and Michael Haliassos<sup>3</sup>

March 30, 2005

### **Abstract:**

Wider participation in stockholding is often presumed to reduce wealth inequality. We measure and decompose changes in US wealth inequality between 1989 and 2001, a period of considerable spread of equity culture. Inequality in equity wealth is found to be important for net wealth inequality, despite equity's limited share. Our findings show that reduced wealth inequality is not a necessary outcome of the spread of equity culture. We estimate contributions of stockholder characteristics to levels and inequality in equity holdings, and we distinguish changes in configuration of the stockholder pool from changes in the influence of given characteristics. Our estimates imply that both the 1989 and the 2001 stockholder pools would have produced higher equity holdings in 1998 than were actually observed for 1998 stockholders. This arises from differences both in optimal holdings and in financial attitudes and practices, suggesting a dilution effect of the boom followed by a cleansing effect of the downturn. Cumulative gains and losses in stockholding are shown to be significantly influenced by length of household investment horizon and portfolio breadth but, controlling for those, use of professional advice is either insignificant or counterproductive.

## 1. Introduction

Participation of households in risky assets, especially in direct and indirect holdings of stocks grew substantially over the 1990s.<sup>1</sup> The increase in household participation in stockholding over the past fifteen years has been so dramatic that its aggregate implications merit careful study. Such implications include effects of increased stockholding participation on the equity premium, stock market volatility, and the distribution of wealth. A small number of interesting theoretical papers on these issues serve to highlight several important conflicting considerations that need to be taken into account, but make obvious that we are still far from conclusive answers.<sup>2</sup>

This paper focuses on implications of the spread of equity culture for the distribution of wealth, using data from several Surveys of Consumer Finances. Wealth inequality is of interest not only in its own right, but also because households at different points of the wealth distribution exhibit different financial and entrepreneurial behavior. Hurst and Lusardi (2004) have recently documented that a positive relationship between wealth and entry into entrepreneurship can be found only at the top five percentiles of the wealth distribution. Carroll (2001) showed that the portfolio behavior of rich households is quite different from that of households lower in the distribution of wealth, and richer households are not simply blown-up versions of poorer households. Wolff (1998) shows that only the top 20 percent of households enjoys higher mean net worth and financial wealth levels between 1983 and 1995, while the other groups undergo real wealth or income losses with the shortfall being more severe for the poor.

There is some theoretical justification for claims that increased stock market participation reduces wealth inequality. Arrow (1987) has stressed the inequality reducing effects of more households gaining access to financial instruments that bear an expected return premium. The findings of Guvenen (2002) support the notion that limited

stock market participation can account for much of US wealth inequality. It would not be unreasonable to infer from these findings that expanding participation is likely to reduce wealth inequality, by reducing the departure from full participation in the stock market.

Theoretical ambiguities arise, however, when full financial information and sophistication are not taken for granted among all participating households. Peress (2002) allowed investment in financial information to be costly and subject to the choice of market participants. In his model, greater participation could encourage more people to get informed about stock performance and sound practices of portfolio management. However, Peress also pointed to a conflicting effect on incentives to acquire information. With an expanded stockholder base, financial risk is spread among a greater number of investors, thus reducing incentives for each to invest in costly information acquisition, including incumbent stockholders.

Our basic premise in this paper is as follows. The empirical stock market participation literature has established that stockholders are not randomly drawn from the population. Certain characteristics, such as being income-rich, more educated, and less risk averse, have been found to make a household more likely to overcome entry costs and become a stockholder.<sup>3</sup> It follows that, as the stockholding participation margin spreads, the composition of the stockholder pool changes. Now, it is natural to think that, as more and more marginal investors are drawn into the market, the configuration of characteristics becomes less conducive to sizeable equity wealth. Yet, this is not necessarily true, as increased participation can be accompanied by substantial exits and entries into the pool. Moreover, it is useful to know if changes in levels of equity wealth as stockholding participation spreads are optimal given the new stockholder characteristics, or whether they result in part from changes in the ability of the stockholder pool to achieve gains and avoid losses in the stock market.

In this paper, we use data from the 1989, 1998, and 2001 waves of the US Surveys of Consumer Finances, the best source on household portfolios worldwide, to study these issues. Our analysis starts with a decomposition of net total wealth inequality and financial wealth inequality into their various sources (sections 2 and 3). We find that inequality in stock wealth has gained considerable importance as a source of overall net wealth inequality, despite the fact that equity represents a relatively small share of net wealth.

We then focus on equity wealth. In Section 4, we estimate the influence of household characteristics on levels and inequality of equity holdings. We use these estimates to construct counterfactual distributions of equity holdings that separate changes in the influence of investor characteristics from changes in the distribution of such characteristics as equity culture spreads. We find that the configurations of stockholder characteristics in both 1989 and in 2001 were more conducive to equity holdings than that of 1998 stockholders.

We next investigate whether these changes in equity holdings are fully accounted for by changes in “fundamental” economic characteristics of stockholders or are partly attributable to changes in ability of the stockholder pool to generate high equity wealth. Section 5 decomposes counterfactual effects of characteristics and shows that both economic fundamentals and financial attitudes and practices are likely to have played a role in changing the distribution of equity levels. Section 6 shows that effects of education, originally included under fundamentals, are sizeable and argues by use of econometric and computational techniques that even part of these may reflect differences in investor abilities. In Section 7, we show that household financial attitudes and practices contribute to achieving cumulative gains or avoiding losses in stockholding,

even when controlling for other factors, both for direct and for indirect stockholding, and for 1998 and 2001. Section 8 offers concluding remarks.

## 2. Inequality Indices

We use data from the United States Surveys of Consumer Finances, for 1989, 1998, and 2001. The data are particularly well suited for analysis of wealth holdings, since they over sample the rich and they are not subject to top-coding of wealthy households carried out in other surveys.<sup>4</sup> Definitions and details on the construction of the variables are provided in the Data Appendix.

Inequality indices often give different pictures of inequality, because they differ in their sensitivity to inequality in various parts of the distribution. We compute four measures of inequality. The first three belong to the so-called “generalized entropy class” (abbreviated as GE). Mean logarithmic deviation (MLD) of variable  $y$  with mean  $\mu$  and  $n$  observations is defined as:

$$MLD \equiv GE(0) = \frac{1}{n} \sum_{i=1}^n \log \frac{\mu}{y_i} \quad (1)$$

The Theil index is given by

$$Theil \equiv GE(1) = \frac{1}{n} \sum_{i=1}^n \frac{y_i}{\mu} \log \frac{y_i}{\mu} \quad (2)$$

while (half of the square of) the coefficient of variation (HSCV) is given by

$$HSCV \equiv GE(2) = \frac{1}{2n\mu^2} \sum_{i=1}^n (y_i - \mu)y_i = \frac{\text{var}(y)}{2\mu^2} \quad (3)$$

It can be shown that the more positive  $a$  is, the more sensitive  $GE(a)$  is to inequality at the top of the distribution. The fourth index is the Gini coefficient, which is most sensitive to income differences about the mode of the distribution:

$$Gini = \frac{2}{n^2 \mu} \sum_{i=1}^n \left(i - \frac{n+1}{2}\right) y_i, \text{ where } y_i\text{'s are in ascending order} \quad (4)$$

Table 1 shows that these four inequality indices for net overall wealth in 1989, 1998, and 2001 yield quite different pictures of the trend in net wealth inequality. MLD suggests a sizeable decrease in inequality between 1989 and 1998, followed by an increase to a level in 2001 that falls short of inequality at the starting point. The Theil and HSCV indices suggest increased inequality in 1998 compared to 1989, followed by a reduction in inequality between 1998 and 2001. The two indices differ in comparing the two end points in the period under consideration, with HSCV implying lower inequality in 2001 even compared to 1989. Finally, Gini suggests a slight increase in net wealth inequality over time.

Differences in implications of inequality indices reflect the difficulty of capturing changes in a whole distribution by a single number. Index differences can be traced to the different weights attached by each index to transfers from rich to poor at various points in the distribution.<sup>5</sup> Theil's index is influenced by the relative distance between the rich and the poor, attaching more weight to transfers *at the lower and at the upper end*. HSCV is very sensitive to changes in the *upper tail* of the distribution: it is very sensitive to inequality at high wealth levels but not so good at capturing inequality at other regions of the distribution (Cowell, 1977; Shorrocks, 1980). The patterns we observe suggest that movements in HSCV and Theil are caused mainly by what happened at the upper end of the wealth distribution, with net wealth inequality increasing during the stock market upswing of the 1990s and diminishing during the subsequent downturn. The Gini coefficient tends to attach more weight to wealth transfers that occur around the *middle* net wealth classes and so may miss and mask changes in inequality that arise from

developments at other parts of the distribution. Gini suggests a slight increase in inequality throughout the period under examination.

### 3. Inequality Decomposition by Sources

The literature of inequality decompositions by source shows that, we can express net total wealth inequality in a given year,  $I_W$ , as an exact sum of the contributions made by its various factor components:

$$I_W = \sum_f S_f \quad (5)$$

A wealth factor component contributes to increased (reduced) inequality if  $S_f > 0$  ( $< 0$ ).

The share of a particular factor  $f$ ,  $s_f$ , in generating inequality is defined as:  $s_f = \frac{S_f}{I_W}$ , and

thus:  $\sum_f s_f = 1$ .

HSCV seems an appropriate choice of index for wealth inequality decompositions, since it has desirable decomposability properties and it can handle the regular incidence of zero assets.<sup>6</sup> In what follows, we will focus on HSCV and on the often used Gini index.

#### 3.1. Decomposition of HSCV by Sources

Shorrocks (1982) proved that, under certain axioms, there is a unique “decomposition rule”, according to which the proportionate contribution of factor  $f$  can be derived – for a broad set of inequality measures – from:

$$s_f = \frac{\text{cov}(f, W)}{\sigma_W^2} \quad (6)$$

This is actually equivalent to the OLS estimated slope coefficient from the regression of wealth factor  $f$  on net total wealth  $W$ .

When inequality is summarized by HSCV,

$$s_f = \rho_{fW} \chi_f \sqrt{\frac{I_f}{I_W}} \quad (7)$$

This expresses the proportionate contribution of factor  $f$  in terms of factor correlation with total net wealth  $\rho_{fW}$ , the factor's share in net total wealth  $\chi_f$ , net total wealth inequality  $I_W$  and the factor inequality  $I_f$ , both measured by the HSCV. Thus, the absolute contribution of factor  $f$  is:  $S_f = \rho_{fW} \chi_f \sqrt{I_W I_f}$ .

The percentage of factor owners  $n_f^+$  and the inequality they exhibit among them  $I_f^+$  have an indirect effect on the factor contribution to inequality, given by:  $I_f = \left(\frac{1}{n_f^+}\right)(I_f^+ + 1) - 1$  (Jenkins, 1995). In our tables presenting wealth decompositions, we report along with factor correlations, factor shares, and factor inequalities, percentages of factor owners, and within factor inequalities.

Finally, we also report a measure of each factor's contribution to the evolution of inequality over time. A factor making an important contribution to total inequality in a given year does not necessarily play a prominent role in inequality changes over time. Following Jenkins (1995) we decompose HSCV trends over time as:

$$\% \Delta I = \frac{I_{t+1} - I_t}{I_t} = \sum_f s_f \% \Delta S_f, \text{ where a large positive value of } s_f \% \Delta S_f \text{ suggests an}$$

important role for factor  $f$  in raising total inequality over time.

Table 2 shows decompositions of inequality, as measured by HSCV, by sources. Risky real assets are the dominant source of overall net wealth inequality, making a more than 50 percent contribution in all three years. Ownership of risky real assets (excluding

primary residence) along with business equity is more prevalent among wealthier segments of the population, and ownership rates do not exhibit any strong trend between 1989 and 2001, hovering around 27 percent. Not surprisingly, risky real assets exhibit high degree of inequality and high correlation with overall net wealth. Yet in 1998, the year that overall inequality spikes by the HSCV measure, the absolute factor contribution of risky real assets and business equity increases only slightly (from 9.62 to 10.9). This is because the dropping factor share and correlation with net total wealth moderate the effects from the increase in this factor's inequality. Given the much higher increase in net total wealth inequality, the proportionate factor contribution actually drops (from 0.72 to 0.60).

Between 1989 and 1998, equity holdings exhibit a high increase in factor share, increased correlation with net total wealth, and increased inequality, all leading to a more than quadruple increase in their absolute factor contribution. In 1998, wealth in equity holdings records a more than 25 percent proportionate contribution towards total inequality from just 7 percent a decade ago. Directly and indirectly held equity plays the dominant role in the *increase* of overall net wealth inequality by 1998.

Between 1998 and 2001, reduction in inequality of equity holdings (attributable mainly to reduction in inequality among equity holders) more than outweighs the increase in their relative correlation and share, contributing to a fall in net total wealth inequality. By contrast, wealth in primary residence, which represents the largest part of total net wealth throughout the period, has a much smaller effect on net wealth inequality and one not consistent with the overall trend.<sup>7</sup>

### **3.2. Decomposition of the Gini Index by Sources**

Despite the different trend in inequality suggested by the Gini coefficient, results

from Gini decompositions lend further support to the significant role of equity holdings for the distribution of households' net wealth. One of the most commonly used decompositions of the Gini index is that of Lerman and Yitzhaki (1985) According to this, the absolute contribution of wealth factor  $f$  to overall inequality can be expressed as:

$$S_f = G_f \chi_f R_{fW} \quad (8)$$

where  $G_f$  is the inequality of factor  $f$  measured by Gini,  $\chi_f$  is the share of factor  $f$  in net total wealth, and  $R_{fW}$  is the “rank correlation ratio” defined as the ratio of the covariance of household's amount of wealth factor  $f$  with its ranking in the cumulative distribution of net total wealth, over the covariance of its amount of wealth factor  $f$  with its ranking in the cumulative distribution of factor  $f$ . Wealth in equity holdings displays one of the highest rank correlation ratios, that is also getting higher over time. This stresses the growing importance of risky financial assets for households' position in the overall net wealth distribution. Table 3 decomposes inequality of net total wealth as summarized by the Gini coefficient. In the period 1989-98, only equity exhibits an increase in its (absolute and proportionate) contributions to net wealth inequality. The main factor behind this increased contribution is the rise in its share of net total wealth over this period.<sup>8</sup>

### **3.3. Contributions of Direct and Indirect Stockholding to Financial Wealth Inequality**

We now take a closer look at financial wealth and distinguish between the contributions of direct and indirect equity holdings to inequality (Table 4). Financial wealth inequality, as summarized by HSCV, follows a qualitatively similar pattern with net total wealth and equity holdings: 14.6 in 1989, rising to 21.9 in 1998, and then dropping to 16.6 in 2001. Key to the increase in financial wealth inequality in 1998 is the

increase in inequality of directly held equity, from 66.6 in 1989 to 162.5 in 1998 (the latter can be mainly attributed to the fact that inequality among stockholders triples this year, reflecting the very different risky wealth levels they attain by the end of the stock market upswing). Directly held equity becomes the main source of inequality in financial wealth by 1998, with its percentage factor contribution rising from just 20 percent in 1989 to almost 52 percent in 1998.

Indirectly held equity also makes an important contribution to changes in financial wealth inequality. The HSCV of indirect stock holdings displays a dramatic reduction from 53.1 in 1989 to 26.7 in 1998. Since within inequality is almost unchanged, this results mostly from the significant increase in the percentage of owners. However, the increases in the factor share of indirect equity holdings and in their correlation with financial wealth dominate the drop in HSCV and produce a positive contribution to the increase in financial wealth inequality between 1989 and 1998.

Direct and indirect equity holdings contribute to lowering financial wealth inequality during the subsequent stock market downturn, as inequality among owners in both categories drops in 2001. Interestingly, participation rates in direct and indirect equity holdings keep increasing somewhat to 2001, despite the downturn.<sup>9</sup>

A closer look at participation can be provided by probit regressions for 1989, 1998, and 2001 data. In Table 5, we see that being affluent, more educated, and less risk averse contribute to the probability of entering the stock market, controlling for other factors. These results are consistent with standard findings in the stock market participation literature. They imply that stockholders are not drawn randomly from the population, but the composition of the stockholder pool changes as stock market participation spreads. We now turn to an examination of the contribution of stockholder characteristics to generating inequality in equity holdings.

#### 4. Regression-based Decomposition of Inequality in Equity Holdings

Regression-based decomposition of inequality in equity holdings allows us to isolate, in a multivariate setting, the inequality contributions of certain demographic characteristics. Such decomposition is conducted on the basis of OLS regressions of the logarithm of equity holdings on a set of covariates including household demographics and financial characteristics. The importance of each explanatory variable for inequality cannot be seen from estimated coefficients alone. Fields (2002, 2003) showed that, given a process for generating  $\ln Y$ , under certain axioms, decomposition of inequality in variable  $\ln Y$  into the contributions of each of the  $J$  covariates (excluding the constant),  $Z_j$  with estimated coefficient  $a_j$  is given by:

$$s_j(\ln Y) = \frac{\text{cov}[a_j Z_j, \ln Y]}{\sigma^2(\ln Y)} = \frac{a_j * \sigma(Z_j) * \text{cor}[Z_j, \ln Y]}{\sigma(\ln Y)} \quad (9)$$

where  $\sum_{j=1}^{J+2} s_j(\ln Y) = 100\%$  (including the constant and the error term) and

$\sum_{j=1}^{J+1} s_j(\ln Y) = R^2(\ln Y)$  (including only the covariates and the constant) hold for any

inequality index  $I(\ln Y_1, \dots, \ln Y_n)$  that is continuous and symmetric, and for which the index under complete equality is zero, i.e.  $I(\mu, \mu, \dots, \mu) = 0$ .

We focus on the contributions that various factors make to inequality in equity holdings in each of the three years. We confine attention to holders of risky assets, i.e. those who have passed the participation threshold. Table 6 presents OLS coefficient estimates. Table 7 examines the total contribution of each variable and shows that, education, age, income, and reporting a bequest motive play the biggest role in generating inequality of equity holdings.<sup>10</sup> By contrast, some other variables that are statistically significant in the regression, such as self employment, marital status, and

willingness to take above average financial risk, play a very limited role in inequality, if any.

In Figure 1, we plot risky wealth densities for 1989, 1998, and 2001. Kernel densities for the logarithm of equity holdings of stockholders in 1989 and 1998 suggest clearly a movement of the distribution to the right. Changes between 1998 and 2001 are less pronounced and more difficult to assess visually, but they still suggest some shift of the distribution to the right.

We next decompose the change in the distribution of equity holdings between two years into (i) a component due to the change in the distribution of *covariates*; and (ii) a component due to changes in the *coefficients* on these covariates at various quantiles.<sup>11</sup> This is done by constructing counterfactual densities that disentangle changes in levels of equity holdings emanating from changes in the composition of stockholders, from those due to changes in the effect of any given characteristic on realized equity levels. The basic methodology, a variant of a technique proposed by Machado and Mata (2003) described in Appendix A, uses results from quantile regressions to simulate appropriate distributions.

When comparing 1998 to 1989, the relevant counterfactual density is the density of the (logarithm of) equity holdings that stockholders in 1989 would have if, given their own characteristics, they experienced the same influence of characteristics on equity holdings ('coefficient effects') as those experienced by stockholders in 1998. The difference between the 1998 and 1989 distributions of equity holdings is decomposed into:

$$f(y^{98}) - f(y^{89}) = \{f(y^{98}) - f^*(y; X^{89}b^{98})\} + \{f^*(y; X^{89}b^{98}) - f(y^{89})\} \quad (10)$$

where  $y$  represents the log of equity wealth,  $X$  is the data matrix and  $b$  is a collection of estimated quantile regression coefficients at various percentiles.

The term in the first curly brackets measures the contribution of household characteristics to the overall difference between the 1998 and 1989 densities of equity holdings. The term in the second curly brackets measures the contribution of the quantile regression coefficients.

The coefficient and covariate effects for 1998-1989 are presented in Figure 2a. Differences in distributions of equity holdings over this period are mainly driven by coefficient effects, and these become progressively more important at higher quantiles of the distribution. This is consistent with the exceptionally strong upward movement of stock market indices over this period and it suggests that a given change in characteristics has more important effects, during upswings, on the equity wealth of households with sizeable equity holdings.

On the other hand, covariate effects are negative, implying that the combination of 1989 characteristics with 1998 coefficients would generate even higher equity holdings than what was actually observed for the more heterogeneous group of 1998 stockholders. In other words, the overall distribution of shareholder characteristics in the wider stockholder base at the end of the 1990s was not as conducive to high equity levels as the 1989 distribution. This was most evident among households with large equity holdings.<sup>12</sup>

Findings are reversed when we compare 1998 with 2001 (Figure 3a). Here the counterfactual distribution is derived by combining 1998 coefficients with 2001 characteristics:

$$f(y^{2001}) - f(y^{98}) = \{f(y^{2001}) - f^*(y; X^{2001}b^{98})\} + \{f^*(y; X^{2001}b^{98}) - f(y^{98})\} \quad (11)$$

We find that coefficient effects are negative, but covariate effects on equity holdings (displayed in the second curly brackets) are positive and increasing beyond the 40<sup>th</sup> percentile of the distribution of stock wealth. This implies that the configuration of

stockholder characteristics of 2001 would have had higher equity levels in 1998, compared to those actually observed for 1998 stockholders. This is quite a striking pattern of effects produced by changes in the configuration of stockholder characteristics as the spread of equity culture progressed during the 1990s and early 2000s, and it is worthwhile probing further into what lies behind it.

As the configuration of the stockholder pool changes, we may in principle find covariate effects because of differences across stockholder pools in optimal levels of equity holdings, or in the ability to produce high equity wealth outcomes, or some combination of the two. Disentangling the two is relevant for knowing whether general equilibrium effects of the spread of equity culture arise solely from changes in optimal asset demands and market liquidity or whether general equilibrium analysis should also allow for changes in the quality of the stockholder pool, measured in terms of its ability to generate high values of equity wealth.

The remainder of the paper is devoted to exploring the presence of such quality effects using three different but complementary approaches. We first examine which part of the counterfactual changes in equity holdings across percentiles is due to changes in characteristics that can be thought of as economic ‘fundamentals’ rather than to changes in the configuration of household financial attitudes and practices. Then, we ask whether even education effects, which we initially considered as purely ‘fundamental’, are confined to determining income processes without influencing stockholder quality. In the final section, we focus on reported cumulative gains or losses in stockholding by 1998 and by 2001, and we test for a role of financial attitudes and practices controlling for other characteristics.<sup>13</sup>

## 5. Fundamentals versus Financial Attitudes and Practices: Counterfactual Analysis

In this section, we proceed by decomposing the counterfactual analysis presented above into a part that can be attributed to economically fundamental characteristics of the stockholder pool, and into one that can be attributed to differences in their financial attitudes and practices. We are conservative in what we consider as fundamental factors, as we classify as ‘fundamentals’ even factors that may also influence attitudes and practices, such as education.<sup>14</sup>

We consider three basic attitudes, namely financial alertness, willingness to take more than average risk, and intension to leave a bequest. We perform the following sequential decomposition:

$$\begin{aligned} f(y^{98}) - f(y^{89}) = & \{f(y^{98}) - f^{**}(y; X_f^{98}, X_a^{89}, b^{98})\} \\ & + \{f^{**}(y; X_f^{98}, X_a^{89}, b^{98}) - f^*(y; X^{89}b^{98})\} \\ & + \{f^*(y; X^{89}b^{98}) - f(y^{89})\} \end{aligned} \quad (12)$$

Where the counterfactual  $f^{**}$  represents the equity wealth distribution that would have prevailed in 1998 if the particular attitudes had been distributed as in 1989. The term in the second curly bracket shows the relative contribution of fundamentals.

Figure 2b exhibits this decomposition of covariate effects for the 1989 to 1998 period. The shaded area represents the effects of changes in covariates that we conservatively assigned to the group of economic ‘fundamentals’. The Figure shows that fundamentals make a contribution to equity levels, but they also leave room for a contribution of attitudes and practices throughout the distribution of equity holdings, but especially at the upper end of the distribution.

Figure 3b carries out an analogous exercise for the period between 1998 and 2001. Here we use the following sequential decomposition:

$$\begin{aligned}
f(y^{2001}) - f(y^{98}) = & \{f(y^{2001}) - f^*(y; X^{2001}b^{98})\} \\
& + \{f^*(y; X^{2001}b^{98}) - f^{**}(y; X_f^{98}, X_a^{2001}, b^{98})\} \\
& + \{f^{**}(y; X_f^{98}, X_a^{2001}, b^{98}) - f(y^{98})\}
\end{aligned} \tag{13}$$

Results are quite similar, with greater room for effects of attitudes above roughly the 70<sup>th</sup> percentile of the distribution of equity holdings.

This counterfactual analysis suggests that the period 1989-1998 has witnessed a dilution of the quality of the stockholder base, as more marginal stockholders were drawn into the market. The subsequent, 1998-2001 period is even more interesting, as it seems to combine an improvement in the stockholder base coupled with an increase in overall participation. To put it differently, this analysis suggests that the stock market downswing has had a ‘cleansing effect’ on the stockholder pool, by encouraging lower-quality investors to leave and (a slightly larger number of) better-quality investors to enter. The next two approaches we take reinforce the view that quality effects are present and contribute further findings.

## **6. Fundamentals versus Attitudes and Practices: Exploring the Role of Education**

### **6.1. Estimation of Education Effects on Inequality**

In the decomposition shown in Figures 2b and 3b, we assigned education effects entirely to effects of ‘economic fundamentals’ and still found that they left room for effects of financial attitudes. It is often argued that education influences not only labor income processes but also an individual’s ability to make sound choices, including financial ones. Here we probe further into the role of education in determination of equity holdings and ask whether estimated effects of education can be attributed entirely to differences in income processes they entail.

Table 8 first computes various measures of inequality of equity holdings in 1998,

considering observed holdings, and observed holdings after removing the estimated effect of education.<sup>15</sup> Then, the same exercise is repeated for each of three educational categories: high-school dropouts, high-school graduates, and households whose head has a college degree or more.

We find that inequality of observed equity holdings, as measured by HSCV, drops as we move to higher education categories. By contrast, the Gini coefficient increases with education. These findings combined suggest that higher education categories exhibit less inequality in the upper tail of the distribution of equity holdings, but more inequality in the middle of the distribution.<sup>16</sup>

Of course, this does not necessarily imply that education per se is the cause of those differences, as these may be partly due to different distribution of other characteristics in the three education categories. The second column of the table reports inequality measures after removing the estimated effect of years of education. The top panel shows that observed heterogeneity in years of education raises HSCV quite dramatically, while effects on Gini and Theil indices tend to be small. The remaining panels show that, in the absence of heterogeneity in years of schooling, differences in inequality across education categories using the HSCV measure would be almost ironed out, while the Gini would be hardly affected.<sup>17</sup> These findings suggest that most of the effect of heterogeneity in education on inequality of equity holdings is observed in the upper tail of the distribution, whether we speak about the population as a whole or about any of the three education categories.

Is lower inequality in equity holdings among households of higher education due to greater ability to handle the challenges of investing in stocks or does it arise from the ‘fundamentals’ of education (age-income profiles and income shock processes) that produce less unequal levels of stock holdings in the upper tail of the distribution even

under optimal behavior? We turn next to a simulation of optimal portfolio behavior using an intertemporal model of household portfolio choice.

## **6.2. Education Effects in Simulation of Optimal Behavior**

We simulate optimal behavior of households that solve an intertemporal model of household portfolio choice, belong to different education categories, and differ only in terms of education-specific income processes (age-income profiles and income shock variances). Distributions of stock holdings within each education group are generated solely by different realizations of income shocks for households that face the same income processes *ex ante* and have the same remaining characteristics.

The portfolio model incorporates finite lifetimes of uncertain length, a retirement period, and income shocks, transitory and permanent (see Appendix B).<sup>18</sup> Consistent with empirical estimates, more educated categories are assumed to face better income prospects, both in terms of steeper income growth and higher expected future income levels compared to their counterparts with lower education; and typically lower variance of income shocks. We simulate stock holdings implied by the model using stochastic draws of transitory and permanent income shocks, and of stock returns.<sup>19</sup>

Results are reported in Table 9. Mean simulated stock holdings for each category display a life-cycle pattern of asset accumulation when young, followed by asset decumulation in retirement. Comparison of mean stock holdings across education categories suggests that, if all other household characteristics were the same and only income processes differed across households of different education categories, lower education households should be holding more stocks on average than more educated households. This is because they face greater future income variance and worse future income prospects. Put differently, higher observed stock holdings among college graduates

participating in the stock market seem to be due to differences in their remaining characteristics and stockholding participation costs, and not to different income processes.

Comparison of HSCV indices across education groups at any given age shows that educational attainment matters for simulated inequality in stock holdings, even under optimal portfolio behavior. Controlling for age and for all other relevant household characteristics, we find a monotonic positive relationship between educational attainment and inequality in stock holdings, with college graduates typically experiencing greater inequality than the other two categories. This suggests that the equalizing effect of higher education at the upper end of the distribution of equity holdings is unlikely to arise from the “fundamental” features of educational attainment, such as age-income profiles and income shocks processes under optimal behavior, leaving space for other factors, such as financial attitudes and practices, to operate even through the education variable.

In the next section, we provide additional evidence in favor of the relevance of attitudes and practices by looking directly at their effects on reported cumulative gains and losses in the stock market.

## **7. Who Gains and Who Loses in the Stock Market?**

We estimate the contribution of household characteristics to gains or losses in stockholding by 1998 and then by 2001, separately for direct and indirect stockholding. Responses in the SCF allow us to measure success or failure with reference to the cumulative experience of each stockholder by 1998 or 2001, though without knowledge of when stocks were initially acquired. Thus, we can see how each stockholder survived a period ending with a considerable stock market rally, as well as one that includes an important part of the subsequent downturn.

## **7.1. Descriptive analysis**

The top two education categories almost share the pool of stockholders in both years, leaving only about 5% of the pool to high-school dropouts. Interestingly, there is a shift in the composition of the pool following the downturn, with the share of college graduates rising from 46.5% to more than 49%, at the expense of each of the lower two education categories (Table 10).

The proportion of stockholders who include professional advice among reported ways in which they make decisions about savings and investments is 59% in 1998 and drops slightly to 57% in 2001, despite the intervening stock market downturn. Under professionals, we include accountants, bankers, brokers, and financial planners. Slightly lower proportions of stockholders, but still the majority, declare that they are influenced by social interactions in decisions about savings and investments. Here we include households who report that they get advice from their spouse or partner, a friend or relative, or some work or business contact.

Table 11 shows how the three education categories fared in their direct stock holdings by the end of 1998 and 2001. By 1998, 80% of all direct stockholders were experiencing cumulative gains on their direct stock investments. Proportions increased with education, but the proportion for college graduates did not exceed 81%. Much less variation was observed in the percentages of those declaring cumulative losses, which also increased with education but very little, ranging between 11.4% and 12%.

By 2001, the percentage of equity holders declaring that they had survived the downturn with cumulative gains in their direct stock investments dropped to 53%. A steeper education gradient was observed, with percentages rising from 41% for high school dropouts to 56% of college graduates with direct holdings. Percentages of those declaring cumulative losses had risen to 35% in the population, ranging from 43% to 33% across

education groups. Unlike in 1998, in 2001 more educated households reported smaller incidence of cumulative losses. Following the stock market downturn, outcomes were more differentiated across education categories, and the slope of the education gradient was greater for gains and a lot greater for losses than in 1998.

Mutual fund investments are generally considered as being less demanding for households, since portfolios are constructed by professional fund managers and diversification is possible for each individual investor participating in a large portfolio. However, even participation in mutual funds is far from being straightforward. One complicating factor is the proliferation of mutual funds, whose number is now of the same order as the number of individual stocks. The question of which stocks to hold seems to have been replaced by the equally pressing question of which mutual funds to hold, given a household's objectives and attitudes to risk. A further factor is the actual quality of professional advice given to shareholders of mutual funds and the potential of investors to pick qualified advisors and to monitor them.

Comparing cumulative outcomes for direct stockholding and for mutual funds among all holders, one does find greater incidence of cumulative gains and smaller incidence of cumulative losses for mutual funds in each of the two years, though marginally so for losses in 2001. Yet, Table 12 shows that, in both 1998 and 2001, cumulative success and failure rates for mutual funds were much more differentiated across education categories than the corresponding rates for direct holdings of stock. For example, in 1998 only 69% of high-school dropouts were reporting cumulative gains, compared to 89% of college graduates. By 2001, 52% of households in the least educated category were reporting cumulative losses, compared to less than 35% of the most educated households.

## 7.2. Regression Analysis

Although these statistics raise suspicions against the often voiced view that mutual fund investment is a much simpler alternative to direct stock holding for households with limited ability to process financial information, they are not sufficient to establish a role for education in determining gains or loss outcomes, or to clarify the sources of this role. Is education relevant because it encourages households to adopt a longer investment horizon, to diversify, and to seek professional advice? Or is education relevant because it determines fundamentals, such as future income and employment prospects, controlling for the degree of financially sound behavior? In order to probe further into these questions, we turn to regression analysis of the incidence of stockholding outcomes, conditional on participation.

We model the incidence of cumulative gains and losses as bivariate probits with selection. One outcome is direct holding of stocks (or mutual fund participation), and the second is observed only if the first outcome occurs, i.e. if households are direct stockholders (or mutual fund shareholders). We run two such estimations for 1998 (one for gains and one for losses), and two for 2001, separately for direct and indirect stockholding.

Bivariate probit estimation with selection allows for correlation among unobserved factors contributing to the probability of the cumulative outcome and to the probability of direct stock ownership. When the correlation is statistically significant, we report conditional marginal effects from bivariate probits that have taken into account selection bias. When it is statistically insignificant, we report marginal effects from standard probits for gains and for losses on the restricted subsamples of direct (or mutual fund) shareholders.

Results for direct stockholding in 1998 and 2001 are reported in Table 13. The period ending in 1998 includes the upsurge in stock prices without the subsequent

downswing, and 80% of direct stockholders reported cumulative gains. In col. 2, we see that married status is the only factor with statistically significant positive contribution (at 5% significance level) to a cumulative gains outcome for direct stockholders in 1998.

We test for the significance of three indicators of financial attitudes and practices. The number of stocks held can be called ‘portfolio breadth’ and suggests an effort to achieve portfolio diversification, although the extent of diversification achieved cannot be assessed without information on which stocks were held and on their covariance properties. Portfolio breadth has a positive and statistically significant contribution to the probability of achieving cumulative gains in 1998. Having a long investment horizon (in excess of 10 years) indicates absence of excessive churning of stock holdings, but it is not found to make a statistically significant positive contribution to cumulative gains among stockholders in 1998. The same is true for reporting use of professional advice.

Interestingly, once we control for these three variables showing financial attitudes and practices and for other remaining characteristics, we no longer find that educational attainment played a statistically significant role in achieving cumulative gains in 1998, although point estimates of marginal effects on the probability of gains are positive and increasing with education. Thus, the observed variation in the incidence of gains across education categories in Table 11 seems to be largely explained by variation in portfolio breadth and possibly in other characteristics that correlate with education, namely marital and employment status.<sup>20</sup>

Cumulative gains were the most usual outcome in 1998. Column 3 examines the incidence of the less likely outcome of cumulative losses. Here we find that long investment horizon had a strongly significant effect in reducing the probability of suffering cumulative losses, by about 4 percentage points. Portfolio breadth is estimated to contribute with the correct sign (significant at 10%), while professional advice has a

statistically insignificant effect, though the point estimate is negative. Again, once we control for these three variables and for other characteristics, education does not make a statistically significant contribution to avoiding cumulative losses in 1998.

Some of the factors that played no role in 1998 gain significance when the period over which cumulative outcomes are assessed is extended to encompass the downswing in the early 2000s (cols. 4 and 5). It should be stressed that results refer to households who chose to stay in or enter the market following the downswing and are observed as stockholders in 2001.<sup>21</sup> Portfolio breadth is now statistically significant in facilitating cumulative gains among direct stockholders and in reducing the probability of cumulative losses. The same is true for having an investment horizon longer than 10 years, with marginal effects of the order of 6 percentage points. However, estimated marginal effects of using professional advice are statistically insignificant and of the wrong sign for direct stockholders.

Even after controlling for these indicators of financial attitudes and practices, being a stockholder with a college degree has a remarkably large and significant positive effect on the probability of surviving the downswing with cumulative gains, raising it by 18 percentage points. Although it is also estimated to reduce the probability of losses, the effect is not statistically significant. Thus, a college degree is estimated to make a difference in producing good outcomes in bad times.

Having received an inheritance or been given substantial assets in a trust or in some other form also has a statistically significant and sizeable contribution to the incidence of making cumulative gains and to avoiding cumulative losses in bad times. It increases the probability of gains by 10 and reduces the probability of losses by 8 percentage points. This variable may be acting as a proxy for portfolios that were initiated earlier than the recent upswing and are therefore less likely to be suffering cumulative losses. Moreover,

since wealthier households are more likely to be leaving bequests, households who have received an inheritance are likely to have also inherited a portfolio structure and some of the financial expertise that contributed to making the previous generation wealthy.

Table 14 presents results for indirectly held equity. In the period ending with the upswing of the late 1990s (cols. 2 and 3), the only notable statistically significant effect refers to breadth in mutual fund holdings, which reduces the probability of experiencing cumulative losses. The relevance of this factor suggests that the degree of diversification inherent in any given mutual fund, though greater than that typically observed among direct stockholders, can be further improved upon by combining a number of different mutual funds. It is also noteworthy that education, length of investment horizon, and use of professional advisors contributed neither to making cumulative gains nor to avoiding cumulative losses on mutual funds in the period that ends with the upswing of the late 1990s.

The period that includes the subsequent downswing stands in stark contrast to the period ending in 1998. A college degree is estimated to have increased the probability of cumulative gains among mutual fund holders by a staggering 30 percentage points, and to have reduced the probability of losses by 22 percentage points, controlling for income, length of investment horizon, receipt of inheritance, portfolio breadth, and other factors. College education appears as an important contributor to success, having even greater impact on the probabilities of gains and of losses for the arguably “softer” option of indirect stockholding than for direct holding of equity.

Portfolio breadth is found to have a strongly statistically significant marginal effect. Holding shares in greater number of mutual funds both increases the probability of cumulative gains and reduces the probability of losses in mutual funds by 2001. Having an investment horizon longer than 10 years contributes to gains and to avoidance of losses by

7 and 8 percentage points, respectively, which is somewhat larger than estimated marginal effects for direct stockholding.

Point estimates for use of professional advice imply a statistically significant (at 10% level) perverse effect of reducing the probability of cumulative gains and increasing the probability of losses, controlling for investment horizon and portfolio breadth. In all our previously reported regressions, use of professional advice failed to make a difference to the cumulative outcome beyond any influence it may have had in lengthening the horizon and in broadening the portfolio of the household. These findings question the overall quality or scope of professional advice given to households, as long as we view the use of such advice as being a function of exogenous factors, such as ignorance or lack of time on the part of the household to delve into the intricate details of financial decision making. They would be weakened by strong evidence that use of financial advice is actually due to the absence of cumulative gains, suggesting endogeneity. We doubt that such factors are dominant here, as the use of financial advisors is typically observed among households with limited knowledge of the market or by financially successful households who do not have the time to monitor their own portfolios.

Finally, being a male or white non-Hispanic mutual fund shareholder raises the probability of surviving the downswing with cumulative gains and lowers the probability of experiencing cumulative losses. Estimated conditional marginal effects are sizeable in both cases. Part of these effects may be due to these variables acting as proxies for future income prospects. At least the result for the race variable may be additionally suggesting that the mutual fund sector is targeting more aggressively households that do not belong to minorities.

All in all, results in this Section suggest that the incidence of cumulative gains or losses in direct stockholding or in mutual funds is not simply determined by overall stock

market performance but also by demographic characteristics and practices of investing households. Education, portfolio breadth, and length of investor horizon seem important for making gains and avoiding losses, especially in the aftermath of stock market downswings. By contrast, use of professional advice is largely insignificant or even counterproductive, controlling for investment horizon and portfolio breadth.

## **8. Concluding Remarks**

In this paper, we have applied a battery of approaches to measuring and decomposing wealth inequality, using high-quality household-level data on portfolios during a critical phase in the spread of equity culture. We found the pattern of inequality in equity holdings to be important for inequality in overall net wealth in the United States over the fifteen-year period under consideration, despite their limited share in net wealth. Inequality decompositions reveal that a significant part of the contribution of equity holdings has to do with changes in inequality within owners of equity. Counterfactual distributions of equity holdings separating changes in the influence of investor characteristics from changes in the distribution of characteristics within the stockholder pool imply that the distribution of characteristics of the 1998 stockholder pool was less conducive to sizeable equity holdings, compared with either 1989 or 2001. We have employed three different approaches to show that this was unlikely to be due simply to changes in optimal holdings associated with fundamental household characteristics, but also to financial attitudes and practices.

All in all, our findings suggest that reduced wealth inequality is far from being an automatic outcome of the spread of stockholding opportunities and of equity culture. Effects of increased participation on wealth inequality depend on how characteristics of the expanding pool of stockholders evolve, including their financial attitudes and

practices in handling complicated and risky financial instruments. The evolution of household characteristics, however, is the net result of exits and entries sensitive to the stock market environment, even if the overall participation rate continues to increase.

The booming stock market of the 1990s seems to have raised the share of marginal stockholders in the pool, with characteristics, attitudes, and practices less conducive to large equity wealth. The subsequent stock market downturn between 1998 and 2001 seems to have encouraged substantial exits and entries, with a net effect of actually improving the tendency of the stockholder pool to have large equity wealth, due partly to higher optimal holdings and partly to better financial attitudes and practices. In this sense, the US experience between 1989 and 2001 seems consistent with a ‘dilution effect’ of the stockholder pool arising from the stock market boom, followed by a ‘cleansing effect’ of the stock market downturn. The relevance of financial attitudes and practices we found for observed equity outcomes suggests a role for financial education, transparency, and high-quality advice, as well as for policies promoting those.

## Appendix A: The Machado-Mata Algorithm

The algorithm for constructing counterfactual densities is a variant of Machado and Mata (2003), recently used by Albrecht et al. (2003) and Nguyen et al. (2003):

1. Draw  $m$  random numbers from a uniform distribution on  $(0, 1)$ :  $\theta_1, \theta_2, \dots, \theta_m$  ; here we set  $m=1000$ .
2. For each  $\theta_i$  where  $i = 1, 2, \dots, m$ , use the 1998 data on stockholders to estimate the Quantile Regression coefficient,  $b^{98}(\theta_i)$ , from the model:

$$Q_{\theta_i}^{98}[y | X^{98}] = X^{98} \beta^{98}(\theta_i)$$

3. Make  $m$  random draws of characteristics and corresponding weights with replacement from the 1989 stockholder pool. Denote the outcomes of these draws by  $x_i^{*89}$  for  $i = 1, 2, \dots, m$ .
4. Generate counterfactual values (a random sample of size  $m$  from the desired distribution):  $y_i^* = x_i^{*89} b^{98}(\theta_i)$ , for  $i = 1, 2, \dots, m$ . Use these values to generate  $f^*(y; X^{89} b^{98})$ .

Then, for each of the three sequences of variables (log equity holdings in 1989 and 1998 and counterfactual values), we calculate percentiles using population weights. The difference between percentiles of the distributions of the endogenous variable in 1998 and 1989 can be decomposed into:

$$f(y^{98}) - f(y^{89}) = \{f(y^{98}) - f^*(y; X^{89} b^{98})\} + \{f^*(y; X^{89} b^{98}) - f(y^{89})\}$$

The term in the first curly brackets represents the contribution of the covariates to the overall difference between the 1998 and 1989 densities. The term in the second curly brackets shows the contribution of the QR coefficients. The method is a generalization of Oaxaca (1973) to the whole distribution.

We further decompose the covariate effects into the contribution made by household characteristics that can be seen as fundamentals and a remaining contribution that is due to particular attitudes and practices. We assess the contribution of three attitudes, namely financial alertness, willingness to take more than average risk, and intension to leave a bequest. To this end we use the following sequential decomposition:

$$\begin{aligned} f(y^{98}) - f(y^{89}) &= \{f(y^{98}) - f^{**}(y; X_f^{98}, X_a^{89}, b^{98})\} \\ &\quad + \{f^{**}(y; X_f^{98}, X_a^{89}, b^{98}) - f^*(y; X^{89} b^{98})\} \\ &\quad + \{f^*(y; X^{89} b^{98}) - f(y^{89})\} \end{aligned}$$

where the counterfactual  $f^{**}$  represents the equity wealth distribution that would have prevailed in 1998 if the particular attitudes had been distributed as in 1989. The term in the first curly bracket shows the relative contribution of attitudes, while in the second the relative contribution of fundamentals.

In order to construct the counterfactual  $f^{**}$  we first divide each of the samples of equity owners in 1989 and 1998 into 8 cells representing all the possible combinations of the three attitudes. We follow steps 1 and 2 from above while in step 3 we make  $m$  random draws with replacement from 1998 sample, generating the 1998 equity wealth distribution implied by the model. Then we consider the subset of households in cell 1. We randomly draw with replacement observations from this subset to generate a relative sample size equal to the fraction of households in cell 1 in 1989. We repeat the last two steps for cells 2 to 8. A similar approach is followed for the period 1998-2001.

## Appendix B: The Portfolio Model

This Appendix describes the main features of the model and calibration settings. More details on the model and its policy functions are to be found in Biliias and Haliassos (2004).

The household with access to stocks is assumed to have finite horizon but uncertain lifetime, and to maximize expected intertemporal utility faced with a menu of a risky and a riskless asset. The household's problem is given by:

$$\text{Max}_{\{C_t, \alpha_t\}_{t=0}^{T-2}} E_0 \sum_{t=0}^{T-1} \beta^t \left( \prod_{j=1}^t \hat{s}_j \right) U(C_t) \quad (14)$$

subject to

$$C_t + S_t + F_t \leq X_t \quad (15)$$

$$X_{t+1} = S_t [R_f + \alpha_t (\tilde{R}_{t+1} - R_f)] + Y_{t+1} \quad (16)$$

$$C_t \geq 0 \quad (17)$$

$$0 \leq \alpha_t \leq 1 \quad (18)$$

All variables are in real terms.  $S_t$  is the real amount of total saving between periods  $t$  and  $t+1$ ,  $\alpha_t$  is the portfolio share of the single risky asset (stocks),  $E_t$  denotes the expectation operator based on information in  $t$ ,  $\beta$  is the discount factor,  $s_j$  is the probability that the household is alive in period  $j$ , conditional on being alive in period  $j-1$ .  $U(C_t)$  is constant relative risk aversion felicity derived from consumption in  $t$ ,  $X_t$  is cash on hand defined as the sum of net wealth and labor income,  $\tilde{R}_{t+1}$  is the risky gross return on stocks between  $t$  and  $t+1$ ,  $R_f$  is the gross riskless rate,  $Y_t$  is non-interest income, and  $P_t$  refers to the permanent component of income, defined below. Income encompasses all after-tax income from transfers and wages, including pension income.  $F_t \geq 0$  is a fixed per period real cost of access to the stock market. Per period access costs are somewhat broader than the usual notion of participation costs, because they also incorporate costs that a household would have to incur to decide its portfolio even if it ends up choosing not to hold any stocks. The presence of constraint (16), which precludes borrowing at the riskless or the risky rate, generates ranges of cash on hand in which it is optimal to hold no stocks.

Income of household  $i$ ,  $Y_{it}$ , is assumed to entail non-diversifiable risk because of moral hazard and adverse selection considerations. Observed income follows  $Y_{it} = P_{it} U_{it}$ ,

where  $U_{it}$  is a transitory shock. During working life, the permanent component,  $P_{it}$ , follows

$$P_{it} = G_t P_{it-1} N_{it} \quad (19)$$

and is thus subject to shocks,  $N_{it}$ . Retirement income is assumed to be subject only to transitory shocks. Shocks are assumed i.i.d. lognormal. The growth factor,  $G_t$ , is assumed to be a function of household characteristics and is calibrated using empirical estimates for three different education categories (less than high-school education, high-school graduates, and college graduates), distinguishing between working life and retirement.

In calibrating income processes, we distinguish between three education categories, based on the educational attainment of the household head: less than high-school education, high-school graduates, and college graduates (or more). Income processes differ across education groups, both in terms of the (deterministic) age-income profiles and of the processes followed by stochastic shocks. The other difference is in the ratio of the fixed participation cost to the permanent component of income, which tends to be greater for lower-education households as a result of the assumption that all households face the same absolute real cost.

The growth factors of the permanent component of income are based on regressions using data from PSID 1983-1990 and are taken from Laibson et al. (2000, Tables 3 and 4). The retirement age for high-school dropouts is set to 61, for high-school graduates to 63, and for college graduates to 65, based on mean ages observed in the data. Estimated age income profiles are hump-shaped during working age for all education categories.

We calibrate variances for income shocks,  $(\sigma_u^2, \sigma_n^2)$ , for the three education categories during working life using estimates of Carroll and Samwick (1997). For high-school dropouts, we use the Carroll-Samwick estimates for those who had completed between 9 and 12 grades: (0.0658, 0.0214); for high-school graduates, we use (0.0431, 0.0277); and for college graduates (0.0385, 0.0146).

We follow Laibson et al. (2000) in calibrating shocks to retirement income. They estimate variances of transitory shocks for high-school dropouts, high-school graduates, and college graduates at 0.077, 0.051, 0.042, respectively.

We use conditional probabilities of survival from the 1998 United States Life Tables (National Vital Statistics Report, 2001). We set the rate of time preference equal to 0.05. The expected rate of return on equity,  $\mu_r$ , is set to 0.06 and the constant real interest rate,  $r$ , to 0.01. Understating the historical equity premium is an often used shortcut to introducing proportional transactions costs. The standard deviation of the equity premium is at its historical value of 18 percent. The benchmark value for risk aversion is  $\rho=2$ . Perceived access costs are unobservable. We use a real amount of 250 dollars, close to empirical estimates of implied participation costs. Assuming the same real cost of participation regardless of education is a useful benchmark, but also consistent with our purpose of focusing on the implications of income processes as distinct from any differences in the ability to process financial information across education groups.

The model is solved using a MATLAB algorithm recently developed by Haliassos and Mavridis, which incorporates some of the computational shortcuts proposed in Carroll (2002).

**Table 1: Net Wealth Inequality Indices**

Year	Generalized Entropy Class			Gini
	GE(0) MLD	GE(1) Theil	GE(2) HSCV	
1989	1.9961	1.5035	13.316	0.7668

**Note:** \*\*\* significance at 1%, \*\* significance at 5%, \* significance at 10%. The sample consists of all households from SCF 1989, 1998, 2001. Marginal effects refer to changes in the ownership probability associated with marginal changes in continuous variables (change in dummy variables from 0 to 1 is assumed), while the remaining covariates are fixed at their weighted means. The significance for each covariate has been computed using standard errors corrected for heteroscedasticity. The joint significance for the variable groups of age, labor market status, and labor income were tested on the basis of LR tests (not reported): In all three cases, for all survey years, the parameter estimates were found jointly significant.

## Data Appendix

### I. Asset Categories for Financial Wealth (Table 4)

#### Directly held stocks: [1]

[1] publicly traded stocks

#### Indirectly held equity: [2] + [3] + [4] + [5]

[2] stock mutual funds (full value if described as stock mutual fund, 1/2 value of combination mutual funds)

[3] IRAs/Keoghs invested in stock (full value if mostly invested in stock, 1/2 value if split between stocks/bonds or stocks/money market, 1/3 value if split between stocks/bonds/money market).

[4] Other managed assets w/equity interest: annuities, trusts, MIAs (full value if mostly invested in stock, 1/2 value if split between stocks/MFs & bonds/CDs, or "mixed/diversified", 1/3 value if "other")

[5] thrift-type retirement accounts invested in stock (full value if mostly invested in stock, 1/2 value if split between stocks and interest earning assets).

**Safe Assets:** Total Financial Assets – Directly held stocks – Indirectly held equity

### II. Asset Categories for Net Total Wealth (Tables 2&3)

**Risky Financial Assets:** Directly held stocks + Indirectly held equity

**Safe Financial Assets:** Total Financial – Risky Financial

#### Net Wealth in Risky Real Assets & Business Equity: [1] + [2] + [3] – [4] – [5]

[1] Other Residential Real Estate (includes land contracts/notes household has made, properties - other than the principal residence - classified under certain codes for family residences, time shares and vacations homes)

[2] Gross equity in Non-residential Real Estate (real estate - other than the principal residence, properties classified under certain codes for family residences, time shares, and vacation homes)

[3] Business Equity (for businesses where the HH has an active interest, value is net equity if business were sold today, plus loans from HH to business, minus loans from business to HH not previously reported, plus value of personal assets used as collateral for business loans that were reported earlier; for businesses where the HH does not have an active interest, market value of the interest)

[4] Debt for Other Residential Property (includes land contracts, residential property other than the principal residence, misc. vacation, and installment debt reported for cottage/vacation home)

[5] Debt for non-residential real estate mortgages and other loans taken out for investment real estate

**Other Wealth:** value of vehicles + other non-financial miscellaneous assets

**Wealth in Primary Residence:** Gross value of primary residence

**Principal Residence Debt:** [6]

[6] Principal Residence Debt (mortgage, home equity loans and HELOCs --mopup LOCs divided between HE and other)

**Consumer Debt:** [7]+[8]+[9]+[10]

[7] Other lines of credit

[8] Credit Card Debt

[9] Installment loans

[10] Other Debt (loans against pensions, loans against life insurance, margin loans, miscellaneous)

### III. Variable Definitions

**No high school diploma** (omitted variable): Highest grade completed (X5901)<12 & No high school diploma or passed equivalent test (X5902=5)

**High school graduate:** Highest grade completed (X5901)<12 & Has got high school diploma (X5902=1) or passed equivalent test (X5902=2) OR Highest grade completed (X5901)=12 OR Highest grade completed (X5901)>12 & No college degree (X5904=5)

**College graduate:** Highest grade completed (X5901)>12 & Has got a college degree (X5904)=1

**Save for “rainy days”:** The survey question is “Now I'd like to ask a few questions about your (family's) savings. People have different reasons for saving. What are your (family's) most important reasons for saving?” The dummy refers to those reporting one of the following reasons: Emergencies; “rainy days”; other unexpected needs; for "security"/independence (X3006=25 or X3007=25).

**Financial alertness:** The survey question is “When making major saving and investment decisions, some people shop around for the very best terms while others don't. What number would you be on the scale?”

The 5-number scale ranges from 1-“almost no shopping” up to 5-“a great deal of shopping”. The dummy represents those declaring that they do a great deal of shopping (X7111=5).

**Credit constrained:** Indicates household response that it has been turned down for credit in the past five years or did not receive amount originally requested or did not apply for credit because it thought it might be turned down.

**Willingness to take above average financial risk:** The survey question is “Which of the following statements comes closest to the amount of financial risk that you and your (spouse/partner) are willing to take when you save or make investments?”

1. take substantial financial risks expecting to earn substantial returns
2. take above average financial risks expecting to earn above average returns
3. take average financial risks expecting to earn average returns
4. not willing to take any financial risks”

The dummy represents those answering 1 or 2. (X3014=1 or X3014=2).

**Health poor:** The survey question is “Would you say your health is excellent, good, fair, or poor?” Those describing their health as being poor are represented by the dummy (X6030=4).

**Income:** income from wages, salaries, professional practice or business unemployment compensation, social security, annuity, or other pensions.

**Bequest motive:** Yes to “Do you expect to leave a sizable estate to others?” (X5825=1).

**Has received inheritance:** Yes to “Have you ever received an inheritance, or been given substantial assets in a trust or in some other form?” (X5801=1).

**Cumulative gains/losses in direct holdings of stocks:** The survey asks stock holders if there is a gain or loss in the value of the currently held stocks since they obtained them (X3916). The same information is available for mutual fund holders (X3831)

**Number of stocks held:** The survey asks stock holders in how many different companies they own stocks (X3914) and mutual fund holders in how many mutual funds they own shares (X3820)

**Investment Horizon>10 years:** The dummy represents those declaring that a period longer than 10 years is important when making their family’s saving and spending plan (X3008)

**Access to professional advice:** “How do you make decisions about savings and investments?” (X7112-X7121 & X6865-X6869) The dummy comprises those asking advice from at least one of the following: accountant, banker, broker, financial planner

## Endnotes

---

<sup>1</sup> For participation trends in the United States since the early 1980s, see Bertaut and Starr-McCluer (2001). International comparisons can be found in the volume edited by Guiso, Haliassos, and Jappelli (2001).

<sup>2</sup> For effects of stock market participation on the equity premium, see for example Heaton and Lucas (1999), Peress (2001), Calvet et al. (2001). For effects regarding market volatility, see Pagano (1989), Allen and Gale (1994), and Herrera (2001).

<sup>3</sup> Limited stockholding participation in the early to mid 1980s was documented in US data by King and Leape (1984), Mankiw and Zeldes (1991), and Haliassos and Bertaut (1995). A number of authors have recently explored determinants of participation in stockholding. See, for example, Haliassos and Bertaut (1995), Cocco, Gomes and Maenhout (1997), Heaton and Lucas (2000), Gollier (2001), Campbell and Viceira (2002), Haliassos and Michaelides (2003), and Gomes and Michaelides (2004).

<sup>4</sup> The Survey excludes only households that belong to the Forbes 400. See also Kennickell (2001).

<sup>5</sup> As Atkinson (1983) points out, “[inequality indices] embody implicit judgments about the weight to be attached to the inequality at different points in the [...] scale”.

<sup>6</sup> A similar argument was made by Jenkins (1995) in favor of using HSCV for analysis of income inequality.

<sup>7</sup> The result mainly comes from the increasing factor correlation, implying a stronger association between housing value and total net wealth over time, which outweighs the decreasing factor shares. Factor shares decrease presumably due to movements in housing prices, since ownership rates move in the opposite direction.

<sup>8</sup> The higher risky shares result from increasing ownership rates and sizeable stock gains in a decade marked by a spread of equity culture and a stock market boom.

<sup>9</sup> The unconditional share of investments in directly held equity as a fraction of total financial wealth declines from 22.6 to 21.3, as increased participation is dominated by lower stock valuations. This is not the case for unconditional shares of indirect equity holdings, which rise from 31.0 to 34.5 between 1998 and 2001.

<sup>10</sup> The overall importance to inequality of a characteristic that is controlled for through a higher order polynomial or a string of dummy variables can be seen by adding up all the relevant coefficients (e.g. “age” in 2001 has a factor inequality weight of 20% = .41 - .21).

<sup>11</sup> Summary statistics suggest that by 1998 the stockholder pool became more heterogeneous. For instance, by the end of the decade in which equity culture spread, the share of college graduates among equity holders was actually somewhat reduced to 46.4%, while in the population it increased by almost 6 percentage points. In addition, both the mean and median non-investment income among equity holders is lower in 1998 compared to 1989, while in the population it is considerably higher, by 15% and 10%, respectively. The picture changes drastically when we look at the composition of 2001 stockholders. These consist mainly of those who persevered through the downswing and of those secure enough to enter the stock market at bad times. Within just three years, college graduates among equity holders reach 49.1%, an increase of almost 3 percentage points. They also show significant increases at all percentiles of their income distribution.

<sup>12</sup> Coefficient and covariate effects deviate across higher percentiles, and both are significant in most percentiles, according to bootstrapped standard errors not reported here.

<sup>13</sup> Yet another, fourth, approach to assessing quality of the stockholder pool would be to construct realized stockholding returns by household and then compare them to some stock market index over the relevant period. Whatever the merits of such an approach, it cannot be implemented in population-wide data, because realized rates of return over specific periods cannot be computed.

<sup>14</sup> We return to this issue in our second approach.

<sup>15</sup> Households were assigned to percentiles of equity holdings by computing predicted equity holdings for each holder under all 19 sets of quantile regression coefficient estimates (evaluated at every five percentiles) and then finding the quantile for which the absolute distance between actual and estimated equity holdings is minimized. We use years of schooling instead of educational dummies, to retain more variation, especially in the small category of high-school dropouts that represents only 5% of the pool of stockholders.

<sup>16</sup> We have also experimented with the Machado Mata algorithm and have constructed several simulated counterfactual densities for 1998, raising the percentage of college graduates at the expense of the other two educational categories. By doing this, we progressively attach more weight to the group with the lowest within inequality. Indeed, the resulting counterfactuals display HSCVs that fall more rapidly than the college graduates’ share increases, lending further support to our finding that education has equalizing effects at the upper tail of the distribution.

---

<sup>17</sup> According to the standard inequality decomposition by subgroups, HSCV can be expressed as the sum of within group and between groups inequality. Given that, after removing the effect of education, HSCV is reduced within each education category, and that it reaches a similar level (lower between groups inequality), it is natural to expect a reduction in HSCV among stockholders. Indeed within and between inequalities drop from 23.7 and .135 to 8.44 and .00053 respectively, after removing the effect of education.

<sup>18</sup> A fuller description of the model, algorithm, and policy functions is in Biliias and Haliassos (2004).

<sup>19</sup> For each education group, we draw 15,000 life histories of such shocks (one triplet for each year in the lifetime of each household), and we use those and the policy functions for holdings of stocks and of the riskless asset to compute stock holdings over the life cycle of each household.

<sup>20</sup> Results in this Section are robust to controlling also for net total wealth excluding direct holdings of stocks and of stocks in mutual funds.

<sup>21</sup> Because of the cross-sectional nature of the SCF, there is no information on households who left the market because of losses.
