# Modelling Long-Run Trends and Cycles in Financial Time Series Data 

#### Abstract

This paper proposes a very general time series framework to capture the long-run behaviour of financial series. The suggested model includes linear and non-linear time trends, and stationary and nonstationary processes based on integer and/or fractional degrees of differentiation. Moreover, the spectrum is allowed to contain more than a single pole or singularity, occurring at zero and non-zero (cyclical) frequencies. This model is used to analyse four annual time series with a long span, namely dividends, earnings, interest rates and long-term government bond yields. The results indicate that the four series exhibit fractional integration with one or two poles in the spectrum. A forecasting comparison shows that a model with a non-linear trend along with fractional integration outperforms alternative models over long horizons.

## 1. Introduction

The statistical modelling of financial time series data such as asset prices plays an important role in portfolio management. Despite the extensive theoretical and empirical literature of the last thirty years, there is still no consensus on what might be the most adequate model specification for many financial series. For instance, whether asset returns of asset prices are predictable or not is still controversial. While the efficiency market hypothesis suggests that they should follow a random walk (see Fama, 1970; Summers, 1986), other authors have found evidence of mean reversion in their behaviour (see, e.g., Poterba and Summers, 1988 and Fama and French, 1988). The standard econometric approach to settle this issue empirically relies on establishing the (integer) order of integration of the series by carrying out nonstationary unit root tests. More recently, however, the possibility of fractional orders of integration has also been taken into account, with a slow rate of decay. Long memory specifications for realised volatility have been shown frequently to forecast very accurately (see, e.g., Li, 2002 or Martens and Zein, 2004), though in some cases the sum of short-memory (ARMA) specifications appears to forecast as accurately as a long-memory (ARFIMA) model (see, e.g., Pong et al, 2004). Using a fractional model, Caporale and Gil-Alana (2002) find that there is no permanent component in US stock market returns, since the series examined is close to being $\mathrm{I}(0)$. Caporale and Gil-Alana (2007) decompose the stochastic process followed by US stock prices into a long-run component described by the fractional differencing parameter (d) and a short-run (ARMA) structure. Empirical support for non-linear asset pricing models (such as the one by Dittmar, 2002) has also been found (see, inter alia, Hossein and Sonnie, 2006).

The present paper takes into account these various strands of the literature on modelling asset prices and proposes a very general time series framework to capture the
long-run behaviour of financial data. The suggested model includes linear and nonlinear time trends, and stationary and nonstationary processes based on integer and/or fractional degrees of differentiation. Moreover, the spectrum is allowed to contain more than a single pole or singularity, occurring at the zero frequency but also at non-zero (cyclical) frequencies. This model is used to analyse four annual time series with a long span, namely dividends, earnings, interest rates and long-term government bond yields, obtainable from Robert Shiller's homepage (http://www.econ.yale.edu/~shiller/). We are able to show that the selected specifications (with linear and non-linear trends, fractional integration and cyclical fractional integration) have better forecasting properties than alternative models used in the literature to analyse these data.

The structure of the paper is as follows. Section 2 describes the model and the statistical approach employed in the paper. Section 3 presents the empirical analysis, considering first the case with linear trends and then the non-linear one. Section 4 assesses the forecasting performance of the selected models, whilst Section 5 offers some concluding comments.

## 2. The model

Let us assume that $\left\{\mathrm{y}_{\mathrm{t}}, \mathrm{t}=1,2, \ldots, \mathrm{~T}\right\}$ is the time series we observe. We consider the following model:

$$
\begin{gather*}
y_{t}=f(t)+x_{t}  \tag{1}\\
(1-L)^{d_{1}}\left(1-2 \cos w_{r} L+L^{2}\right)^{d_{2}} x_{t}=u_{t},  \tag{2}\\
\phi_{p}(L) u_{t}=\theta_{q}(L) \varepsilon_{t}, \tag{3}
\end{gather*}
$$

where f is a function of time that may be of a linear/non-linear nature; L is the lag operator (i.e., $L^{s} x_{t}=x_{t-s}$ ); $d_{1}$ is the order of integration corresponding to the long-run or zero frequency; $\mathrm{w}_{\mathrm{r}}=2 \pi / \mathrm{r}$, with r representing the number of periods per cycle; $\mathrm{d}_{2}$ is the
order of integration with respect to the non-zero (cyclical) frequency, and $u_{t}$ is assumed to be an $I(0)$ process, that may follow a general stationary ARMA(p, q) process, where p and q indicate the orders of the autoregressive and moving average components respectively. Note that $d_{1}$ and $d_{2}$ are allowed be any real values and thus we do not restrict ourselves to integer degrees of differentiation.

The set-up described in (1) - (3) is fairly general, including the standard ARMA model (with or without trends), if $\mathrm{d}_{1}=\mathrm{d}_{2}=0$; the ARIMA case, if $\mathrm{d}_{1}$ is integer and $\mathrm{d}_{2}=$ 0 ; the ARFIMA specification, if $\mathrm{d}_{1}$ is fractional and $\mathrm{d}_{2}=0$, along with other more complex representations.

We now focus on equation (2), and first assume that $\mathrm{d}_{2}=0$. Then, the spectral density function of $\mathrm{x}_{\mathrm{t}}$ is given by:

$$
\begin{equation*}
f(\lambda ; \tau)=\frac{\sigma^{2}}{2 \pi}\left|\frac{\theta\left(e^{i \lambda}\right)}{\phi\left(e^{i \lambda}\right)}\right|^{2}\left|1-e^{i \lambda}\right|^{-2 d_{1}} \tag{4}
\end{equation*}
$$

and it contains a pole or singularity at the long-run or zero frequency. Further, note that the polynomial $(1-L)^{d_{1}}$ can be expressed in terms of its Binomial expansion, such that, for all real $\mathrm{d}_{1}$,

$$
\begin{equation*}
(1-L)^{d_{1}}=\sum_{j=0}^{\infty}\binom{d_{1}}{j}(-1)^{j} L^{j}=1-d_{1} L+\frac{d_{1}\left(d_{1}-1\right)}{2} L^{2}-\ldots, \tag{5}
\end{equation*}
$$

implying that the higher is the value of $d_{1}$, the higher is the degree of association between observations distant in time. Thus, the parameter $\mathrm{d}_{1}$ plays a crucial role in determining the degree of persistence of the series. Although the time series literature for very long only considered the cases of integer values of $d_{1}$ (stationarity if $d_{1}=0$, and nonstationarity with $d_{1}=1$ ), more recently fractional values of $d_{1}$ have been widely
employed when modelling macroeconomic and financial data. ${ }^{1}$ Suppose now that $d_{1}=0$ in (2). Then, the process $x_{t}$ has a spectral density function given by:

$$
\begin{equation*}
f(\lambda ; \tau)=\frac{\sigma^{2}}{2 \pi}\left|\frac{\theta\left(e^{i \lambda}\right)}{\phi\left(e^{i \lambda}\right)}\right|^{2}\left|2\left(\cos (\lambda)-\cos \left(w_{r}\right)\right)\right|^{-2 d_{2}} \tag{6}
\end{equation*}
$$

and is characterised by having a pole at a non-zero frequency. Moreover, the polynomial $\left(1-2 \cos w_{r} L+L^{2}\right)^{d_{2}}$ can be expressed as a Gegenbauer polynomial, such that, defining $\mu=\cos w_{r}$, for all $d_{2} \neq 0$,

$$
\begin{equation*}
\left(1-2 \mu L+L^{2}\right)^{-d_{2}}=\sum_{j=0}^{\infty} C_{j, d_{2}}(\mu) L^{j}, \tag{7}
\end{equation*}
$$

where $C_{j, d_{2}}(\mu)$ are orthogonal Gegenbauer polynomial coefficients recursively defined as:

$$
\begin{gathered}
C_{0, d_{2}}(\mu)=1, \\
C_{1, d_{2}}(\mu)=2 \mu d_{2}, \\
C_{j, d_{2}}(\mu)=2 \mu\left(\frac{d_{2}-1}{j}+1\right) C_{j-1, d_{2}}(\mu)-\left(2 \frac{d_{2}-1}{j}+1\right) C_{j-2, d_{2}}(\mu), \quad j=2,3, \ldots
\end{gathered}
$$

(see, inter alia, Magnus et al., 1966, or Rainville, 1960, for further details on Gegenbauer polynomials). Gray et al. $(1989,1994)$ showed that this process is stationary if $d_{2}<0.5$ for $\left|\mu=\cos w_{r}\right|<1$ and if $d_{2}<0.25$ for $|\mu|=1$. If $d_{2}=1$, the process is said to contain a unit root cycle (Ahtola and Tiao, 1987; Bierens, 2001); other applications using fractional values of $\mathrm{d}_{2}$ can be found in Gil-Alana (2001), Ahn, Knopova and Leonenko (2004), Soares and Souza (2006), etc. ${ }^{2}$

[^0]In the empirical analysis carried out in the following section we use a method developed by Robinson (1994) that enables us to test a model such as (1) - (3). It is a testing procedure based on the Lagrange Multiplier (LM) principle that uses the Whittle function in the frequency domain. It can be used to test the null hypothesis:

$$
\begin{equation*}
H_{o}: d \equiv\left(d_{1}, d_{2}\right)^{T}=\left(d_{10}, d_{2 o}\right)^{T} \equiv d_{o} \tag{8}
\end{equation*}
$$

in (1) - (3) where $d_{10}$ and $d_{20}$ may be any real values, thus encompassing stationary and nonstationary hypotheses. The specific form of the test statistic (denoted by $\hat{R}$ ) is presented in the appendix. Under very general regularity conditions, Robinson (1994) showed that for this particular version of his tests,

$$
\begin{equation*}
\hat{R} \rightarrow_{d} \quad \chi_{2}^{2}, \quad \text { as } \quad T \rightarrow \infty . \tag{9}
\end{equation*}
$$

Thus, unlike in other procedures, we are in a classical large-sample testing situation. A test of (8) will reject $H_{0}$ against the alternative $H_{a}: d \neq d_{0}$ if $\hat{R}>\chi_{2, \alpha}^{2}$, where $\operatorname{Prob}\left(\chi_{2}^{2}\right.$ $\left.>\chi_{2, \alpha}^{2}\right)=\alpha$. Furthermore the test is efficient in the Pitman sense against local departures from the null, that is, if the test is implemented against local departures of the form: $\mathrm{H}_{\mathrm{a}}$ : $\mathrm{d}=\mathrm{d}_{\mathrm{o}}+\delta \mathrm{T}^{-1 / 2}$, for $\delta \neq 0$, the limit distribution is a $\chi_{2}^{2}(v)$, with a non-centrality parameter $v$ that is optimal under Gaussianity of $u_{t}$.

There exist other procedures for estimating and testing the fractionally differenced parameters, some of them also based on the likelihood function. As in other standard large-sample testing situations, Wald and LR test statistics against fractional alternatives will have the same null and local limit theory as the LM tests of Robinson (1994). Ooms (1997) proposed tests based on seasonal fractional models: they are Wald tests, and thus require efficient estimates of the fractional differencing parameters. He used a modified periodogram regression estimation procedure due to Hassler (1994). Also, Hosoya (1997) established the limit theory for long-memory processes with the
singularities not restricted at the zero frequency, and proposed a set of quasi loglikelihood statistics to be applied to raw time series. ${ }^{3}$ Unlike these previous methods, the tests of Robinson (1994) do not require estimation of the long-memory parameters since the differenced series have short memory under the null. Similarly, with respect to the zero frequency, Sowell (1992) employed a Wald testing procedure, though again this approach requires an efficient estimate of $d_{1}$, and while such estimates can be obtained, the LM procedure of Robinson (1994) seems computationally more attractive. ${ }^{4}$

## 3. Empirical Analysis

The data analysed in this paper have been obtained from Robert Shiller's homepage (http://www.econ.yale.edu/~shiller/). They are described in chapter 26 of Shiller's (1989) book on "Market Volatility", where further details can be found, and are constantly updated and revised. Specifically, they are the following series: dividends (an index), earnings (also an index), one-year interest rate (this series is the result of converting the January and July rates into an annual yield), long-term government bond yield (this is the yield on the 10 -year Treasury bonds after 1953). The sample period goes from 1871 to 2006 for the first two series, 2004 for the third one, and 2007 for the fourth one. In all cases, we leave out the last ten observations to use them for the forecasting comparison carried out in Section 4.

## [INSERT FIGURE 1 ABOUT HERE]

[^1]Figure 1 contains plots of the four series. As can be seen, both dividends and earnings appear to be quite stable for about a century, and then increase sharply in the last few decades of the sample. Interest rates and government bond yields fluctuate a lot more throughout the sample, but also seem to increase towards the end of the sample, before a significant fall.

In the following two subsections, we examine first a model with linear trends, and then one with non-linear structures. In both cases we allow for long-range dependence at the zero and non-zero (cyclical) frequencies.

### 3.1 The case of linear trends

First we consider the case of linear trends, and assume that the model contains two cyclical structures, one for the long-term behaviour of the series and the other for the cyclical component. We allow both components to display long-memory behaviour, and test the null hypothesis in (8),

$$
H_{o}: d \equiv\left(d_{1}, d_{2}\right)^{T}=\left(d_{10}, d_{2 o}\right)^{T} \equiv d_{o}
$$

in the following model,

$$
\begin{gather*}
y_{t}=\alpha+\beta t+x_{t}  \tag{10}\\
(1-L)^{d_{1}}\left(1-2 \cos w_{r} L+L^{2}\right)^{d_{2}} x_{t}=u_{t} \tag{11}
\end{gather*}
$$

under the assumption that the disturbance term $u_{t}$ is white noise, $\operatorname{AR}(1)$ and $\operatorname{AR}(2)$ respectively. Higher AR orders were also employed and the results do not substantially alter the conclusions based on these two first orders. In all cases, we test $H_{0}$ for $\left(d_{10}\right.$, $\mathrm{d}_{20}$ )-values from -1 to 3 with 0.01 increments, and $\mathrm{r}=2,3, \ldots, \mathrm{~T} / 2,{ }^{5}$ choosing as

[^2]estimates of $\mathrm{d}_{1}$ and $\mathrm{d}_{2}$ the values of $\mathrm{d}_{10}$ and $\mathrm{d}_{20}$ that produce the lowest statistics. These values should be an approximation to the maximum likelihood estimates, noting that Robinson's (1994) method is based on the Whittle function, which is an approximation to the likelihood function. ${ }^{6}$ Given that some of the coefficients in (10) were not significant, we also carried out the computations in a model with only an intercept (i.e. $\beta=0$ a priori) and with no regressors at all ( $\alpha=\beta=0$ a priori). The results for the four series are displayed in Tables 1A-4A.

Also, noting that in some cases the order of integration for the cyclical part $\left(\mathrm{d}_{2}\right)$ was not statistically significantly different from zero, we also perform the analysis with a single fractional differencing parameter, i.e., employing

$$
\begin{equation*}
(1-L)^{d_{1}} x_{t}=u_{t}, \tag{12}
\end{equation*}
$$

rather than (11). The results for this case are displayed in Tables 1B-4B. We describe first of all the results for the trend-cyclical case.

## [INSERT TABLES 1A - 4A ABOUT HERE]

The first remark to make is that the parameter $r$ (indicating the number of time periods per cycle) is constrained between 2 and 15 in all cases, being around 8 in the majority of cases. This is consistent with the empirical findings in the business cycle literature (Canova, 1998; Burnside, 1998; King and Rebelo, 1999; etc.) according to which cycles have a periodicity between five and ten years. It is also noteworthy that the order of integration at the long-run or zero frequency (i.e., $\mathrm{d}_{1}$ ) is substantially higher than its corresponding value at the cyclical frequency $\left(\mathrm{d}_{2}\right)$, especially for earnings and

[^3]interest rates. For these two series the unit root null cannot be rejected at the long-run frequency $\left(d_{1}=1\right)$, while $d_{2}$ is found to be strictly below 1 in all cases. In Tables $1 \mathrm{~A}-$ 4A we report in bold the cases where the null hypothesis of white noise errors cannot be rejected at conventional statistical levels. There are two such cases for dividends, a single one for earnings, six for interest rates and five for government bond yields. Among these selected models we choose the best specification on the basis of LR tests and other likelihood criteria. The selected model for each series is as follows. For dividends,
\[

$$
\begin{equation*}
y_{t}=-6.891+x_{t} ; \quad(1-L)^{1.48}\left(1-2 \cos w_{10} L+L^{2}\right)^{0.52} x_{t}=\varepsilon_{t} . \tag{1A}
\end{equation*}
$$

\]

For earnings,

$$
\begin{gather*}
y_{t}=10.348+x_{t} ; \quad(1-L)^{1.19}\left(1-2 \cos w_{7} L+L^{2}\right)^{0.39} x_{t}=u_{t} ;  \tag{2A}\\
u_{t}=-0.284 u_{t-1}-0.503 u_{t-2}+\varepsilon_{t} .
\end{gather*}
$$

For interest rates,

$$
\begin{equation*}
(1-L)^{0.76}\left(1-2 \cos w_{8} L+L^{2}\right)^{0.18} x_{t}=u_{t} ; \quad u_{t}=-0.217 u_{t-1}-0.211 u_{t-2}+\varepsilon_{t} . \tag{3A}
\end{equation*}
$$

Finally, for the government bond yields,

$$
\begin{gather*}
y_{t}=-23.090+x_{t} ; \quad(1-L)^{0.96}\left(1-2 \cos w_{8} L+L^{2}\right)^{0.28} x_{t}=u_{t} .  \tag{4A}\\
u_{t}=-0.182 u_{t-1}+\varepsilon_{t} .1
\end{gather*}
$$

Considering the confidence bands for the orders of integration of these selected models we see that for dividends and earnings (Tables $1 A$ and $2 A$ ), $d_{1}$ is strictly above 1 while $\mathrm{d}_{2}$ is constrained between 0 and 1 . On the other hand, for interest rates and bond yields (Tables $3 A$ and $4 A$ ) we cannot reject the null hypotheses of $d_{1}=1$ and $d_{2}=0$.

## [INSERT TABLES 1B - 4B ABOUT HERE]

Next we examine the case of a single pole at the long-run or zero frequency (Tables 1B-4B). Here we notice that for dividends the order of integration is much higher than 1 , being even above 2 in three cases. For earnings and government bond yields, some values are below 1 while others are above 1 . Finally, for interest rates, the estimated order of integration is below 1 in all cases and in six out of nine cases the unit root null is rejected in favour of smaller orders of integration. Using this specification, the selected model for dividends is the following:

$$
\begin{equation*}
(1-L)^{1.57} x_{t}=u_{t} ; \quad u_{t}=0.677 u_{t-1}-0.211 u_{t-2}+\varepsilon_{t} \tag{1B}
\end{equation*}
$$

In case of earnings, the chosen specification is:

$$
\begin{equation*}
y_{t}=0.575-0.434 t+x_{t} ; \quad(1-L)^{1.38} x_{t}=u_{t} ; \quad u_{t}=0.023 u_{t-1}-0.445 u_{t-2}+\varepsilon_{t} . \tag{2B}
\end{equation*}
$$

For interest rates,

$$
\begin{equation*}
(1-L)^{0.64} x_{t}=u_{t} ; \quad u_{t}=0.244 u_{t-1}-0.083 u_{t-2}+\varepsilon_{t} \tag{3B}
\end{equation*}
$$

and finally, for government bond yields

$$
\begin{equation*}
(1-L)^{1.00} x_{t}=u_{t} ; \quad u_{t}=-0.159 u_{t-1}+\varepsilon_{t} . \tag{4B}
\end{equation*}
$$

According to these models the four series are nonstationary, and the unit root hypothesis is rejected in favour of higher orders of integration in case of the dividend series.

### 3.2 The case of non-linear trends

Next we allow for possible non-linearities, and assume that the four series exhibit a single break. ${ }^{7}$ Figure 1 suggests that there might be a break around 1973, the time of the first oil price crisis. We experimented with a change in the level, in the slope and in both of them, and came to the conclusion that a level change was the most plausible one for government bond yields, while for the remaining three series we allowed for a

[^4]change in both level and slope after the break. Specifically, we consider a model of the form:
\[

$$
\begin{equation*}
y_{t}=\alpha_{1} I(t<1973)+\alpha_{2} I(t \geq 1973)+x_{t}, \tag{13}
\end{equation*}
$$

\]

for government bond yields, and

$$
\begin{equation*}
y_{t}=\alpha_{1} I(t<1973)+\alpha_{2} I(t \geq 1973)+\beta t I(t \geq 1973)+x_{t}, \tag{14}
\end{equation*}
$$

for the remaining three series, allowing two fractional structures as in (11) (in Tables 1C $-4 C$ ) and with a single fractional differencing polynomial at the zero frequency as in (12) (in Tables 1D - 4D): ${ }^{8}$

## [INSERT TABLES 1C - 4D ABOUT HERE]

Starting again with the case of two poles in the spectrum (i.e., using equation 11), the selected models for dividends (with $\mathrm{T}^{*}=1973$ ) in Tables $1 \mathrm{C}-4 \mathrm{C}$ were:

$$
\begin{align*}
& y_{t}=-6.006 I\left(t<T^{*}\right)-20.204 I\left(t \geq T^{*}\right)+0.452 t I\left(t \geq T^{*}\right)+x_{t} \\
& (1-L)^{1.56}\left(1-2 \cos w_{11} L+L^{2}\right)^{0.53} x_{t}=u_{t} ; \quad u_{t}=0.308 u_{t-1}+\varepsilon_{t} . \tag{1C}
\end{align*}
$$

For earnings,

$$
\begin{align*}
& y_{t}=-121.003 I\left(t<T^{*}\right)-104.15 I\left(t \geq T^{*}\right)-1.039 t I\left(t \geq T^{*}\right)+x_{t} ; \\
& (1-L)^{1.32}\left(1-2 \cos w_{7} L+L^{2}\right)^{0.52} x_{t}=u_{t} ; \quad u_{t}=-0.117 u_{t-1}-0.260 u_{t-2}+\varepsilon_{t} . \tag{2C}
\end{align*}
$$

For interest rates,

$$
\begin{align*}
& y_{t}=-75.817 I\left(t<T^{*}\right)-63.114 I\left(t \geq T^{*}\right)-0.636 t I\left(t \geq T^{*}\right)+x_{t}  \tag{3C}\\
& (1-L)^{0.38}\left(1-2 \cos w_{15} L+L^{2}\right)^{1.23} x_{t}=u_{t} ; \quad u_{t}=-0.237 u_{t-1}+\varepsilon_{t} .
\end{align*}
$$

and finally, for government bond yields,

[^5]\[

$$
\begin{align*}
& y_{t}=-25.644 I\left(t<T^{*}\right)-28.013 I\left(t \geq T^{*}\right)+x_{t} ; \\
& (1-L)^{0.95}\left(1-2 \cos w_{3} L+L^{2}\right)^{0.14} x_{t}=u_{t} ; \quad u_{t}=-0.088 u_{t-1}+\varepsilon_{t} . \tag{4C}
\end{align*}
$$
\]

It can be seen that the number of periods per cycle varies substantially depending on the series. Specifically, it is 11 for dividends, 7 for earnings, 15 for interest rates, and 3 for government bond yields. The order of integration at the long-run or zero frequency is higher than the cyclical one for dividends, earnings and government bond yields, while the opposite holds for interest rates. For the first two series, $d_{1}$ is significantly higher than 1 , while $\mathrm{d}_{2}$ is in the interval $(0,1)$ for the three latter series. Surprisingly, for the interest rate $\mathrm{d}_{1}$ is strictly smaller than 1 while $\mathrm{d}_{2}$ is significantly above 1 .

## [INSERT TABLES 1D - 4D ABOUT HERE]

When we assume that there is a single pole occurring at the long-run or zero frequency, (Tables 1D - 4D), the deterministic terms are found to be mostly insignificant in the case of dividends and earnings, while they are all significant in the case of interest rates and government bond yields. The order of integration appears to be highly sensitive to the chosen specification for the disturbance term, especially for dividends and earnings. For instance, for dividends, $\mathrm{d}_{1}$ is above 2 in case of a white
 strictly smaller than 1 with an $\operatorname{AR}(2) u_{t}$. The selected models in this case are the following: for dividends,

$$
\begin{align*}
& y_{t}=-1.744 I\left(t<T^{*}\right)-2.878 I\left(t \geq T^{*}\right)+0.485 t I\left(t \geq T^{*}\right)+x_{t} ;  \tag{1D}\\
& (1-L)^{0.63} x_{t}=u_{t} ; \quad u_{t}=1.372 u_{t-1}-0.745 u_{t-2}+\varepsilon_{t} .
\end{align*}
$$

For earnings,

$$
\begin{align*}
& y_{t}=0.231 I\left(t<T^{*}\right)+0.269 I\left(t \geq T^{*}\right)+1.641 t I\left(t \geq T^{*}\right)+x_{t} ;  \tag{2D}\\
& (1-L)^{1.17} x_{t}=u_{t} ; \quad u_{t}=0.162 u_{t-1}-0.401 u_{t-2}+\varepsilon_{t} .
\end{align*}
$$

For interest rates,

$$
\begin{align*}
& y_{t}=2.751 I\left(t<T^{*}\right)+7.105 I\left(t \geq T^{*}\right)-0.258 t I\left(t \geq T^{*}\right)+x_{t} ; \\
& (1-L)^{0.45} x_{t}=u_{t} ; \quad u_{t}=0.333 u_{t-1}+0.007 u_{t-2}+\varepsilon_{t} . \tag{3D}
\end{align*}
$$

and for government bond yields,

$$
\begin{align*}
& y_{t}=5.279 I\left(t<T^{*}\right)+5.761 I\left(t \geq T^{*}\right)+x_{t} ;  \tag{4D}\\
& (1-L)^{0.99} x_{t}=u_{t} ; \quad u_{t}=-0.183 u_{t-1}-0.007 u_{t-2}+\varepsilon_{t} .
\end{align*}
$$

According to these specifications, dividends, government bond yields and earnings are nonstationary variables, while interest rates is the only one with a fractional differencing parameter in the stationary region ( $\mathrm{d}<0.5$ ). However, the confidence intervals indicate that dividends is the only series for which the unit root null $(\mathrm{d}=1)$ is rejected.

## 4. Forecasting performance

This section examines the forecasting performance of the models previously selected. For each of the series we consider the four model specifications given by equations (1A) - (4D). First, we compute the $\mathrm{k}(=1,2, \ldots, 10)$-ahead prediction errors of each model, obtained by expanding the fractional polynomials in (5) and (7). Tables $5-8$ report the Root Mean Squared Errors (RMSE) of each specification for each series. It can be seen that for dividends (Table 5) model (1B) appears to be the best based on the 1-period ahead prediction. However, for longer horizons, model (1D) (i.e., a single fractional polynomial at the long-run frequency along with a non-linear trend) seems to perform best in all cases. A similar conclusion is reached for earnings (Table 6) and government bond yields (Table 8). Thus, based on the 1-period ahead predictions, the
model with a single fractional differencing polynomial (equations (2B) and (4B)) performs best, while the one with a non-linear trend is preferred in the remaining cases (equations (2D) and (4D)). Finally, for interest rates (Table 7) models (3A) and (3D) are the most adequate ones: based on the $1,2,5,6$ and 7 -period ahead predictions, the model with a non-linear trend and a single fractional polynomial seems to be the most adequate. However, when the forecasting horizon is $3,4,8,9$ and 10 periods ahead, the specification with two fractional polynomials is the preferred one.

## [INSERT TABLES 5-8 ABOUT HERE]

Overall, for dividends, earnings and government bond yields, the model with a single fractional polynomial at the zero frequency predicts better 1-period ahead; however, for longer horizons, a model with a non-linear trend (and also a fractional process at the zero frequency) outperforms the rival models. For interest rates, the results are slightly more ambiguous: the model with two polynomials (at the zero and the cyclical frequency) seems to be the most adequate one in some cases, but a nonlinear model with a single polynomial at the zero frequency appears to be preferable in other cases.

The results presented so far as based on the RMSE. However, this criterion along with other methods such as the Mean Absolute Prediction Error (MAPE), Mean Squared Error (MSE), Mean Absolute Deviation (MAD), etc., is a purely descriptive device. ${ }^{9}$ Several statistical tests for comparing different forecasting models are now available. One of them, widely employed in the time series literature, is the asymptotic

[^6]test for a zero expected loss differential due to Diebold and Mariano (1995). ${ }^{10}$ Harvey, Leybourne and Newbold (1997) note that the Diebold-Mariano test statistic could be seriously over-sized as the prediction horizon increases, and therefore provide a modified Diebold-Mariano test statistic given by:
$$
\mathrm{M}-\mathrm{DM}=\mathrm{DM} \sqrt{\frac{\mathrm{n}+1-2 \mathrm{~h}+\mathrm{h}(\mathrm{~h}-1) / \mathrm{n}}{\mathrm{n}}},
$$
where DM is the original Diebold-Mariano statistic, h is the prediction horizon and n is the time span for the predictions. Harvey et al. (1997) and Clark and McCracken (2001) show that this modified test statistic performs better than the DM test statistic (though still poorly in finite samples), and also that the power of the test is improved when p values are computed with a Student t -distribution.

Using the M-DM test statistic, we further evaluate the relative forecast performance of the different models by making pairwise comparisons. We consider 2, 4, 6 and 8-period ahead forecasts on a 10-period horizon. The results are displayed in Tables $9-12$, and are consistent with the previous ones.

## [INSERT TABLES 9-12 ABOUT HERE]

In particular, models (1D), (2D), (3D) and (4D) are preferred in most cases, especially based on the 2- and 4-period ahead prediction horizons. Only for interest rates does model (3A) outperform (3D) in some cases.

[^7]
## 5. Conclusions

In this paper we have introduced a new time series approach to modelling long-run trends and cycles in financial time series data. The proposed model is general enough to include linear and non-linear trends along with fractional integration at zero and nonzero (cyclical) frequencies. It is based on the testing procedure developed by Robinson (1994) for stationary and nonstationary hypotheses. We have used our framework to investigate the behaviour of four financial time series already examined in many earlier studies. Specifically, we have used the annual dataset including dividends, earnings, interest rates and government bond yields, which was constructed (and is constantly updated) by Robert Shiller.

The results can be summarised as follows. It appears that the four series of interest can be characterised in terms of long-memory processes with two poles in the spectrum, one corresponding to the long-run or zero frequency, and the other one to the cyclical component. The latter exhibits a periodicity ranging between 3 and 15 years depending on the series and the model considered. In general, the order of integration is higher at the zero frequency, implying that the degree of persistence is higher in this component. When non-linear trends are incorporated, the models outperform the linear ones in terms of their forecasting accuracy, especially over longer horizons.

This paper can be extended in several directions. First, multiple cyclical structures of the form advocated by Ferrara and Guegan (2001) and others can be considered. In fact, the interaction between cyclical (fractional) processes may produce autocorrelations decaying in a very complicated way that has not been much investigated yet. Other more complex non-linear structures (like the Threshold AutoRegressive, TAR, Momentum Threshold AutoRegressive, M-TAR or Smooth Transition Autoregressive, STAR-form (see, e.g. Enders and Granger, 1998; Enders and

Siklos, 2001; Skalin and Teräsvirta, 2002) can also be included in the regression model (1). Finally, the date(s) of the structural break(s) can be endogenously determined in the context of the general model described by equations (1) - (3). Future research will address these issues.

## Appendix

The test statistic proposed by Robinson (1994) for testing $\mathrm{H}_{0}(8)$ in (1) - (3) is given by:

$$
\hat{R}=\frac{T}{\hat{\sigma}^{4}} \hat{a}^{\prime} \hat{A}^{-1} \hat{a},
$$

where T is the sample size, and

$$
\begin{gathered}
\hat{a}=\frac{-2 \pi}{T} \sum_{j}^{*} \psi\left(\lambda_{j}\right) g\left(\lambda_{j} ; \hat{\tau}\right)^{-1} I\left(\lambda_{j}\right) ; \quad \hat{\sigma}^{2}=\sigma^{2}(\hat{\tau})=\frac{2 \pi}{T} \sum_{j=1}^{T-1} g\left(\lambda_{j} ; \hat{\tau}\right)^{-1} I\left(\lambda_{j}\right), \\
\hat{A}=\frac{2}{T}\left(\sum_{j}^{*} \psi\left(\lambda_{j}\right) \psi\left(\lambda_{j}\right)^{\prime}-\sum_{j}^{*} \psi\left(\lambda_{j}\right) \hat{\varepsilon}\left(\lambda_{j}\right)^{\prime}\left(\sum_{j}^{*} \hat{\varepsilon}\left(\lambda_{j}\right) \hat{\varepsilon}\left(\lambda_{j}\right)^{)^{\prime}}\right)^{-1} \sum_{j}^{*} \hat{\varepsilon}\left(\lambda_{j}\right) \psi\left(\lambda_{j}\right)^{\prime}\right) \\
\left.\psi\left(\lambda_{j}\right)^{\prime}=\mid \psi_{1}\left(\lambda_{j}\right), \psi_{2}\left(\lambda_{j}\right)\right] ; \quad \hat{\varepsilon}\left(\lambda_{j}\right)=\frac{\partial}{\partial \tau} \log g\left(\lambda_{j} ; \hat{\tau}\right) ; \quad \psi_{1}\left(\lambda_{j}\right)=\log \left|2 \sin \frac{\lambda_{j}}{2}\right| ; \\
\psi_{2}\left(\lambda_{j}\right)=\log \left|2\left(\cos \lambda_{j}-\cos w_{r}\right)\right|, \text { with } \lambda_{\mathrm{j}}=2 \pi \mathrm{j} / \mathrm{T}, \text { and the summation in * is over all }
\end{gathered}
$$ frequencies which are bounded in the spectrum. $I\left(\lambda_{j}\right)$ is the periodogram of $\hat{u}_{t}=(1-L)^{d_{1 o}}\left(1-2 \cos w_{r} L+L^{2}\right)^{d} 2 o y_{t}-\hat{\beta}^{\prime} \bar{z}_{t}$, with

$\hat{\beta}=\left(\sum_{t=1}^{T} \bar{z}_{t} \bar{z}_{t}\right)^{-1} \sum_{t=1}^{T} \bar{z}_{t}(1-L)^{d_{1 o}}\left(1-2 \cos w_{r} L+L^{2}\right)^{d} 2 o y_{t} ;$
$\bar{z}_{t}=(1-L)^{d_{l o}}\left(1-2 \cos w_{r} L+L^{2}\right)^{d_{2 o}} z_{t}, \quad$ evaluated $\quad$ at $\quad \lambda_{\mathrm{j}}=2 \pi \mathrm{j} / \mathrm{T}$ and $\hat{\tau}=$ $\arg \min _{\tau \in T^{*}} \sigma^{2}(\tau)$, with $\mathrm{T}^{*}$ as a suitable subset of the $\mathrm{R}^{\mathrm{q}}$ Euclidean space. Finally, the function $g$ above is a known function coming from the spectral density of $u_{t}$ :

$$
f(\lambda ; \tau)=\frac{\sigma^{2}}{2 \pi} g(\lambda ; \tau), \quad-\pi<\lambda \leq \pi .
$$

Note that these tests are purely parametric and, therefore, they require specific modelling assumptions about the short-memory specification of $u_{t}$. Thus, if $u_{t}$ is white
noise, $g \equiv 1$, and if $u_{t}$ is an AR process of the form $\phi(\mathrm{L}) \mathrm{u}_{\mathrm{t}}=\varepsilon_{\mathrm{t}}, \mathrm{g}=\left|\phi\left(\mathrm{e}^{\mathrm{i} \lambda}\right)\right|^{-2}$, with $\sigma^{2}=$ $\mathrm{V}\left(\varepsilon_{\mathrm{t}}\right)$, so that the AR coefficients are a function of $\tau$.

2330 Guglielmo Maria Caporale, Juncal Cuñado and Luis A. Gil-Alana, Modelling Long-Run Trends and Cycles in Financial Time Series Data, June 2008

[^0]:    ${ }^{1}$ Empirical applications using fractional values of $\mathrm{d}_{1}$ include Diebold and Rudebusch (1989), Sowell (1992), Gil-Alana and Robinson (1997), etc.
    ${ }^{2}$ Models with multiple cyclical structures ( $k$-factor Gegenbauer processes) with multiple poles in the spectrum have been examined, among others, by Ferrara and Guegan (2001), Sadek and Khotanzad (2004) and Gil-Alana (2007a).

[^1]:    ${ }^{3}$ Models of this form (with a pole at the non-zero frequency) were also considered, among others, by Giraitis, Hidalgo and Robinson (2001), Hidalgo and Soulier (2004) and Hidalgo (2005). These authors assume that the pole in the spectrum is unknown and suggest various parametric and semiparametric methods to estimate the fractional parameter $\left(\mathrm{d}_{2}\right)$, along with the frequency of the pole in the spectrum (see also Arteche and Robinson, 2000, and Arteche, 2002).
    ${ }^{4}$ See also Tanaka (1999) for a time domain representation of Robinson's (1994) tests.

[^2]:    ${ }^{5}$ Note that in case of $r=1$, the polynomial $\left(1-2 \cos w_{r} L+L^{2}\right)^{d_{2}}$ becomes $(1-L)^{2 d_{2}}$, implying the existence of a pole at the long run or zero frequency.

[^3]:    ${ }^{6}$ Several Monte Carlo experiments based on this approach were conducted by Caporale and Gil-Alana (2006), and Gil-Alana (2007). It is shown in these papers that this method correctly determines the orders of integration at the two frequencies for samples of similar size to those employed in this article.

[^4]:    ${ }^{7}$ Multiple breaks could also be considered. However, we believe that the series examined in this paper can be adequately described including a single structural break. Note that allowing for multiple breaks would result in short subsamples and innaccurate estimates of the coefficients.

[^5]:    ${ }^{8}$ We also considered other break dates for the four series, and the coefficients in (13) and (14) were insignificant in the majority of the cases.

[^6]:    ${ }^{9}$ The accuracy of different forecasting methods is a topic of continuing interest and research (see, e.g., Makridakis et al., 1998 and Makridakis and Hibon, 2000, for a review of the forecasting accuracy of competing forecasting models).

[^7]:    ${ }^{10}$ An alternative approach is the bootstrap-based test of Ashley (1998), though his method is computationally more intensive.
