& ECONOMIC RESEARCH

Non-technical summary

Traditionally, labour supply studies have taken income and hours of work as the only variables influencing individuals' choices in the labour market. However, research on subjective well-being has shown that other job domains, such as job security, are considered fundamental components of a job. In this paper, we propose a model which incorporates additional job attributes in the analysis of labour supply. In particular, we allow individuals to choose among jobs characterised by bundles of income, hours of work and job insecurity.

We use data on single female employees from wave 10 of the British Household Panel Survey. The BHPS provides information concerning satisfaction with job security at work. Despite the subjective nature of this variable, studies have shown that perceived job insecurity provides reliable information about objective indicators of insecure jobs and contains useful private information, which is otherwise not directly available in surveys.

Our results suggest that job security is an important factor affecting labour supply decisions. In particular, job insecurity has a negative and significant effect on individuals' utility. Moreover, the incorporation of job insecurity in the model produces a better fit of the data and results in higher wage elasticities. Finally, a decrease in job insecurity increases participation by around 2.5 percentage points. This result suggests that policies aimed at improving working conditions could be used to create incentives in the labour market. Further research is necessary in order to contrast these results with analysis using objective information of job insecurity.

The effect of job insecurity on labour supply

September 10, 2013

Abstract

The aim of this paper is to analyse the effect of job insecurity on labour supply. We propose an extension of traditional discrete choice models of labour supply in order to allow for the introduction of non-pecuniary job attributes in the analysis. In our extended model, the choice alternatives are characterised by bundles of income, hours of work and job insecurity. We compare the predictive power and labour supply elasticities obtained with our model to those of a traditional model where only income and discrete hours choices characterise a job. The results show that once job insecurity is included in the discrete choice alternatives, the predictive power of the model improves significantly. Labour supply elasticities are significantly higher than those obtained with a traditional model and increase with the level of job insecurity. Finally, a decrease of job insecurity at work has a positive and significant effect on participation. Policies aimed at improving working conditions could, in this sense, be useful to create incentives in labour market.

Keywords: Discrete choice, labour supply, job insecurity.

1 Introduction

During the last decades, significant progress has been made on issues related to labour supply specification and estimation. However, an important question that has been largely left aside is the effect of working conditions on labour supply. The aim of this paper is to develop a discrete choice model of labour supply which incorporates working conditions in the job choice in order to compare the estimated labour supply responses in this model to those of a model where only a discrete hours set characterises job alternatives.

Discrete choice models of labour supply have become increasingly popular as they overcome most difficulties encountered by the traditional approach based on a continuous set of hours. Most difficulties related to the estimation of continuous labour supply models arise due to non-linearities and non-convexities in the budget sets produced by the presence of complex tax and benefit systems. Further complications arise when the purpose is to estimate labour supply for couples, as the utility function has to be maximised subject to a three dimensional budget constraint, with female leisure, male leisure and total household consumption (see Creedy and Kalb, 2005). Different studies based on the continuous approach have accounted for non-convex budget sets and joint labour supply (see Arrufat and Zabalza, 1986; Hausman, 1985; Hausman and Ruud, 1984). However, because of computational difficulties, the specification of the utility function and labour supply functions needs to be restrictively simple. For instance, Hausman and Ruud (1984) calculate estimates of joint labour supply with non-convex budget sets, specifying a flexible functional form of the utility function but remark that the methodology becomes very difficult to apply when other functional forms are used.

Contrary to continuous labour supply models, the idea behind the discrete choice approach is to define a finite number of working hours alternatives and to explicitly specify a utility function characterising the individual's utility at each of the alternatives of the discrete hours set. The estimation of the discrete choice model provides the parameters defining the shape of the utility function. The main critiques to discrete labour supply models concern the incomplete use of information and the rounding error generated by the discretisation of the choice set. However, this approach offers the main advantage that it facilitates dealing with non-linear and non-convex budget sets as well as accounting for multiple goods in the utility function.

Most studies, using either the discrete or the continuous approach, take income (consumption) and hours of work (leisure) as the only choice variables affecting individuals' labour supply decisions. However, we agree with Dagsvik and Strøm (2006) that "hours of work and income are only two out of several job related attributes, which are important for individual behaviour in the labour market". From the literature on job satisfaction we know that adverse working

conditions have an important effect on labour market decisions, through their impact on individuals' satisfaction at work. For instance, worker's intentions to quit increase due to low job satisfaction produced by poor working conditions (Böckerman and Ilmakunnas, 2009). Adverse working conditions also have an effect on decisions related to absenteeism (Clegg, 1983) as well as on early retirement (Siegrist et al., 2007). It seems, therefore, reasonable to consider that individuals care about other aspects of work than merely earnings, when they make labour supply decisions.

Within the discrete choice setup, few studies allow for the introduction of non-pecuniary job attributes in the estimation of labour supply. In Dagsvik (1994) and Dagsvik and Strøm (1992) a model of labour supply which accounts for the importance of qualitative factors of jobs is proposed. This model of discrete choice labour supply assumes that the alternatives are characterised by "job packages" which are defined by a bundle of hours of work, wage rates and other non-pecuniary job attributes. Other studies on labour supply such as Aaberge, Dagsvik and Strøm (1995), Aaberge and Colombino (2013) and Dagsvik and Strøm (2006) use a similar methodology. However, to the best of our knowledge, only job sector has been used as a variable representing non-pecuniary job attributes. Dagsvik and Strøm (2006) differentiate, for instance, between private and public sectors, assuming that jobs in these sectors may differ in terms of non-pecuniary attributes. In a recent paper, Kunze and Suppa (2013) investigate the effect of introducing job characteristics in discrete choice models of labour supply, where alternatives are defined over discrete hours choices but interactions between job characteristics, income and leisure enter the utility function. Contrary to Kunze and Suppa (2013), in this paper, we propose a discrete choice model where the choice alternatives are characterised by bundles of income, hours of work and working conditions, job insecurity in our case, in order to allow for more flexibility in the choices available to individuals.

Job insecurity is considered to be one of the most important domains at work (Clark, 2001 and 2010). Moreover, job insecurity has proved to significantly affect individuals' outcomes such as well-being (Clark, 2001 and 2010; Green et al., 2013), health (Ferrie, 1998; Burgard et al., 2009) and organizational commitment (Hellgreen et al., 1999; Lord and Hartley, 1998; Rosenblatt et al., 1999). For these reasons, we would expect job insecurity to affect labour supply. It is important to remark that the concept of job insecurity embodies several factors which need to be taken into account. According to Greenhalgh and Rosenblatt (1984) job insecurity is defined as the perceived powerlessness to maintain the desired job continuity. The idea that job insecurity refers to individuals' perception of their job situation highlights the fact that both a subjective and an objective component characterise this concept. Individuals evaluate their level of job insecurity based on objective information from their jobs. Despite the subjective nature of this variable, studies have shown that perceived job insecurity provides reliable information about objective indicators of insecure jobs. In particular, perceived job insecurity is significantly associated with temporary

employment and job sector; public sector being considered more secure than the private sector (Näswall and De Witte, 2003; Deloffre and Rioux, 2003; Campbell et al., 2007; and Clark and Postel-Vinay, 2009). Moreover, perceived job insecurity has proved to be a good predictor of future unemployment experiences even after controlling for observed objective variables, implying that self-perceived job insecurity contains useful private information about jobs, which is otherwise not directly available in surveys (Campbell et al., 2007; and Deloffre and Rioux, 2003). In fact, restructurations such as privatization of formerly public companies, as well as layoffs have been shown to increase self-perceived job insecurity (Nelson et al., 1995; and Ferrie et al., 1995). While acknowledging the particularities related to the concept of job insecurity, in this paper we consider it as a proxy for an indicator of the objective insecurity characterising a job. Throughout our analysis, we discuss the implications of such assumption given the type of information available in the British Household Panel Survey (BHPS) used in our study.

Our contribution to the literature is twofold. First, we provide an extension of discrete choice labour supply models in order to allow for the introduction of non-pecuniary job attributes in the analysis, in our case job insecurity. We analyse how such extension affects labour supply elasticities. Moreover, we complement the literature on the consequences of job insecurity. In particular, we show that job insecurity has a significant effect on labour supply decisions, which could be of interest to design labour market policies based on non-monetary incentives. The paper is structured as follows. Section 2 presents the discrete choice models to be used in our labour supply analysis. First, we present the traditional labour supply model where only hours of work define the choice set. Then, the extended conditional logit is introduced in order to allow the choice set to be characterised by bundles of hours of work and job insecurity. Section 3 describes the data and presents some summary statistics. Section 4 presents the estimates of the structural labour supply models. Section 5 discusses labour responses in terms of wage elasticities and changes in the predicted probabilities from a decrease of job insecurity. Finally, section 6 concludes.

2 Discrete choice models of labour supply

In this section we describe the model most widely used to estimate discrete choice labour supply, namely the conditional logit model. The model is derived under the assumption of utility maximisation. Consider individual i chooses among a finite number of job alternatives, J . The utility obtained from alternative j is U_{ij} , $j = 1, \dots, J$. Individual i chooses alternative j if and only if $U_{ij} > U_{ik}$, $\forall k \neq j$. The utility function can be decomposed in a deterministic and a stochastic component:¹ $U_{ij} = V_{ij} + \varepsilon_{ij}$, where the distribution of the random vector $\varepsilon_i = \{\varepsilon_{i1}, \dots, \varepsilon_{iJ}\}$ is given by $F(\varepsilon_i)$. The probability that a particular alternative j is chosen is:

$$\begin{aligned} P_{ij} &= \text{Prob}(U_{ij} > U_{ik}, \forall k \neq j) \\ &= \text{Prob}(V_{ij} + \varepsilon_{ij} > V_{ik} + \varepsilon_{ik}, \forall k \neq j) \\ &= \text{Prob}(\varepsilon_{ik} < \varepsilon_{ij} + V_{ij} - V_{ik}, \forall k \neq j) \end{aligned}$$

Depending on the specification of the distribution of the random component, different discrete choice models can be obtained. The conditional logit model is obtained assuming that the stochastic component, ε_{ij} is independent and identically distributed over alternatives and follows a type-one extreme value distribution, given by:

$$F(\varepsilon_{ij}) = e^{-e^{-\varepsilon_{ij}}}$$

Under the conditional logit setup, the probability that alternative j is chosen is given by:²

$$\begin{aligned} P_{ij} &= \text{Prob}(\varepsilon_{ik} < \varepsilon_{ij} + V_{ij} - V_{ik}, \forall k \neq j) \\ &= \frac{e^{V_{ij}}}{\sum_{k=1}^J e^{V_{ik}}}. \end{aligned}$$

In our basic model, individuals choose among a finite number of working hours alternatives in order to maximise their utility, defined over net income and hours of work. We assume that the gross wage rates are fixed and independent of the hours of work. The decision is taken given the gross wage rates and the tax and benefit system.³

¹For this reason, these models are also known as random utility models.

²See McFadden (1974) for a proof.

³A tax and benefit microsimulation is performed in order to calculate the individuals' net income from their gross income (see section 4).

More formally, let h_i be the number of hours worked by individual i . We define J discrete hours alternatives so that h_{ij} represents the number of hours worked by individual i under alternative j , with $j = 1, \dots, J$. In our model, four alternatives are defined, $J = 4$: inactivity, part-time, full-time, overtime. Let y_{ij} be individual i 's net income given the hours choice h_{ij} and x_i a vector of individual characteristics. The net income y_{ij} , when $h_i = h_{ij}$ is chosen, is defined as:

$$y_{ij} = w_i * h_{ij} + \mu_i + G(w_i, h_{ij}, \mu_i, x_i)$$

where w_i are gross hourly wage rates, μ_i is non-labour income and the function $G(w_i, h_{ij}, \mu_i, x_i)$ represents the tax-benefit rules which depend on gross wages, hours of work, non-labour income and individual characteristics. Several functional forms can be used to specify the deterministic part of the utility function. Here, we define it as a second order polynomial. In our basic conditional logit model, the deterministic part of the utility function is given by:

$$V(y_{ij}, h_{ij}, x_i) = \alpha_1 y_{ij}^2 + \alpha_2 h_{ij}^2 + \alpha_3 y_{ij} h_{ij} + (\beta_1 x_i') y_{ij} + (\beta_2 x_i') h_{ij} ,$$

while in our extended model, job insecurity is introduced as a non-pecuniary job attribute affecting labour supply. Three job insecurity levels are defined and, therefore, a total of ten alternatives representing combinations of income, hours of work and job insecurity levels are available. More formally, let s_{ij} , represent the level of job insecurity of individual i under alternative j . The deterministic part of the utility function, in our extended model is given by:

$$V(y_{ij}, h_{ij}, s_{ij}, x_i) = \alpha_1 y_{ij}^2 + \alpha_2 h_{ij}^2 + \alpha_3 s_{ij}^2 + \alpha_4 y_{ij} * h_{ij} + \alpha_5 y_{ij} * s_{ij} \\ + \alpha_6 h_{ij} * s_{ij} + (\beta_1 x_i') y_{ij} + (\beta_2 x_i') h_{ij} + (\beta_3 x_i') s_{ij}$$

The interactions between personal characteristics and job attributes serves to account for observed heterogeneity in preferences. Discrete choice labour supply models also allow to account for unobserved heterogeneity in preferences, by introducing random terms in the deterministic part of the utility function (see Train, 1998; and Train, 2003). In our empirical analysis, unobserved heterogeneity of preferences is not accounted for given the small size of our sample.

The sample likelihood function for the conditional logit model is given by:

$$L = \prod_{i=1}^N \prod_{j=1}^J [P_{ij}(y_{ij}, h_{ij}, x_i)]^{d_{ij}}$$

where d_{ij} is a dummy equal to one if individual i chooses alternative j and zero otherwise.

Note that in order to construct the discrete choice alternatives in labour supply models it is usually assumed that gross hourly wages are fixed and independent of hours of work.⁴ While independence between wages and hours of work is in general accepted in the structural labour supply literature, in our extended models the relationship between wages and job insecurity deserves more attention. In fact, if job insecurity is considered a disamenity some sort of compensating wage differentials might exist for jobs with higher insecurity, which would need to be taken into account in our labour supply model.⁵ For instance, consider an individual currently in a job with low job insecurity, in order to construct all her possible choice alternatives, we need to define what would be her wage under the alternative of middle and high insecurity. In this study, we take into account the relationship between wages and job insecurity by randomly assigning wages by education groups from the wage distribution, as will be explained in Section 3.

3 Data

The data for our analysis comes from wave 10 of the British Household Panel Survey containing information for years 2000 and 2001. The BHPS is a nationally representative survey for the United Kingdom, which provides information about individual and household characteristics, wages, other income sources and working conditions. Wave 10 of the BHPS contains 15,603 individuals, however, we restrict our analysis to single females, who gave full interview. This restriction is made for two reasons. First, focusing on single individuals enables us to neglect interactions within the household in the context of labour supply. Second, the sample of single males is too small for the estimation of the models and a joint estimation of males and females biases the results for women. As it is usually done in the literature, we further exclude individuals in self-employment because their labour supply decisions may differ considerably from

⁴Some exceptions are studies by Aaberge and coauthors. See for instance Aaberge and Colombino (2013).

⁵For a theoretical discussion about compensating wage differentials see Rosen (1987).

those of salaried workers and their income information from surveys is considered less reliable than for employees. Disabled individuals, full-time student and pensioners are also excluded in order to keep only those individuals available for the labour market. This leaves us with a sample of 750 females.

Before restricting our analysis to our sample of interest we need to treat the problem of non-observed wages for non-workers. We do this by estimating a two-step Heckman selection model for women, using the whole sample. We use as regressors the usual variables found in the literature: age, education and region dummies are used for the wage equation while non-labour income, being married and having children of different ages are added in the selection equation. The results of the estimation are shown in Table 1.

Most variables present the expected signs, both in the selection and in the wage equations. In particular, wages and the probability of participation increase with age at a decreasing rate. The higher the level of education, the higher the probability of participation and the higher the wage. Being married decreases the probability of participation for women, as expected. Participation is lower with the presence of young children in the household and these effects are significant. Non-labour income has the expected negative and significant effect on participation. Finally, the coefficient for the inverse Mill's ratio is positive and significant, implying a selectivity and therefore that the observed wages are higher than the wage offers of a random sample.

Using the results obtained with the Heckman selection model, gross hourly wages are imputed for non-workers. Once the information on gross hourly wages is available for all individuals, we need to calculate the disposable income for each discrete hours alternative. For this, we developed our own tax and benefit microsimulation model for the BHPS, based on EUROMOD version 21A (see Sutherland and Gutierrez, 2004). Eleven tax and benefit rules are simulated: minimum wage, national insurance employee contributions, contributory job seekers allowance, winter fuel allowance, income tax, children's tax credit, child benefit, working families tax credit, income support, housing benefit and council tax benefit. Other benefits are not simulated but are included in the calculation of disposable income.⁶

Consider now the distribution of weekly hours of women in our sample, presented in Figure 1. We observe important peaks for inactivity and full-time work (around 40 hours per week), as well as a small peak for part-time work (around 20 hours per week). Taking this into consideration, we define four discrete hours points, characterising inactivity, part-time work, full-time work and over-work: $h = \{0, 20, 40, 55\}$ which correspond to the intervals $0 - 5, 6 - 34, 35 - 45, > 45$. These discrete hours points represent the set of alternatives in our basic model.

⁶ A detailed description of the tax and benefit microsimulation model for the BHPS can be made available on request from the author.

Figure 1: Distribution of female weekly hours of work

In the extended model, job insecurity is used as a non-pecuniary job attribute to be included in the job choice bundle. The BHPS provides information concerning satisfaction with job security at work. Job security takes values between 1 and 7 with 1 representing that the individual is "not satisfied at all" with job security at work and 7, that the individual is "completely satisfied". As discussed in the introduction, despite the subjective nature of this variable self-perceived job insecurity is associated with objective indicators of insecure jobs, such as temporary contracts (see Näswall and De Witte, 2003; Deloffre and Rioux, 2003; Campbell et al., 2007; and Clark and Postel-Vinay, 2009). Moreover, satisfaction with job insecurity is correlated with other type of information about self-perceived job insecurity, such as the likelihood of becoming unemployed. For our extended labour supply model, we generate a job insecurity variable taking values 2, 4 and 6, where 2 represents "low job insecurity" (values 5 to 7 from the original variable; satisfied with job security), 4 represents "middle job insecurity" (value 4 from the original variable; neither satisfied nor dissatisfied) and 6 "high job insecurity" (values 1 to 3 from the original variable; dissatisfied with job security). By regrouping the original values in such way, we expect to capture better those individuals in insecure jobs (those dissatisfied with their job security) and at the same time this allows us to save computational time by reducing the number of choice alternatives. Ten discrete choice alternatives are therefore defined for the extended model, representing bundles

of hours of work and job insecurity: $(h, insec)$, where $h = \{0, 20, 40, 55\}$ and $insec = \{2, 4, 6\}$.⁷

As mentioned in the previous section, in order to construct the discrete choice alternatives in our extended labour supply models, we need to consider the relationship between wages and job insecurity. In the data, for each individual we observe a gross hourly wage and a particular level of job insecurity. In order to define the wage rate related to other levels of job insecurity, we first impute wages by randomly assigning from the wage distribution of individuals with the same level of education but which are observed in a different job insecurity group. In this way, for each individual in our sample we obtain three gross hourly wage rates related to low, middle and high job insecurity. The average hourly wages for each level of insecurity are presented in the Table 2. We observe that on average wages increase with the level of job insecurity, which is in line with the idea of compensating wage differentials (see Rosen, 1987).

Table 2. Average gross hourly wages by job insecurity level (£/week)

	mean	std. dev.
low job insecurity	8.1525	5.5656
middle job insecurity	8.1737	5.1319
high job insecurity	8.2691	4.8355

In order to avoid big differences between the observed wage and the imputed wages for other insecurity levels. We construct our wage-insecurity levels with respect to the average gross hourly wages of the whole population. Consider for instance that the job of individual i is characterised by a gross hourly wage w_i and a low level of job insecurity. The gross hourly wage of individual i under middle job insecurity will then be given by $w_i + w_i(8.1737 - 8.1525)/8.1525$ and under high insecurity by $w_i + w_i(8.2691 - 8.1525)/8.1525$.

The remainder of this section provides some summary statistics for each discrete hours alternative of our sample of interest. Means and standard deviations of the variables used in our labour supply model are presented in Appendix A. Table 3 confirms that the two main groups are full-time work and inactivity. Average age is slightly higher in the part-time and overtime work groups. The inactivity group presents the lowest percentage of individuals with higher education. In particular, only 24.26% of the inactives have higher education, compared to 68.75%, in overtime work. In terms of job insecurity, the percentage of women dissatisfied with their job security situation is the highest for overtime jobs.

⁷The results are robust for different values of discrete hours of work and job insecurity.

Table 3. Discrete employment statistics

Hours per week	Share (%)	Age	Higher education (%)	Net income per week	Job insecurity (% dissatisfied)
0	31.33	36.49	24.26	203.40	-
20	27.87	38.92	39.71	221.66	11.96
40	36.53	37.67	56.57	304.30	13.87
55	4.27	39.13	68.75	322.08	18.75

4 Empirical results

This section presents the results of the structural labour supply estimation. Two models are estimated and compared. The first model is the conditional logit model traditionally used in the discrete choice literature to estimate labour supply, in which only discrete hours alternatives define the choice set. The second model consists of an extension to the basic conditional logit model, where the choice set is now defined by combinations of hours of work and job insecurity and where job insecurity is set to zero for the inactives.⁸ In both models, age, higher education dummies and dummies for children of different ages are used as regressors to account for observed heterogeneity in preferences. Table 4 presents the estimated parameters for these models.

⁸A nested logit model was also estimated, in which alternatives are grouped into two nests representing inactivity and participation. The inactivity nest contains a single alternative while the participation nest is formed by alternatives characterised by bundles of hours of work and job insecurity. The results obtained with the nested logit model are similar to those presented in the paper.

x child 3-4	-	-	0.078	(0.122)
x child 5-11	-	-	0.126*	(0.068)
x child 12-18	-	-	-0.050	(0.069)

Notes: The main variables have been rescaled as follows:

y =income/1000; h =hours/10; age=age/10.

Standard errors in parentheses; * p <0.05. ** p <0.01. *** p <0.001

In general our results are in line with our expectations and coefficients across the models estimated go in the same direction. For both models, marginal utility of income is positive for over 99% of observations and as the coefficient of income square is negative, concavity in income for the utility function is respected. Marginal utility of hours of work is negative for around 78% of observations in the basic labour supply model, while under the extended model this holds for a slightly lower percentage of cases, of around 70%. Turning to job insecurity, marginal utility is negative for around 90% of observations in our extended model. Moreover, the estimated effects of job insecurity are significant, confirming the importance of accounting for non-pecuniary job attributes on labour supply.

In line with our expectations, single women with young children have lower preferences for work and these effects are significant in both models estimated. In particular, the strongest negative effect is for women with very young children aged under 3 years-old. Similarly, for both the basic and extended model, individuals with higher education have higher preferences for work and the interaction between hours of work and age presents a negative and significant coefficient. Turning to job insecurity, we remark that only the interaction with age presents a significant coefficient, however, the coefficient is positive, while we would expect preferences for job insecurity to decrease with age. Women with children aged less than 3 present lower preferences for job insecurity, as expected, however, the effect is not significant.

The ability of our models to fit the data can be tested by comparing predicted and observed frequencies. Predicted frequencies are obtained by averaging up individual probabilities for each discrete hours alternative over the whole sample, while observed frequencies are simply the frequencies of each observed choice over the whole sample. Table 5 shows that the basic conditional logit, where only hours of work define the choice set, performs poorly in terms of fitting the data. Full-time is considerably underestimated and part-time is strongly overestimated. These results are in line with the literature, where such problems have been treated mainly by adding alternative specific dummies (Van Soest, 1995) or fixed costs of work (Blundell et al., 2000). Here we consider whether the additional information in terms of job characteristics serves to improve the predictive power of the model. This seems to be indeed the case, as the introduction of job insecurity into the model improves considerably the fit of the data.

Table 5. Observed vs predicted frequencies

Alternatives	Observed	Predicted	
		Conditional: hours	Conditional: insecurity
Inactivity	31.33	28.19	32.00
Part-time	27.87	37.19	25.77
Full-time	36.53	25.97	38.93
Overtime	4.27	8.66	3.30
Inactivity	31.33	-	32.00
Part-time			
low insecurity	22.93	-	20.11
mid. insecurity	1.60	-	2.28
high insecurity	3.33	-	3.38
Full-time			
low insecurity	29.20	-	30.76
mid. insecurity	2.27	-	3.36
high insecurity	5.07	-	4.81
Overtime			
low insecurity	3.33	-	2.64
mid. insecurity	0.13	-	0.28
high insecurity	0.80	-	0.38

5 Labour supply elasticities and responses to changes in job insecurity

The parameter estimates obtained in the previous section can be used to calculate labour supply elasticities and to analyse the effects of policy reforms on participation and labour supply. The aim of this section is twofold. First, wage elasticities obtained with our models are compared. Then, using our extended model, we analyse the effect of a change in job insecurity on labour supply.

Labour supply elasticities in discrete choice models are calculated numerically using the estimated parameters of the utility function (see Creedy and Kalb, 2005). First, we increase gross hourly wages by 1% and compute the new disposable income for each alternative using our tax and benefit microsimulation model. Then, with the parameters from the utility function, obtained in the previous estimation, we calculate the average simulated probability of being at each alternative for both the old and the new value of disposable income.

These probabilities are then used to compute the expected value of labour supply before and after the wage increase, following:

$$E[h|y, x] = \sum_{j=1}^J P_{ij} * h_j$$

Finally, labour supply elasticities are computed numerically by dividing the percentage change in expected labour supply by the percentage change in wages, 1% in this case. Table 6 shows the elasticities obtained for men and women with both the conditional the nested logit models.

Table 6. Labour supply wage elasticities

	Conditional logit: hours	Conditional logit: insecurity
Total	0.126	0.153*
low job insecurity	-	0.141*
middle job insecurity	-	0.158*
high job insecurity	-	0.158*

*significantly different than the elasticity of the basic conditional logit

The models estimated provide labour supply elasticities which are quite in line with previous studies. In fact, elasticities for single females are in general between 0 and 0.3. Our basic conditional logit model provides a labour supply elasticity of 0.126, while our extended labour supply model provides a higher elasticity of 0.158. In order to test whether the difference is significant, we used bootstrapping techniques with 1000 repetitions. The elasticity obtained with our extended labour supply model turned out to be significantly different than that of the basic model. A further distinction can be made in our extended conditional logit model, by calculating elasticities for different levels of job insecurity. Labour supply elasticities are lower under low job insecurity compared to middle and high insecurity. This result suggests that wage increases would have weaker effects for women facing good conditions at work, in terms of job security.

In addition to the calculation of labour supply elasticities, our extended model allows us to analyse the effect of job insecurity on labour supply. However, because of the qualitative nature of our job insecurity variable, the same methodology used to calculate wage elasticities cannot be applied. Here we simulate the effect of a decrease of job insecurity by observing the change in predicted probabilities calculated by our model. We decrease levels of job insecurity by the equivalent of one standard deviation of job insecurity (std. dev.

1.392) for individuals with middle and high insecurity. Table 7 presents the predicted probabilities calculated with our model before and after the decrease in job insecurity.

Table 7. The effect of a decrease in job insecurity

	Predicted probabilities	
	Conditional logit: insecurity	
	before	after
Inactivity	32.00	29.52
Part-time	25.77	27.02
Full-time	38.93	40.09
Overtime	3.30	3.37

Our results show that a decrease in job insecurity has a positive effect on participation. In fact, the probability of inactivity decreases by around 2.5 percentage points. All working alternatives present an increase, the most important being part-time and full-time. This result is particularly interesting in terms of policy because objectives aimed at providing incentives for participation could also be achieved through the channel of improving non-pecuniary job attributes, and not only through monetary incentives. In order to have an idea of the magnitude that the decrease in inactivity represents, we calculated the increase in overall gross wages necessary to obtain an equivalent decrease in inactivity. An increase in overall gross wages of around 20% would be needed in order to obtain a similar decrease in the probability of inactivity. These results provide an interesting insight into the effect of non-pecuniary job attributes on labour supply, however, it is important to remark that this labour supply model doesn't take into account the reaction of firms to policies aimed at improving working conditions. In fact, from the demand side, providing better working conditions might represent additional costs which could be linked to a decrease in wages. This would result in a negative effect of labour supply and therefore the total effect would be ambiguous. The incorporation of labour demand within our setting is an important step for future research.

6 Conclusion

The aim of this paper was to provide an insight into the effect of non-pecuniary job attributes on labour supply. Two models were estimated and compared. First, we estimated a conditional logit model where the choice set is defined only in terms of discrete hours alternatives. This is the approach most widely used to estimate discrete choice labour supply. Then, we proposed an extension to the model in which the choice set is characterised by bundles of income, hours of work and job characteristics, job insecurity in our case. The estimation of these structural labour supply models was done using maximum likelihood.

Different observations can be drawn from our results. First of all, as expected, job insecurity has a negative effect on individuals' utility, with a calculated marginal utility which is negative for around 90% of the observations. Second, the predictive power of the model improves considerably when job insecurity is included as an attribute of choice, compared to the basic conditional logit model without alternative specific dummies or fixed costs of work. Third, labour supply elasticities calculated with the extended labour supply model are higher than those of the traditional conditional logit model and these differences are significant. Moreover, wage elasticities for women working under low job insecurity are lower than those of females in middle and high insecurity jobs implying that individuals working under good job security conditions would respond less to wage changes. Finally, a decrease of job insecurity decreases the probability of inactivity by around 2.5 percentage points. This result is particularly interesting as it suggests that policies aimed at improving working conditions could be used to create incentives for labour market participation.

An important aspect behind our results is the use of self-reported working conditions, in our case self-perceived job insecurity. This is the type of information available in most household surveys. While perceived job insecurity has been shown to be associated with objective indicators of insecure jobs, it is important to bare in mind that a subjective component characterises such measures. In particular, it could be the case, for some individuals, that an improvement in objective job security factors would not be reflected in a better subjective perception of job security. For this reason, the findings obtained in this study should be contrasted with future analysis using objective measures of working conditions. In the case of job insecurity, for instance, an indicator of objective insecurity could be constructed based on information concerning temporary employment, sector of work, presence of job security guarantees at the firm level (available in linked employer-employee data), among others.

To conclude, we believe that the incorporation of working conditions in the analysis of labour supply offers potential opportunities for future research. In particular, multiple factors characterise jobs therefore a better understanding of the main attributes influencing labour market participation could be useful from

a policy perspective. Moreover, it should be possible to consider to which extent (if any) incorporating job attributes in behavioural microsimulation models affects *ex-ante* evaluations of policy reforms. Finally, from a methodological point of view, the incorporation of additional job attributes highlights the importance of accounting for possible correlations between wages and job characteristics as part of the analysis of labour supply.
