## Optimal Pricing in the Telecommunications Market

by Harald Lang and Stefan Lundgren

### Summary

The paper addresses the question whether current tariffs for telecommunications services at the Swedish telecommunications company, Televerket (TVT), are optimal as second-best "Ramsey" prices. Focusing on two tariffs for telecommunications services – those on subscription and calling time – the paper estimates whether there is room for an increase of consumers' surplus with current net revenue for TVT unchanged. To this end, a micro model is constructed in which consumers differ as to "taste" for using a telephone and as to income. In order to make or receive calls, the consumer has to buy a subscription. The utility maximising consumer chooses if to subscribe or not and, if subscribing, how much to call. The resulting individual demands are aggregated over a density of taste and income. This simple model gives the following two relations between elasticities, where  $S$  is the number of subscriptions,  $X$  the number of calling-minutes,  $p_s$  and  $p_x$  the corresponding prices:

$$\frac{\epsilon X}{\epsilon p_s} = 2 \frac{\epsilon S}{\epsilon p_s} \frac{x_m}{x}$$

$$\frac{\epsilon S}{\epsilon p_x} = \frac{\epsilon S}{\epsilon p_s} \frac{p_x x_m}{p_s}$$

Here  $x$  is the average calling time for all subscribers,  $x_m$  is a weighed average of calling time over marginal subscribers. These formulas give us the cross-elasticities  $\epsilon X/\epsilon p_s$  and  $\epsilon S/\epsilon p_x$  once the own-price elasticity  $\epsilon S/\epsilon p_s$  and the levels of  $x$  and  $x_m$  are known. The value of  $\epsilon S/\epsilon p_s$  is taken from the literature; the value of  $x$  from a data set that has been collected jointly by IUI and TVT: about 5000 subscribers' calling times has been measured for three (non-adjacent) weeks.

This data set has also been used to estimate the own-price elasticity  $\epsilon x/\epsilon p_x$  when the number of subscribers is held fixed. The demand  $x(p_x)$  is assumed be exponential, i.e.,  $\epsilon x/\epsilon p_x$  is proportional to  $p_x$ . The tariff for calling time is differentiated in two dimensions: as to distance zone and as to point in time of the week (day-night, holiday-weekday). Demand is assumed to show substitution effects across points in time, but not across different distance zones. This makes it possible to estimate  $\epsilon x/\epsilon p_x$  (and in principle also the cross

elasticity across points in time, although these are not accurate). The result is that  $\epsilon_X/\epsilon_{p_X} = 0.012 \cdot p_X$ , where  $p$  is öre/minute. However, total demand  $X$  is also influenced via  $S$  so, from the micro model, (we assume that  $x=x_m$ ) the total effect is

$$\frac{\epsilon_X}{\epsilon_{p_X}} = \frac{\epsilon_X}{\epsilon_{p_X}} + 2 \frac{\epsilon_S}{\epsilon_{p_S}} \frac{X p_X}{p_S}$$

The consumers' surplus is affected also via external effects: the network externalities of subscriptions. We argue that the value for other consumers of a subscription at the margin is equal to  $p_S$ .

Equipped with these numbers, we calculate the optimal marginal price adjustment that keep TVT's net revenue constant. The result suggests that price on subscription and very long distance calls are too high, whereas price on local calls is too low. The results are presented in appendix C.

APPENDIX A:  
The Model of Demand

A consumer has the utility  $u(x,y;\theta,S)$ , where  $x$  is his consumption of telephone call time,  $y$  consumption of other goods,  $\theta$  is a "taste" parameter and  $S$  is the total number of subscribers.  $x=\{x_{ji}(t)\}$ , where  $x_{ji}(t)$  is a phone call in distance zone  $j$ , at time period  $i$  of duration  $t$ . With  $p_y$  price on good  $y$ ,  $p_s$  price on subscription,  $I$  income and  $p_{ji}(t)$  the telephone call tariff, the consumer chooses to subscribe iff  $u^S \geq u^n$ , where

$$u^S(p,p_s,\theta,I,S) \equiv \max_{x,y} u(x,y;\theta,S) \text{ s.t. } \sum_{i,j} \int_0^\infty p_{ji}(t)x(t) dt + p_y y + p_s = I$$

$$u^n(\theta,I,S) \equiv \max_y u(0,y;\theta,S) \text{ s.t. } p_y y = I$$

We define  $v \equiv u^S - u^n$  which is assumed be increasing in  $\theta$ . This means that the consumer subscribes iff  $\theta \geq \theta_0(I)$  where  $\theta_0(I)$  defined by

$$v(p,p_s,\theta_0,I,S) = 0. \tag{1}$$

From now on we simplify notation so  $x \equiv$  demand for telephone call time, and  $p_x$  price on calling time. A fuller account of the model is given in the Swedish version (the rationale for the more complicated version is that tariffs are not proportional).

The consumers are supposed to be distributed in  $\theta$  and  $I$  according to the density function  $g(\theta,I)$ . Hence aggregated demand for calling time is

$$X = \int_0^\infty \int_{\theta_0(I)}^\infty x(\theta,I)g(\theta,I) d\theta dI$$

and the total number of subscribers is

$$S = \int_0^\infty \int_{\theta_0(I)}^\infty g(\theta,I) d\theta dI \tag{2}$$

It is important to note that  $S$  enters the utility function. In fact, we show in the fuller Swedish version that under the assumption that subscriptions are neither substitutes nor complements for each other, the derivative (CS= consumer's surplus)  $\partial CS/\partial S = p_s$ .

As an example, let us derive the second elasticity formula given in the Summary. The full derivations of all formulas are given in the Swedish version.

Differentiating (2) w.r.t.  $p_s$  gives

$$\frac{\partial S}{\partial p_s} = - \int_0^{\infty} g(\theta_0(I), I) \frac{\partial \theta_0}{\partial p_s} dI$$

and from (1)

$$\frac{\partial \theta_0}{\partial p_s} = - \frac{v_{p_s} + v_s \frac{\partial S}{\partial p_s}}{v_\theta}$$

hence

$$\frac{\partial S}{\partial p_s} = \int_0^{\infty} g(\theta_0(I), I) \frac{v_{p_s} + v_s \frac{\partial S}{\partial p_s}}{v_\theta} dI$$

We define

$$H = \int_0^{\infty} g(\theta_0(I), I) \frac{v_s}{v_\theta} dI$$

and get

$$(1-H) \frac{\partial S}{\partial p_s} = \int_0^{\infty} g(\theta_0(I), I) \frac{v_{p_s}}{v_\theta} dI \quad (3)$$

We also define  $h(I)$  by

$$h(I) = \frac{g(\theta_0(I), I) v_{p_s} (\theta_0(I), I) / v_\theta (\theta_0(I), I)}{(1-H) \frac{\partial S}{\partial p_s}} \quad (4)$$

which is thus a density function: it integrates to 1 and is positive since both numerator and denominator are negative.

The following formula is derived in the same way as (3):

$$(1-H) \frac{\partial S}{\partial p_x} = \int_0^{\infty} g(\theta_0(I), I) \frac{v_{p_x}}{v_\theta} dI \quad (5)$$

By Roy's identity,

$$v_{p_x} = -u_I^S x, \quad v_{p_s} = -u_I^S, \quad \text{i.e.,}$$

$$v_{p_x} = v_{p_s} x$$

Inserting this into (5), we get, using (4),

$$\begin{aligned} (1-H) \frac{\partial S}{\partial p_x} &= \int_0^{\infty} g(\theta_0(I), I) \frac{v_{p_s} x}{v_\theta} dI \\ &= (1-H) \frac{\partial S}{\partial p_s} \int_0^{\infty} h(I) x(\theta_0(I), I) dI \end{aligned} \quad (6)$$

Here the last integral is a weighed average of marginal consumers' demand for calling time. We introduce the notation

$$x_m \equiv \int_0^{\infty} h(I)x(\theta_0(I), I) dI$$

and by (3) and (6) we get

$$\frac{\partial S}{\partial p_x} = \frac{\partial S}{\partial p_s} x_m \quad \text{i.e.,} \quad \frac{\epsilon_S}{\epsilon_{p_x}} = \frac{\epsilon_S}{\epsilon_{p_s}} \frac{p_x x_m}{p_s}$$

APPENDIX B:

Demand Elasticity of Telephone Call Time

The model

It is often observed that the demand elasticity for calling time is increasing in price. Partly leaning against this, we assume that the elasticity  $E$  is proportional to price  $p$ :  $E = \theta p$ . This corresponds to the demand function  $x_{d,t} = A \cdot e^{-\theta p}$ , where  $x_{d,t}$  is expected demand at time  $t$  for calling time for distance zone  $d$  type calls under, say, one hour. The constant  $A$  is assumed to vary with point in time,  $t$ , with  $d$  and with other prices. A subscriber who contemplates to make a zone  $d$  call must decide at which time  $t$  to make the call, and he is then assumed to take prices for type  $d$  calls at various times into account, but not explicitly the distance zone  $d$ . This leads to a specification  $A=f(d)h(t,q)$  where  $q$  is the vector of prices for type  $d$  calls at time periods other than  $t$ .

We assume that the income effect is negligible, and this causes a (Slutsky) symmetry restriction on demand. The simplest demand function we can figure out consistent with the above restrictions is

$$x_{d,t} = f(d)e^{-\theta p}(g(t)-c \cdot e^{-\theta p'})$$

where  $p'$  is the sum of all prices for type  $d$  calls at time periods different from  $t$ . Actually,  $c$  could depend on  $d$ , but we restrict  $c$  to be a constant to avoid an over-parameterisation problem.

The Data

The data set consists of information on total calling time divided into 24 categories for about 4000 individuals during 3 weeks: one week in March 1988, one in June and one in September. The 24 categories are defined by 4 periods of time during the week, and 6 distance zones. The time periods are weekdays 8-12, 12-18, 18-22, and other time; the distance zones are national trunk calls <45 km, long distance calls <45 km, 45-90 km, 90-180 km, 180-270 km and >270 km. In each of these 24 categories, the price on calling time is constant during each measured week, but there is a substantial price change between the first measuring period and the second. The equation has been estimated separately for the three weeks. It would seem natural to exploit the price shift between the measuring weeks, but we haven't done that for the reasons that there is a lot of seasonal variation of demand and also a strong time trend. In order to correct for these

(as well other exogenous shifts), we need a much longer time series than we have access to.

Estimation

Since  $x_{d,t}$  is expected demand, the regression equation is

$$x_{d,t} = f(d)e^{-\theta p}(g(t)-c \cdot e^{-\theta p'}) + \epsilon_{d,t}$$

where  $E[\epsilon_{d,t}] = 0$  and  $E[\epsilon_{d,t}^2] = \sigma_{d,t}^2$ , and  $E[\epsilon_{d,t}\epsilon_{\delta,\tau}] = 0$  if  $d \neq \delta$  or  $t \neq \tau$ . The estimation technique is non-linear least squares, with the standard errors computed according to the formula referenced in White [1980] but adjusted for degrees of freedom. The results are presented in table 1. As we can see, the March equation suffers from multicollinearity; the lower fit compared to the June equation explains about 80% higher standard deviations, but most of the actual ones are well over 500% larger. However, the June and September equations yield very similar results, and  $\theta$  is reasonably well defined in these equations. We have no good explanation to offer why the March equation performs so badly. If the results for  $\theta$  are weighed together to minimise the variance, we get ( $p$  is in öre/min)

June+September	March+June+September
$\hat{\theta} = -0.0127$ SD=0.00329	$\hat{\theta} = -0.0122$ SD=0.00316

In principle it is also possible to compute the cross elasticities for calls between different time periods. However, we refrain from doing this for two reasons. First, these cross effects are rather crudely specified (the parameter  $c$  is not allowed to vary with  $d$ , for instance); secondly, the estimates of the coefficients determining them are not accurate enough to merit much interest in the result. Thus, we confine the analysis to the own-price elasticity  $\theta p$ .

Table 1

The estimated equation is  $s = e^{\sum \alpha_i D_i} (e^{\sum \beta_j T_j} - \delta e^{\theta p'}) e^{\theta p}$   
 where  $D_i$  are dummies for the distance categories,  $T_j$   
 dummies for the time periods ( $\beta_1=1$ );  $s$  is total calling  
 time in seconds per subscriber during one full week;  $p$   
 and  $p'$  are in öre/min.

coefficient	March	June	September
$\alpha_1$	1.39 (2.76)	2.31 (0.646)	2.63 (0.957)

APPENDIX C:  
Simulation Results

EA is the marginal external utility of a subscription. We can show that (under reasonable assumptions) this is (close to) Pa, the price on subscription. However, we also use EA = Pa/2 in the simulations.

Q is a parameter in the aggregate demand for calling time. If  $\bar{x}$  = average calls made by a subscriber, then  $Q \cdot \bar{x}$  new calls are generated by a marginal subscriber. One can argue that  $Q=2$  (the new subscriber makes  $\bar{x}$  calls and receives  $\bar{x}$  calls), but we also use  $Q=1$  and  $Q=2$  in the simulations.

"Lambda" is a Lagrange multiplier. If dr is a marginal change in revenues for TVT due to price changes, then the resulting loss of consumers' surplus is Lambda·dr.

The marginal price adjustments are in percentage points and normalised so that their squared sum equals 100.
