## Abstract

We investigate divisions within the citation network in economics using citation data between 1990 and 2010. We consider all partitions of top institutions into two equal-sized clusters, and pick the one that minimizes cross-cluster citations. The strongest division is much stronger than could be expected to be found under idiosyncratic citation patterns, and is consistent with the reputed freshwater/saltwater division in macroeconomics. The division is stable over time, but varies across the fields of economics.

**Keywords:** citations, clustering, influence, schools of thought

**JEL Codes:** A11, D85, I23

# 1 Introduction

We ask whether the academic discipline of Economics is divided into clusters of universities where authors tend to cite authors from the same cluster more than could be expected under idiosyncratic differences in citation patterns. We use citation data between top economics journals to construct the citation matrix between authors' home institutions. We compare all possible partitions of top universities into two equal-size clusters. We find a very significant division between top universities in this citation network, and it is consistent with what is commonly thought as the divide between "freshwater" and "saltwater" schools.

The likelihood of citing a paper by an author from another university in the same "cluster" is about 16% higher than the likelihood of citing a paper by an author from the other cluster. We assess the statistical significance of this division using simulations. In each simulated citation network, the likelihood of citation propensities is independent across university pairs, while average citation propensities and the distribution of pairwise deviations from average propensities each university match their empirical counterparts. The division is statistically extremely significant, and is robust to considering different extents of "top universities" and across time periods. However, there are significant differences across fields of economics, with macroeconomics and econometrics exhibiting the strongest division and economic theory no division at all.

## 2 Data

### 2.1 Data Sources

We use the citation data of articles published in 102 economics journals between 1990 and 2010, where the set of top journals was taken from the classification by Combes and Linnemer (2010).<sup>1</sup> The data was obtained from Thomson Scientific's Web of Science, which is an online database pooling journal articles' data from major databases including Science Citation Index Expanded (SCI-EXPANDED), Social Sciences Citation Index (SSCI), Arts and Humanities Citation Index (A&HCI). Notes, editorials, proceedings, reviews, and discussions were not included. The resulting data cover 97,526 unique articles with 34,431 unique contact authors and 1187 unique affiliations associated with these contact authors.

Our data set contains information on articles cited in the reference sections of these articles. Data on cited articles consist of year of publication, name of journal and name of the contact author.<sup>2</sup>

---

<sup>1</sup>For the complete list of journals and their summary statistics, see Table A1 in the online appendix.

<sup>2</sup>Only the name of the contact author is available, even if the cited paper has more than one

## 2.2 Construction of the Citation Matrix

We use articles published between 1990 and 2010 and articles cited by them to construct a citation matrix between institutions. Data on contact authors of citing articles contain also their affiliation at the time of publication. However, author affiliations for cited articles are not directly observed. Hence we construct a career path for each author from 1977 to 2010 by using affiliation information of citing articles. For this task we also use data on articles published between 1977 and 1989, in order to enlarge the set of cited articles that can be matched with an author affiliation. If an author did not publish in our sample journals in a year then we use his or her next known affiliation; if no affiliation is observed between the cited year and 2010, then we use the last previously observed affiliation. Using this procedure, we are able to identify 36,189 unique authors of a total of 1,662,212 cited articles in the reference sections of 91,635 unique articles written by 32,572 unique authors. Authors of a total of 753,230 cited articles could not be matched with an affiliation. The observed affiliations form a total of 1187 citing and 1192 cited institutions.

We measure citations in units, so that every article conveys one unit of citations, regardless of how many documents it cites. For example, if an article by an author from MIT cites 20 articles, and 4 of them by Harvard authors, then this counts as  $4/20 = 0.2$  units of citations from MIT to Harvard.<sup>3</sup> Cited publications whose author cannot be matched with an affiliation are treated as authored at an institution called "Unknown".

Citation data is gathered in the aggregate citation matrix, which gives the sum of unit citations from all articles. The element at row  $i$  and column  $j$  is the sum of unit citations by authors from institution  $i$  to articles by authors from institution  $j$ . To analyze of subsets of journals and publication years we restrict the summation to subsets of articles, whereas when analyzing subsets of institutions we just keep the relevant submatrix of the aggregate citation matrix.

## 2.3 Summary Statistics

Figure 1 shows the distribution of articles in our data by publication year. Steady increase in the annual number of articles reflects an increase in the number of journals as well as increase in articles per journal-year. Of the 102 journals in the set 79 were in existence in 1990 and 96 in 2000. The average number of articles published in a journal per year increased from 50 in 1990 to 54 in 2000, and to 73 in 2010.

---

author.

<sup>3</sup>It would be ideal to also divide citations for multi-author documents proportionally between the authors, but observing only on the contact author affiliation precludes this.

Figure 1 also shows the distribution of out-citations that are used in the construction of our citation matrix by publication year. The number of out-citations in a given year is the number of articles (in citation units) for which an author affiliation could be identified. Number of in-citations in a given year equals total citation units received by articles published in that year and for which an author affiliation could be identified.

Selected summary statistics of the citation matrix are reported in Table 1. Self-cites, which are dropped from the final analysis, are reported separately. Cites to articles whose contact author could not be matched with an institution are listed as "cites to unknown". All cites are measured in units-per-citing-article, so the sum of outgoing cites, self-cites, and cites to unknown adds up to the total number of articles published by contact authors from each institution.

### 3 Analysis

There are authors from 1192 institutions in the data. To analyze their possible division we restrict the analysis to a subset of top institutions. We define the "top" by the ranking of institutions by influence in the network of citations, using eigenvalue centrality; for details, see Pinski and Narin (1976).<sup>4</sup> Self-citations are removed before calculating influence. Table 1 lists the influence measure for the top 50 institutions by influence. Our main specification considers the division between the top 20 academic institutions.

Our goal is to find out whether institutions can be divided into "clusters" within which authors cite each other more than could be expected under idiosyncratic citation patterns. Self-citations are a potential confounding factor, because citations within an institution are necessarily also within-cluster citations. Over 10% of cites in our data are institutional self-cites.<sup>5</sup> We ignore all self-citations, effectively replacing the diagonal elements of the citation matrix with zeroes.

To measure clustering we use a slightly modified version of  $Q$ -modularity of Girvan and Newman (2002).<sup>6</sup> For a given partition of institutions to clusters,  $Q$  measures the difference between the actual and expected proportion of cites between clusters, where the expectation is calculated under independently distributed citation patterns. The strongest division in the network is that which maximizes modularity. Our ad-

---

<sup>4</sup>Davis and Papanek (1984) provide an early study of department rankings based on citation counts. For rankings of academic journals using network influence, see Liebowitz and Palmer (1984), and *Eigenfactor.org*. Amir and Knauff (2008) and Terviö (2011) apply this method to data on PhD placement / faculty hiring data.

<sup>5</sup>Note that we cannot distinguish between authors citing themselves, and authors citing their peers at the same institution, because we only have data on contact author affiliation.

<sup>6</sup>Newman (2004) shows that this method, although originally defined for binary networks, is also suitable for weighted networks.

ditional normalization takes into account the impact of removing self-citations on expected citation patterns. Without this correction, the expectation benchmark would always predict a significant amount of self-citations. With the correction, expected self-citations are set to zero. Intuitively, the expected citation patterns are calculated under the hypothesis that authors at all institutions distribute their outbound non-self cites at a probability that depends only on target institution, not on sender institution. Analyzing proportions instead of cite counts also serves as a normalization that gives each institution equal weight in defining the strength of deviations from expectation, regardless of its share of all citations.

Denote the aggregate citation matrix for the set of  $n$  institutions by  $M$ . The normalized citation matrix  $T$  has typical elements

$$T_{ij} = M_{ij} / \sum_{i \neq h} M_{ih} \text{ for } i \neq h \quad (1)$$

and  $T_{ii} = 0$ . Row  $i$  measures citations as proportions of outbound non-self cites from institution  $i$ . We define its expectation as the average fraction of non-self citations by departments other than  $i$  going to department  $j$ :

$$E_{ij} = \frac{1}{n-2} \sum_{h \neq i} T_{hj} \text{ for } h \neq j \quad (2)$$

and  $E_{ii} = 0$ , for  $i = 1, \dots, n$ . Finally, the citation information that is used in the analysis is contained in the matrix of deviations from expected citation patterns  $\Omega = T - E$ .

Table 2 shows the unit citations between the top 20 academic institutions, i.e., the matrix  $M$ . The background colors of the table represent a heat map of the pairwise deviations from expected citation patterns, i.e., the elements of  $\Omega$ . If a row department cites a column department more than expected then the corresponding element is red, if citing is less than expected then the element is blue; darkness captures the magnitude of the deviation.

We consider all partitions of the set of  $n$  institutions into two equal-sized clusters. The existence of discrete clusters is, of course, an abstraction; the point of this exercise is to uncover a dimension of differentiation in the citation patterns of institutions. Formally, consider any partition of the set of  $n$  institutions into subset  $A$  and its complement. Our measure for the strength of the division is

$$Q(A|\Omega) = e'_A \Omega e_A + (l - e_A)' \Omega (l - e_A), \quad (3)$$

where  $e_A$  is the membership vector for subset  $A$ , equal to unity for members and zero for non-members, and  $l$  is a vector of ones. This measure gives the sum of total deviations from the expected proportion of normalized citations for within-cluster pairs

of institutions. (Deviations add up to zero, so the amount of deviations for between-cluster pairs of institutions is necessarily just the negative of  $Q$  and can be omitted.)

We define the strongest division to be the partition  $A$  into two clusters of  $n/2$  institutions that maximizes  $Q(A|\Omega)$ .<sup>7</sup> Thus, for a set of  $n$  institutions, with  $n$  even, there are  $c_n = \frac{1}{2} \binom{n}{n/2}$  different ways of dividing them into two equal-sized clusters. The problem of finding the optimal partition of a graph is NP-hard, and standard algorithms do not necessarily find the strongest partition. We use the brute force method and select the strongest of all possible partitions.

**Clustering results** The strongest division is depicted in the last columns of Table 1 for  $n = 12, 16, 20, 24$ . We call the cluster that includes Harvard "the Saltwater cluster" and the other "the Freshwater cluster."<sup>8</sup> Most departments always show up in the same cluster. Chicago, Northwestern, Penn, and Rochester are always in the Freshwater cluster; MIT, Stanford, Princeton, Berkeley, and Columbia are always in the Saltwater cluster. The only institutions whose cluster membership varies by specification are Yale and Michigan.

The magnitude of the division can be illustrated by considering the relative propensities to cite within and between clusters. Among the top 20 academic institutions, the average number of unit citations between a pair of institutions in different clusters is 11.76, while the average for institution pairs in the same cluster is 13.67, that is 16% higher. Among the top 16 academic institutions, the average number of unit citations between a pair of institutions in different clusters is 14.91, while the average for institution pairs in the same cluster is 17.32, that is 16% higher.

**Strength of attachment** The relative strength of attachment to the Salt and Freshwater clusters can be measured for any institution that hosts authors that publish in our sample of journal articles. Table 1 lists the "relative salt" measure for the 50 most influential institutions. It measures the average deviation from the expected share of outgoing citations to Saltwater members in excess of the share going to members of the Freshwater cluster. True to name, the saltiest of saltwater schools appear to be Berkeley and MIT, while Minnesota and Rochester are the freshest of the fresh. Chicago appears surprisingly "neutral" along with Stanford, Yale, and Columbia. Note that, as self-citations were removed and as Chicago is by far the most heavily cited Freshwater department, a disproportionate share of its citations to the Freshwa-

---

<sup>7</sup>There could, in principle, be several maximizers, but this never occurs in our data.

<sup>8</sup>Stanford economist Robert E. Hall first came up with the freshwater/saltwater term in the 1970s, based on the then workplaces of a group of leading macroeconomists with a distinctive style of research: Robert E. Lucas at Chicago, Thomas Sargent at Minnesota, and Robert Barro at Rochester. See "Fresh Water' Economists Gain," New York Times, July 23, 1988.

ter cluster are ignored in the analysis. Outside academia, the Federal Reserve Bank appears quite "fresh" while World Bank and IMF are somewhat "salty." The joint pattern of attachment to clusters and influence in the citation network and is depicted in Figure 2. The rough pyramid shape of the scatter plot reveals how more influential institutions tend to be less "partisan" in terms of the salt/fresh division.

More precisely, redefine  $\Omega$  to include all departments and not just the top  $n$ . We define the "salt content" of department  $i$  as

$$S_i = \frac{e_i' \Omega e_S}{(l - e_i)' e_S} - \frac{e_i' \Omega e_F}{(l - e_i)' e_F}, \quad (4)$$

where  $e_i$  is the  $i$ th unit vector, and  $e_S$  and  $e_F$  are the membership vectors of Saltwater and Freshwater clusters. The divisors account for the removal of self-cites: top institutions are themselves members of a cluster, and have one less potential citation partner in their own cluster. Finally, "relative salt" is obtained by subtracting the mean salt content of all departments (0.385).

## 4 Is the division statistically significant?

Given the large number of possible partitions, it would often be possible to find partitions where the division appears strong even for a random pattern of deviations. To test the statistical significance of the division, we have to take into account that the partition has been selected as the strongest possible from the set of possible partitions, precisely in order to maximize the strength of the apparent division.

We measure the statistical significance of the division by comparing the strength of the strongest division found in the actual sample to its bootstrapped distribution. The bootstrap distribution is obtained by generating random permutations of the deviation matrix  $\Omega$  and measuring the strength of the strongest division found for each permutation. In these permutations we randomly reorder the off-diagonal elements of  $\Omega$ , separately for each column, treating all possible permutations as equally likely. These simulated deviation matrices describe a world where the average share of incoming citations is held fixed for each university, but deviations from average non-self citation patterns are idiosyncratic. Furthermore, in the simulation, the distribution of pairwise deviations  $\Omega_{ij}$  is the same as in actual data, but a tendency to cite a particular institution more does not imply a tendency to cite another particular institution more.

The strongest partition under the random benchmark always appears "statistically significant" to a naive test that treats the strongest partition as given. We conducted 10,000 simulations for each  $n = 12, 16, 20$ , and 2000 for  $n = 24$ . In all of these simulations there is only one instance where it is possible to find a division as strong

as we find in the actual data, for  $n = 16$ . Therefore we conclude that the division is statistically very significant.

## 5 Subsamples

**Time periods** We repeat the cluster analysis for a subset of citation years, using a rolling 10-year window starting from 1990-99 and ending in 2001-10, with the set of departments fixed at the top 16 academic departments as calculated for the whole time period. The strongest division is the same throughout the period, but there appears to be a secular trend towards a weaker division.

The time period results are summarized in Figure 3, which plots the strength of attachment to saltwater cluster (as defined in that period) against the last year of the 10-year time window. A noticeable development is the increasing "saltiness" of Chicago. Towards the end of the period, Chicago has a higher relative propensity to cite authors at saltwater schools than the average of all 1187 institutions in the data. Despite this, Chicago shows up in the Freshwater cluster in every time period, because it is so heavily cited by other Freshwater departments. Even though Chicago appears "more salty" than some of the Saltwater departments, an alternative partition where it switches places with a weakly attached Saltwater department would result in more cross-cluster citing and make the division weaker.

**Fields** We analyze the citations between the subset of 4 most influential field journals for nine fields, with journal fields defined by Combes and Linnemer (2010). Unfortunately we do not have the JEL codes by article, so we do not include articles in general interest journals. The most influential journals are defined using the same influence measure as for institutions in the previous section, calculated from the matrix of unit citations between all 102 journals in our data. See Table A1 in the supplementary appendix for summary statistics by journal.

Table 3 shows the strongest division by field. The analysis is in each case conducted for the 16 most influential academic departments as measured for the relevant citation network. We define the  $p$ -value as the fraction of simulations where the strongest division into two clusters is as strong or stronger as the one found in actual data. With all journals included this  $p$ -value is therefore 0.0001. Among the individual fields, macroeconomics and econometrics show the strongest division, at  $p = 0.0000$ . By contrast, microeconomic theory appears to show no clustering at all, with  $p = 0.973$ . Public economics (0.027) and Growth/Development (0.054) also exhibit a clear division, while the remaining fields show only weak evidence for a division, with  $p$ -values between 0.1 and 0.2. Table A2 in the supplementary appendix provides more details by field.

## 6 Conclusion

The network of citations in economics between authors' exhibits a division where authors from certain institutions are significantly less likely to cite across cluster lines. The division is the same as was found in hiring/placement data in Terviö (2011), and adheres to the common notions of "Freshwater" and "Saltwater" schools.<sup>9</sup> Same factors are likely to be behind it. It is plausible that some of it is explained by tendency to cite their former colleagues and mentors. Of course, citation data alone cannot tell whether the division is more based on methodological or ideological differences. The division is strongest when restricting the set of journals to only macroeconomics, whereas restricting to economic theory takes away the division, with other fields in between in the strength of the division.

Articles from all sample journals from 1990 to 2010. *Non-academic institutions in italics.*

Influence in the network of citations is calculated after dropping self-citations by institutions from the data.

"Relative salt" measures the propensity to cite members of Saltwater cluster relative to Freshwater cluster (with clusters defined for Top 20).

Table 2. Unit citations from row to column department for the top 20 academic departments. Colors depict deviations from expected citations patterns in the absence of clustering (excluding self-citations). Red depicts citations above and blue below expected intensity, darker shades depict stronger deviations. Institutions are ordered by the strength of their connection to the saltwater cluster.

Table 3. Significance of Division by Field

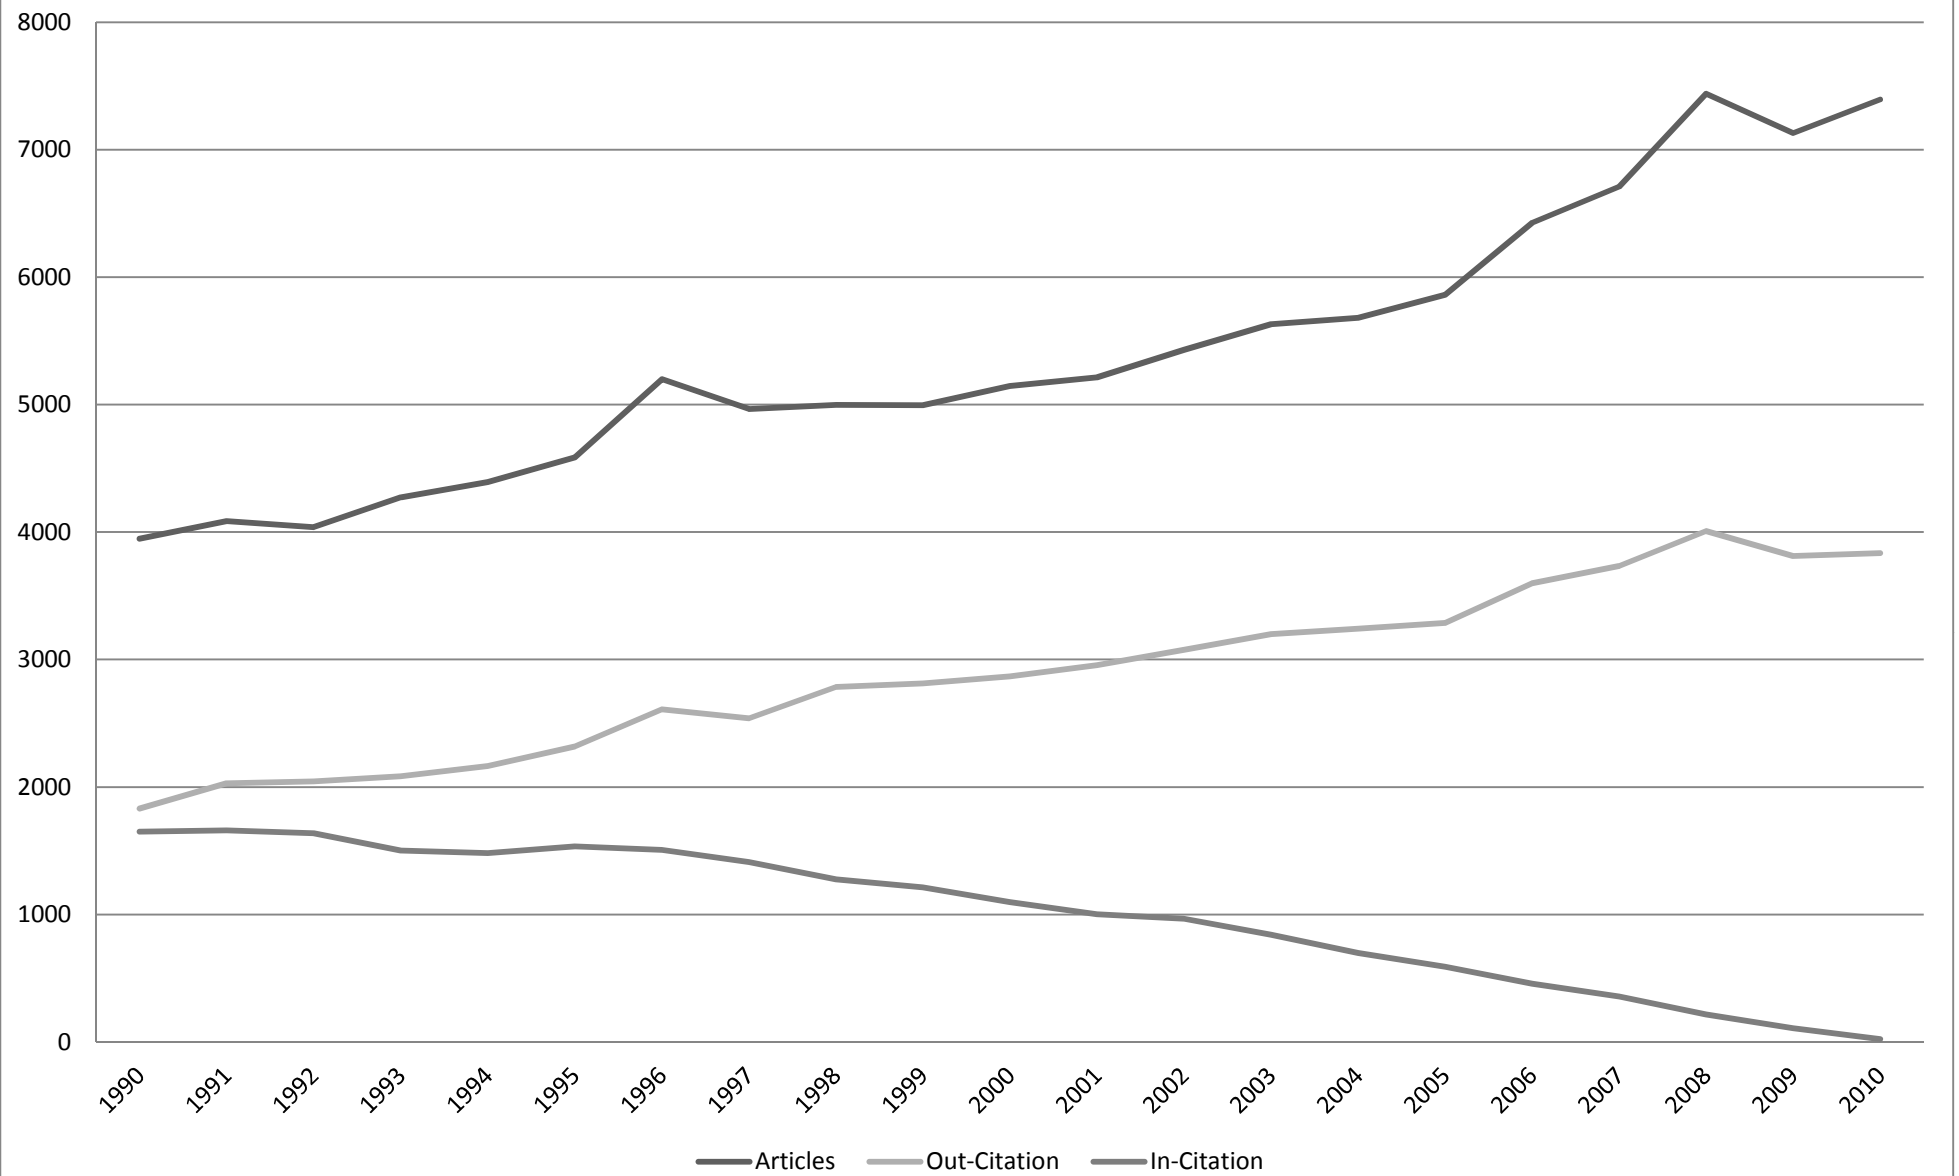

<i>Field</i>	<i>p-value</i>
Macroeconomics/Monetary	0.0000
Microeconomic theory	0.9734
Industrial Organization	0.1515
Econometrics	0.0000
Labor	0.1113
Growth/Development	0.0535
Finance	0.1911
Public	0.0270
International	0.1829
All	0.0001

Includes top 16 most influential departments by field, and 10,000 simulations for the 4 most influential field journals.

For details by field, see Table A2 in the appendix.

Figure 1. Publications and Unit Citations by Publication Year, 1990-2010

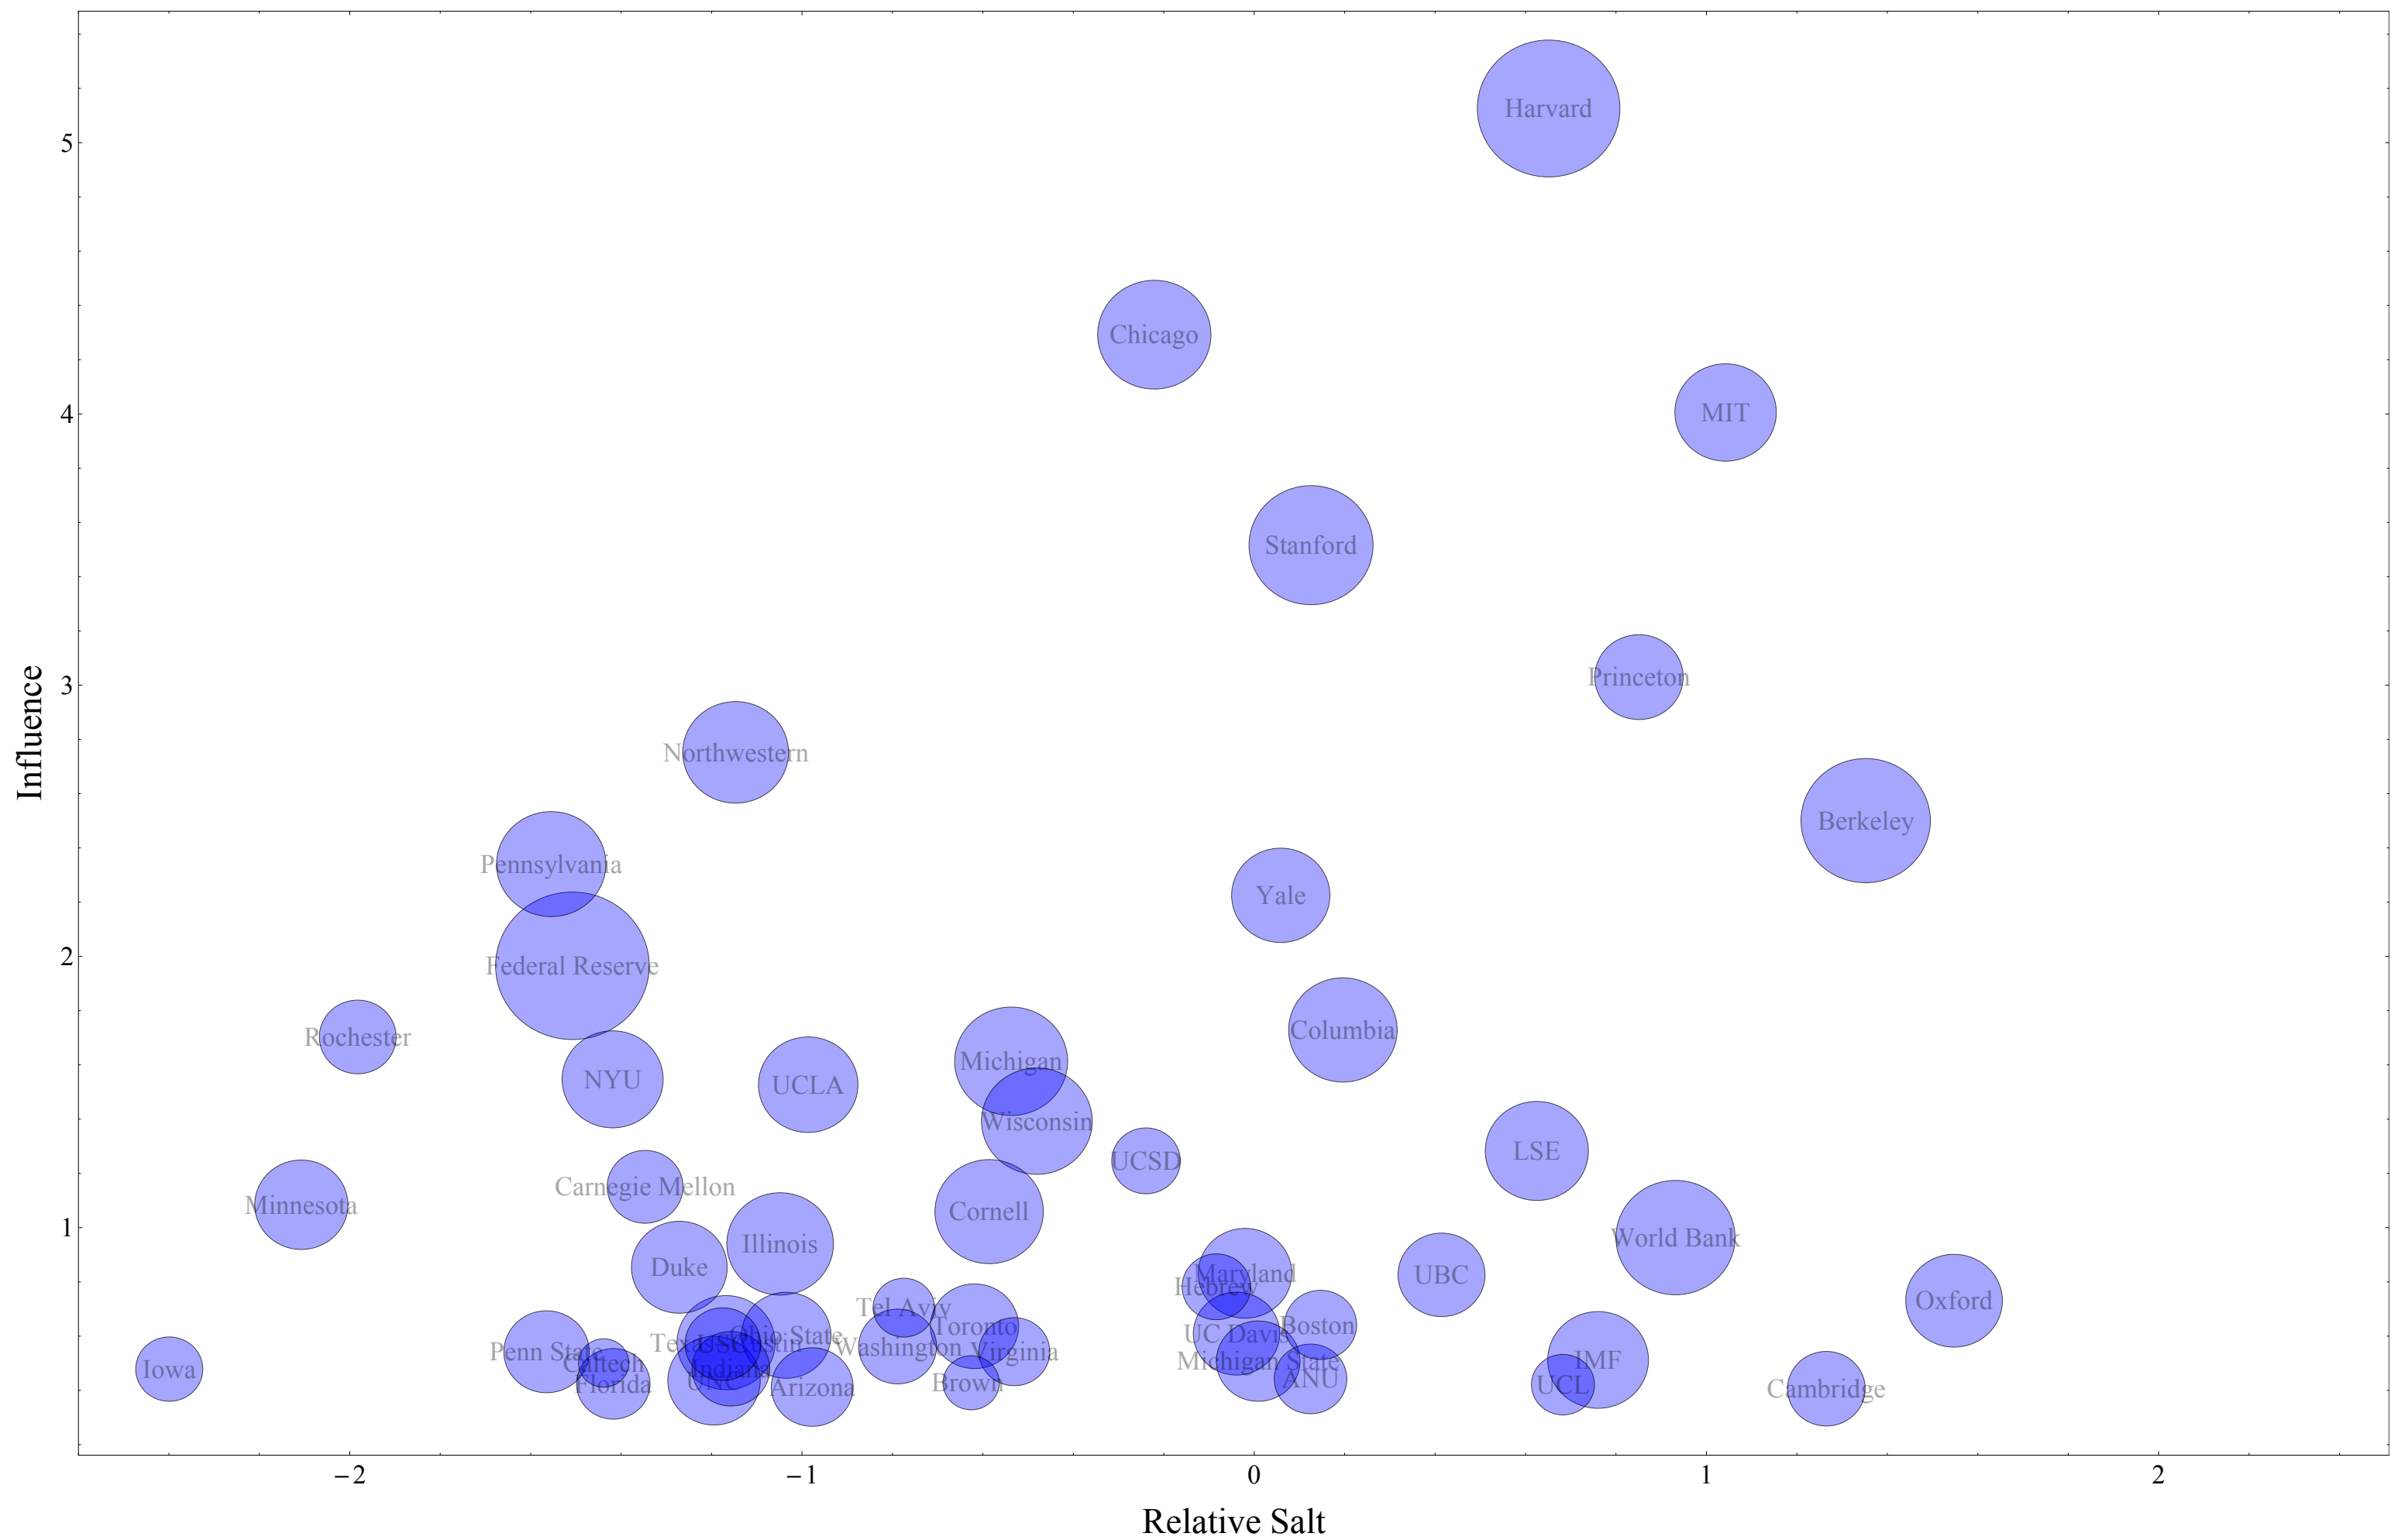

Figure 2. Relative strength of attachment to the clusters (more positive = more Saltwater than Freshwater) and influence in the citation network, for the 50 most influential institutions. Bubble size is proportional to the number of unique authors.

Figure 3. Time series of the strength of attachment and cluster membership for academic institutions that form the top 16 for the whole period 1990-2010 (Last year of the 10-year moving window shown)
