results (see, e.g., Bond and van Reenen, 2007, p. 4452; Blundell and Bond, 1998, p. 116; Blundell and Bond, 2000, p. 339; Blundell et al., 2000). Additionally, we use the more robust two-step version of the estimator, which leads to an additional efficiency increase if the standard errors are Windmeijercorrected (see, e.g., Bond, 2002, p. 147; Roodman, 2009, p. 97; Windmeijer, 2005,

<sup>&</sup>lt;sup>17</sup> In the empirical analysis and interpretation of the results it is important to note that the interaction terms might be affected by endogeneity since the dummy variable depends on firms' employment adjustment, which determines also  $l_t$ . Therefore, a new employment level  $l_t$  after adjustment might also affects the dummy variable. But Jaramillo et al. (1993, p. 642) consider this with reference to Heckman (1978) not as a problem due to the use of a dynamic panel estimation according to Arellano and Bond (1991). We use a dynamic panel as well with a similar approach.

<sup>&</sup>lt;sup>18</sup> For details about the analysis of dynamic panel models we refer to Baltagi (2008, ch. 8).

pp. 44–46).

Every plant adjusts employment according to equation (4) or (5) if pure convex adjustment costs are assumed. But if a fixed and convex structure is assumed, these equations are just relevant for those plants which actually decide to adjust. And not every plant selects itself in the status of employment adjustment so that equation (4) or (5) is not relevant for every plant. The selection process, which leads to the sample of adjusting plants, is based on the fixed cost component. Depending on fixed adjustment costs, the plant will only adjust employment if the profit gained from adjustment exceeds costs or, put differently, if the difference to the optimal level  $L^*$ is big enough. Hence, adjustment only occurs and plants select themselves in the status of employment adjustment if

$$k < |L_{t-1} - L_t^*| \tag{6}$$

with a threshold value k. Otherwise the plant will keep the employment level of the previous period  $(L_t = L_{t-1} + \nu_t)$ . For fixed and convex adjustment costs, we thus arrive at a switching-regression where the inequality (6) determines whether the employment level  $L_t$  is changed according to equations (4) or (5), respectively, or whether the employment level  $L_t$  stays constant  $(L_t = L_{t-1} + \nu_t)$ .<sup>19</sup> There are different approaches estimating a switching-regression (e.g., D-method). In our analysis we use a two-step procedure according to Maddala (1994, pp. 223–228). In a first step a probit model is estimated for the selection or switching. Afterwards, in a second step the current equation – in our case equation (4) or (5) – is estimated with a selection term à la Heckman estimated from the probit model.<sup>2021</sup> To obtain correct standard errors, the bootstrap is used.

The basis for the probit model is inequality (6), which determines the latent variable. The firm's decision about employment adjustment depends on the following inequality and thus  $L_t \neq L_{t-1}$  if:

$$|L_{t-1} - L_t^*| - k > 0$$
  
 $\Leftrightarrow |L_{t-1} - \sum_i X_i| - k > 0$ 

in which  $\sum_{i} X_{i}$  are the determinants of  $L_{t}^{*}$ . The relation described by equation (2)

<sup>&</sup>lt;sup>19</sup> For details on switching-regressions see, e.g., Cameron and Trivedi (2005, p. 555–557), Goldfeld and Quandt (1976) as well as Maddala (1986).

<sup>&</sup>lt;sup>20</sup> There are other studies which analyze fixed adjustment costs by using a Heckman approach (see, e.g., Nilsen et al., 2007). But Nilsen et al. (2007), for instance, do not use a dynamic panel model as the second step.

<sup>&</sup>lt;sup>21</sup> For details on sample selection and dynamic panel data models and applications see, e.g., Garcia et al. (2007), Jiménez-Martín (2006), Jiménez-Martín and Garcia (2010) as well as Lodigiani and Salomone (2012).

is also given for  $L_{t-1}$  and so labor demand in t-1 depends on  $L_{t-2}$  as well as  $L_{t-1}^*$ .<sup>22</sup> This leads to the following condition for  $L_t \neq L_{t-1}$ :

$$\Rightarrow |\gamma_1 L_{t-2} + \gamma_2 L_{t-1}^* - L_t^*| - k > 0 \Rightarrow |\gamma_1 L_{t-2} + \gamma_2 \sum_i \Delta X_{it-1} - \sum_i \Delta X_{it}| - k > 0$$

Besides  $L_{t-2}$ , the decision for adjustment depends on the change of  $L^*$  or its determinants from the previous to the current period. In the analysis the model for the latent variable in the probit model is given by:

$$y_t^* = \rho l_{t-2} + \boldsymbol{\sigma} |\Delta \boldsymbol{x}_t| + \boldsymbol{\theta} \boldsymbol{z}_t + u_t .$$
(7)

In addition to  $l_{t-2}$ , the vector  $|\triangle x_t|$  in equation (7) contains the absolute value of the percentage change of turnover and wage bill per employee as well as the absolute values of changes in percentage points of the various employment shares. Furthermore,  $|\Delta x_t|$  contains two dummy variables indicating whether managers' valuation of the profit situation has increased or decreased and two dummy variables indicating whether the production technology has been upgraded or downgraded. We also include two dummy variables indicating whether managers are expecting a change of turnover in the current period after expecting no change in the previous period and whether managers are expecting no change of turnover in the current period after expecting a change in the previous period. These variables represent also the exclusion restrictions. Labor demand depends on the level-variables and is not determined by the changes. Finally, the vector  $z_t$  includes some of the variables from equation (4), which we expect to show an impact on fixed adjustment costs, too. These variables affect the threshold value k in equation (6). The existence of a works council or a collective agreement, which leads to higher adjustment costs, results in a higher k. Therefore, the profit gained from adjustment and so the difference  $|L_{t-1} - L_t^*|$  has to be bigger. We also include dummy variables indicating whether the managers regarded the profit situation in the previous year as very good or good, reflecting a modern production technology, indicating whether managers expect an increasing or decreasing turnover and sets of industry and year dummies.<sup>23</sup>

<sup>&</sup>lt;sup>22</sup> The reason for the use of equation (2) although  $L_{t-1}$  and  $X_i$  are both observed separately is technical simplification. Note that the selection depends not on  $L_{t-1}$  and  $X_i$  as single variables but on the difference of these two, which is not directly given in the data and not easy to generate.

<sup>&</sup>lt;sup>23</sup> The panel nature of the data is considered by using year dummies and clustering standard errors at establishment level.

## 5 Empirical Results

First, we estimate the model with pure convex adjustment costs. In doing so, we also investigate a potential asymmetry in adjustment costs. Second, we estimate the model with fixed and convex costs in a switching-regression approach. This estimation is only done for plants which actually adjust employment. Afterwards, we compare the results of both models and decide which better suits the data.

Table 2 reports the estimation results of the model with convex, symmetric adjustment costs (specification (4)).<sup>24</sup> The coefficient  $\alpha_1$  for the lagged logarithmic number of employees covered by social security has the value 0.6746 in Western Germany. It represents a median adjustment of approximately 1.8 years, implying a lower adjustment speed compared to the result of Kölling (1998, p. 143), who, analyzing West German plants during 1993–1996, finds a median adjustment of around 0.7 years.<sup>25</sup> However, our result is in line with results from other studies for Germany. The bulk of these studies show a median adjustment between 0.7 and 7.7 years.<sup>26</sup> Furthermore, Table 5 contains the elasticities of labor demand regarding nominal wage rate and turnover, respectively: The long-run value for the wage rate is -0.27 and for turnover 0.10. These results are also in line with other studies for Germany. The share of qualified employees has a negative sign and so their higher productivity enables the plant to produce the same output with fewer people. As expected, the coefficient of the share of part-time employees is greater than zero. The plant needs more employees for the same output. Furthermore, we find a positive effect for the share of fixed-term employees as well as for the share of employees covered by social security. Moreover, a good profit situation leads to higher labor demand which is also reflected by the signs of the dummy variables for the expected turnover. In contrast, the existence of a works council reduces labor demand.

Table 2 also contains various summary statistics to assess the quality of the models estimated. The value of the Hansen test indicates a misspecification.<sup>27</sup> However, one has to consider that the Hansen test provides no unambiguous and

<sup>&</sup>lt;sup>24</sup> Summary statistics are reported in Table A.1 in the Appendix.

<sup>&</sup>lt;sup>25</sup> The median adjustment is the time span the plant needs to do half of the adjustment towards the optimum. It is based on the equation  $\alpha_1^t = 0.5$ , which is solved for t (see Hamermesh, 1993, p. 248) and which has the dimension 'years'. For an alternative interpretation of  $\alpha_1$  see Funke et al. (1998, p. 231).  $(1 - \alpha_1)$  is the share of the adjustment towards the optimum, occurring between the previous and the current period.

<sup>&</sup>lt;sup>26</sup> The reasons for the wide range of results might be, among other things, a different observation period or a different estimation method.

<sup>&</sup>lt;sup>27</sup> In order to improve the Hansen test, we ran several alternative models. An estimation of the models with two lags still leads to a Hansen test which indicates a misspecification. Another reason for the indication of misspecification might be the assumption of strict exogeneity for all regressor variables, especially turnover, wage and the variables for the employment structure. But assuming endogeneity for turnover, wage and the variables for the employment structure still results in a Hansen test that indicates a misspecification.

<sup>1</sup> The table presents coefficients and standard errors that are calculated from a bootstrapping with 150 replications. Reference categories of the dummy variable groups: no turnover change expected, agriculture and forestry, 1996 and 1997 (Eastern Germany: additional 1998 and 1999). Significance levels: \* p<0.1; \*\* p<0.05; \*\*\* p<0.01. In order to avoid a correlation with the error term, we use  $l_{t-2}$  instead of  $l_{t-1}$  for the interaction. The model for Eastern Germany is estimated with two lags to get an Arellano/Bond-Test which does not indicate second-order serial correlation in the first-differenced residuals. Arellano-Bond (m1 | m2) are tests for first- and second-order serial correlation in the first differenced residuals. For the Theil U statistics the years 2008 to 2010 are predicted based on an estimation of the years 1996 to 2007. ‡Indicates that the information refers to the previous year. Source: IAB Establishment Panel, waves 1996–2010 strong statements (see Roodman, 2009, p. 98) and that even with a positive result it is possible that the model is biased (see Wooldridge, 2010, p. 135). We continue to rely on our model because an Arellano-Bond-Test does not indicate a second-order serial correlation in the first-differenced residuals.<sup>28</sup> The table also shows the value of the Theil U statistic as a measure for the predictive power (see Greene, 2012, p. 128). The basis for the calculation is an estimation for the period 1996–2007 which is then used to predict the years 2008–2010. A higher value indicates a lower predictive power, but a single value is not meaningful. We use the Theil U statistic to compare the predictive power of different models.

For Eastern German plants the coefficient  $\alpha_1$  has the value 0.6600 which implies a median adjustment after approx. 1.7 years. Apparently, the adjustment process is faster and so adjustment costs are lower in Eastern Germany compared to Western Germany, which has also been found by Bellmann and Pahnke (2006, pp. 212– 213) as well as Fuchs (2010, pp. 168–169). However, the difference to Western Germany is not statistically significant as the confidence intervals overlap. The longrun elasticities in Eastern Germany are 0.07 for turnover and -0.23 for wage rate. The other coefficients are not qualitatively different to Western Germany. Only the effect for the existence of a works council is statistically insignificant for Eastern German plants, and modern production technology has a statistically significant positive sign. Apparently, plants with modern technology have higher productivity and demand more employees. Since an Arellano-Bond-Test indicates no second-order serial correlation in the first-differenced residuals, we use the model although the Hansen test indicates a misspecification.

Next, we analyze a potential asymmetry of the adjustment costs by estimating model (5) including the interaction terms for the direction of adjustment (see Table 3).<sup>29</sup> For Western and Eastern Germany the coefficient  $\Delta \alpha_1$  is less than zero, suggesting that employment adjustment proceeds faster in case of an employment increase. Besides, all the interaction terms together are statistically significant, indicating asymmetric adjustment costs with dismissal costs exceeding hiring costs.<sup>30</sup> Furthermore, the Theil U statistics indicate that the model with asymmetric

<sup>&</sup>lt;sup>28</sup> Fuchs (2010, p. 123) uses the same argument for a further analysis of her (seemingly misspecified) model. All Arellano-Bond-Tests in our study indicate no second-order serial correlation in the first-differenced residuals unless otherwise mentioned.

<sup>&</sup>lt;sup>29</sup> The model for Eastern Germany is estimated with  $l_{t-1}$  and additional  $l_{t-2}$  such that the Arellano-Bond-Test does not indicate a second-order serial correlation in the first-differenced residuals.

<sup>&</sup>lt;sup>30</sup> Note that the analysis is not a clear comparison of plants increasing employment with plants decreasing employment because the reference category for the dummy variable are plants that decrease or do not change employment. Therefore as a robustness check, we also estimate the model with a dummy variable indicating whether the plant decreases employment (not reported in the paper). This also results in estimates indicating that dismissal costs exceeds hiring costs.

adjustment costs has a higher predictive power.

So far, the results indicate that adjustment costs are asymmetric with dismissal costs exceeding hiring costs.<sup>31</sup> In a next step, Table 4 presents the results for the model with fixed and convex as well as asymmetric adjustment costs.<sup>32</sup> The results of the probit model which is estimated in the first step to calculate the selection terms are given in Table A.2 in the Appendix.<sup>33</sup> In Western Germany the coefficient  $\alpha_1$  has the value 0.7877, which results in a median adjustment of approximately 2.9 years. As in the pure convex case, we have evidence for asymmetric adjustment costs in Western and Eastern Germany. Thus, the 2.9 years are the median adjustment for employment decrease in Western Germany. If employment increases, the plant adjusts approximately 0.7 years faster. The corresponding values are 2.4 years (employment decrease) and 1.8 years (employment increase) for Eastern German plants and hence the difference is 0.6 years. The long-run elasticity for the wage rate is -0.19/-0.43 (employment increase/decrease) in Western Germany and -0.12/-0.76 in Eastern Germany. As the effect of turnover is statistically insignificant, we report no long-run elasticities for turnover. The other coefficients are qualitatively similar to the previous models, as long as they are statistically significant. Along with turnover, the share of fixed-term employees, the existence of a works council and an expected turnover increase are statistically insignificant in Western Germany. With fixed and convex, asymmetric adjustment costs, the effect of modern technology is statistically significant for Western German plants. Apart from turnover, also the statistical significance of the share of fixed-term employees (now insignificant) and an expected turnover increase (now statistically significant) also change compared to the model with symmetric convex or asymmetric convex in Eastern Germany.

Coming back to the question whether the adjustment costs are purely convex or fixed and convex, we have no straightforward test to answer this question. Yet, our analysis gives us some important hints in favor of a fixed and convex specification. First of all, the selection terms are statistically significant in Western and Eastern Germany meaning that selection in the status of employment adjustment plays a role. Furthermore, a model with fixed and convex costs has a higher predictive power

<sup>&</sup>lt;sup>31</sup> More precisely, as the analysis is based on all separations, it is not only dismissal costs but separation costs in total which exceed hiring costs.

<sup>&</sup>lt;sup>32</sup> Only plants which adjust their employment (change their number of employees covered by social security from the previous to the present year) are considered in this analysis. This sample selection is corrected by including a selection term in the model (see section 4).

<sup>&</sup>lt;sup>33</sup> As a robustness check, we estimated the probit model also with  $l_{t-1}$  instead of  $l_{t-2}$  as well as with the change of the employment shares from the pre-previous to the previous period instead of the change from the previous to the current one. But these variations lead to a lower predictive power in the probit model, do not really result in a different outcome for the second step and the Hansen test still indicates a misspecification. Using neither  $l_{t-1}$  nor  $l_{t-2}$ the Hansen test is getting even worse. We also estimated the probit model without the levelvariables, although some of these are statistically significant (see Table A.2 in the Appendix). Again, this does neither improve the Hansen test nor the predictive power of the probit model.

(Theil U statistic). We also find a higher predictive power assuming pure convex costs if the model is estimated just for plants which actually adjust employment. However, if only these plants are considered, the selection term has to be included, resulting in our model with fixed and convex adjustment costs. Based on all this evidence we prefer a fixed and convex specification instead of a pure convex one. The result of asymmetric adjustment costs does not depend on the assumption of purely convex or fixed and convex cost structure.<sup>34</sup>

Table 5 summarizes the main results for the adjustment coefficient and elasticities of the several models in this study. As mentioned already, the values are in line with previous studies for Germany such as Addison and Teixeira (2005), Bellmann and Pahnke (2006), Bohachova et al. (2011), Breitung (1992), Buch and Lipponer (2010), Flaig and Rottmann (2001), Flaig and Steiner (1989), Franz and König (1986), Fuchs (2010), Koellreuter (1980), Kölling (1998), Pfeiffer (1999) as well as Rottmann and Ruschinski (1998). These studies differ in database, observation period, observed regions, analyzed sectors, estimation approaches and the specification of adjustment costs. While Flaig and Rottmann (2001), Flaig and Steiner (1989), Koellreuter (1980), as well as Pfeiffer (1999) use a static estimation approach, other studies employ a dynamic approach. Our study is the only existing one apart from Kölling (1998) that allows for asymmetric adjustment costs. In addition, it extends the sparse literature analyzing dynamic labor demand models for eastern Germany by Fuchs (2010) and by Pfeiffer (1999).

## 6 Changing Adjustment Behavior over Time

Our observation period from 1996 to 2010 contains two business cycles and thus several economic up- and downturns.<sup>35</sup> The first cycle comprises the years 1996 to 2003 and the second one starts in 2004. With these two cycles it is possible to investigate whether firms' adjustment behavior has changed over time. For such an analysis we need to compare entire business cycles instead of single years. If two single years are compared, these two years could originate from different economic phases of the business cycle. This may lead to a comparison of employment adjustment in economic upturn (predominantly hirings) with that in economic

<sup>&</sup>lt;sup>34</sup> We also estimate the models separately for the production and the service sector (results not reported in the paper). Both estimations indicate fixed and convex, asymmetric adjustment costs. Furthermore, the elasticities for turnover and wage in the production sector are in line with Flaig and Rottmann (2001) as well as Pfeiffer (1999).

<sup>&</sup>lt;sup>35</sup> In Germany, no clear definition and scheduling of economic phases exists. For that reason there is no comprehensive classification of the years 1996 to 2010. Based on the development of the GDP, the Ifo Business Climate Index and findings of the German Council of Economic Experts as well as the Federal Statistical Office we apply the following classification: 1996– 2000, 2004–2007 and 2010 upturns; 2001–2003 and 2008–2009 downturns.

downturns (predominantly firings). This could result in a difference in the estimated effects caused by asymmetry and not just because of a changing over time.

We find evidence for a change in adjustment behavior of German plants in several studies. The German Council of Economic Experts compares firms' adjustment behavior and the labor market reaction of three different economic upturns (1993II– 1995II; 1999II-2001I; 2004IV-2007II). Their results indicate a change in the adjustment of employment. Especially in the last upturn the economic recovery was employment-intensive and many full-time jobs covered by social security were created (see GCEE, 2007, items 482–492). The flexibility and the dynamic of the labor market increased, which was - among other things - the result of labor market reforms in the years 2003 to 2005. This is also found by Gartner and Klinger (2010), who compare the economic upturns 1998II-2001I and 2004IV-2008I as well as the economic downturns 2001II–2004III and 2008II–2010II. Furthermore, they find a lower turnover rate of employment in the second business cycle (see Gartner and Klinger, 2010, p. 729). A change towards a lower fluctuation in the number of employees is also found by Burda and Hunt (2011) who compare the recession 2008–2009 with previous ones, Herzog-Stein and Seifert (2010) who compare the recession 2008-2009 with the recession 1973-1975, as well as Rothe (2009) who compares the upturns 1998I–2002IV, 2006I–2008II and the downturns in between. Apart from less adjustment activity with respect to the number of employees, a greater adjustment of working hours can be discovered due to better flexibility (see Burda and Hunt, 2011), although the instrument of working time adjustment was also used in previous recessions (see Herzog-Stein and Seifert, 2010, pp. 553–555).

All in all, there is clear evidence of changing adjustment behavior. But except for Burda and Hunt (2011) who also compare current employment levels with predicted ones, all the studies mentioned above use descriptive analyses of aggregated data. In contrast, we apply an econometric approach with establishment data. Using the dynamic labor demand model from Section 5 with fixed, convex, and asymmetric adjustment costs, we analyze a possible change in adjustment behavior. We do so by interacting the lagged logarithmic number of employees covered by social security with a dummy variable indicating whether the observation is from the first business cycle from 1996 to 2003. We restrict the interaction on the lagged logarithmic number of employees covered by social security and interact not all regressor variables because a possible change in firms' labor demand, which would be analyzed in case of interacting all regressor variables, is not part of this analysis. This paper rather focuses on a possible change in adjustment behavior reflected by the adjustment speed.<sup>36</sup>

<sup>&</sup>lt;sup>36</sup> Although it is not in the focus of this analysis, we also estimated the model which contains interactions of all regressor variables with the dummy variable indicating whether the

<sup>1</sup> The table presents coefficients and standard errors that are calculated from a bootstrapping with 150 replications. Reference categories of the dummy variable groups: no turnover change expected, agriculture and forestry, 1996 and 1997 (Eastern Germany: additional 1998 and 1999). Significance levels: \* p<0.1; \*\* p<0.05; \*\*\* p<0.01. In order to avoid a correlation with the error term, we use  $l_{t-2}$  instead of  $l_{t-1}$  for the interaction. The model for Eastern Germany is estimated with two lags to get an Arellano/Bond-Test which does not indicate second-order serial correlation in the first-differenced residuals. Arellano-Bond (m1 | m2) are tests for first- and second-order serial correlation in the first differenced residuals.  $\ddagger$ Indicates that the information refers to the previous year. Source: IAB Establishment Panel, waves 1996–2010 Table 6 reports the results of this estimation. The interaction term is significantly positive in both Western and Eastern Germany. Based on the coefficients, the median adjustment of Western German plants is approximately 0.14/0.22 years (employment increase/employment decrease) larger in the first business cycle compared with the second business cycle. The corresponding values are 0.22/0.34 years for Eastern Germany. Compared with the analysis without interaction term (see table 4), a few differences can be found. The coefficients for adjustment,  $\alpha_1$ , are lower if the interaction term is included. Furthermore, the short-run elasticity of labor demand with regard to wage rate has decreased in Western Germany. The statistical significance level for the coefficients has changed only marginally, except for the dummy variable for the modern production technology in Eastern Germany that is now insignificant.

These differences in firms' adjustment behavior between the business cycles can also be found in an analysis with pure convex, asymmetric adjustment costs (not reported in the paper). Thus, the assumption on the functional form does not drive this result. The employment adjustment in the second business cycle proceeds at a higher speed.<sup>37</sup> The plants spread the adjustment over a shorter period of time as it is indicated by the lower median adjustment. This might be evidence of lower adjustment costs. A higher flexibility in the adjustment of employment can be a reason for that. However, our results contrast with studies mentioned above based on a descriptive analysis of aggregated data. These studies find a lower fluctuation in recent years. An explanation might be that some plants adjust with a higher speed and at the same time fewer plants decide to adjust at all. But this explanation is not tenable in light of the analysis with assumed pure convex and asymmetric adjustment costs because all plants, adjusting or not, are included. Fewer plants with employment adjustment in the second cycle would lead to a negative interaction term which we do not observe. Still, there is an explanation for the differences between the results of our study and the results of the studies mentioned above. The opportunity of working time adjustment improved over time as a result, for example, of the increased use of working time accounts (see Burda and Hunt, 2011, p. 299). As this has made working time adjustment easier, less adjustment of the number of employees is needed. However, once plants have to adjust employment, they now adjust in a faster way because the possibility of employment adjustment

observation is from the first business cycle (results not reported here). However, these interactions are not jointly statistically significant. Thus, this result strengthens our decision to restrict the interaction on the lagged logarithmic number of employees covered by social security.

<sup>&</sup>lt;sup>37</sup> Strictly speaking a third business cycle starts with the year 2010. Therefore, the analysis is repeated excluding the year 2010 (results not reported in the paper). The results do not change. An analysis without the year 2010 also indicates a faster adjustment in the second business cycle.

has also improved in the course of several labor market reforms (see Herzog-Stein and Seifert, 2010, p. 552).

In addition to better opportunities for working time adjustment, there are also changes of other labor market institutions which affect firms' adjustment behavior and therefore may explain the empirical result of a faster adjustment. In 2004 the firm-size threshold of the German dismissal protection law was increased from 5 to 10 employees (in the legal sense of the German dismissal protection law). The result was decreased dismissal protection for employees in firms with size of 10 and less, although incumbent employees in these firms still had their prior dismissal protection (see Bauernschuster, 2011, p. 4). Less dismissal protection results in decreased dismissal costs for these small firms which should lead to a faster adjustment of the number of employees. This can also explain the higher adjustment speed in the second business cycle. But it is not totally convincing. The dismissal protection just changed for firms with 6 to 10 employees whereas there were no changes for the bulk of firms. Furthermore, empirical evidence for Germany does not show unambiguously that less dismissal protection leads to more and faster employment adjustment (see, e.g., Abraham and Houseman, 1994; Bauer et al., 2007; Buechtemann, 1993; Schramm and Endemann, 2010).

Changes in collective bargaining might additional explain the empirical results. Since the middle of the 1990s there is a decline of collective agreement coverage in Germany observable (see Ellguth and Kohaut, 2011b, p. 245). As some aspects of collective agreements (such as severance pay and specific employment protection) result in higher adjustment costs, the decline of collective agreement coverage leads to lower adjustment costs. This could explain the higher adjustment speed since firms' coverage rate of sectoral bargaining was on average 9 percentage points lower in the second business cycle.

Another change regarding collective bargaining in Germany is the increased use of collective opening clauses which relate to different aspects of the sectoral collective agreements (see Brändle et al., 2011; Kohaut and Schnabel, 2007). Some clauses lead to more flexibility in working time adjustment and have the same effects on firms' adjustment behavior as improved opportunity of working time adjustment in general. But opening clauses also increase the flexibility of wages. Therefore, a firm can adjust wages instead of adjusting the number of employees to improve profits in a bad economic situation. Although this an explanation for the results of the mentioned studies using aggregated data, it does not lead to a faster adjustment of the number of employees. However, the increased use of opening clauses started already in the middle of the 1990s and is thus not specific to the second business cycle.

Firms' adjustment behavior is also affected by changes in temporary agency

employment. Since the reform of the Temporary Employment Agencies Act (*Arbeitnehmerüberlassungsgesetz*) in 2003 the use of temporary agency employment is eased for firms and the number of temporary agency employees has increased (see, e.g., Antoni and Jahn, 2009; Hirsch and Müller, 2012). Temporary agency employment is an alternative instrument for the adjustment of firms' labor volume. If it is easier to use temporary agency employment, less adjustment of the number of employees covered by social security is needed. This can also explain the aggregate results, but should not directly affect the adjustment speed.

These considerations suggest that some of the changes of labor market institutions in Germany can explain the aggregate picture of less adjustment of the number of employees but not directly the increased adjustment speed. However, the faster adjustment can indirectly be the result of the institutional changes. Most of these changes imply that less adjustment of the number of employees is needed so that the firms do not have to hire and dismiss so many people at once. The results are lower (convex) adjustment costs due to the convexity of adjustment. Moreover, if only a few employees are affected, the works council may not interfere strongly in the dismissal, which again decreases adjustment costs. These various kinds of lower costs result in a faster adjustment of the number of employees.

### 7 Conclusions

Using a large and representative establishment data set for Germany, we investigate firms' labor adjustment behavior in terms of the number of employees covered by social security. The results of our empirical analysis indicate that adjustment costs are characterized by a convex structure including a fixed component. Thus firms do not adjust employment permanently, and there are periods with no employment adjustment. Furthermore, the cost structure is found to be asymmetric: In case of an employment increase, the adjustment runs faster compared with a decrease suggesting that dismissal costs exceed the costs of hiring. These results are in line with the existing literature. Based on our preferred baseline model the long-term wage elasticity is -0.19 in case of an employment increase and -0.43 in case of an employment decrease in Western Germany. The corresponding values are -0.12 and -0.76 for Eastern Germany. Thus the elasticities are higher (in absolute terms) in case of a reduction in employment.

Moreover, we identify a change in firms' employment adjustment over time. The adjustment was spread over a longer period of time in the business cycle from 1996 to 2003 and thus the adjustment speed was lower compared to the following business cycle from 2004 to 2010. This indicates lower adjustment costs in the business cycle after 2003, which might be related to recent reforms and more flexibility in the labor

market. Nowadays, the plants seem to be able to adjust their employment covered by social security more quickly.

For a further investigation of labor adjustment, we would need information on working time to include this adjustment dimension in the analysis, thus providing a more complete picture of firms' labor adjustment. Several studies have shown an intensified use of working time adjustment in the recent past, which may also affect the change in the adjustment of the number of employees. Because of recent reforms of temporary agency employment in Germany, this type of employment may have become more important for firms' employment adjustment. The faster adjustment of the employment covered by social security in the second business cycle found in this study may reflect this, among other things. Future research should thus take temporary agency employment explicitly into account and analyze its role as an alternative adjustment instrument.

Industry dummies	yes <sup>***</sup>		yes <sup>***</sup>	
Year dummies	yes		yes <sup>***</sup>	
Number of observations (plant-years)	45470		34692	
Wald (44)	$9115.50^{***}$			

<sup>1</sup> The table presents coefficients and standard errors clustered at the establishment level. Reference categories of the dummy variable groups: no turnover change expected, agriculture and forestry, no change of the profit situation, no change of the production technology, no change of the turnover expectations and 1996. Significance levels: \* p<0.1; \*\* p<0.05; \*\*\* p<0.01. ‡indicates that the information refers to the previous year.

 $l_{t-2}$  is only observable for Eastern Germany from 1997 onwards. Therefore, the estimation for Eastern Germany is based on the years 1997 to 2010.

<sup>3</sup> For a converging probit model in Eastern Germany we use an IRLS-Algorithm instead of the default Newton-Raphson-Algorithm. Thus a Wald statistic and the pseudo R-squared are not generated.

<sup>4</sup> The dummy variable reflects a plant expecting a change of the turnover, while expecting no change in the previous period.

<sup>5</sup> The dummy variable reflects a plant expecting no change of the turnover, while expecting a change in the previous period.
