Abstract

We report results from a validation study of Nielsen Homescan data. We use data from a large grocery chain to match thousands of individual transactions that were recorded by both the retailer (at the store) and the Nielsen Homescan panelist (at home). First, we report how often shopping trips are not reported, and how often trip information, product information, price, and quantity are reported with error. We focus on recording errors in prices, which are more prevalent, and show that they can be classified to two categories, one due to standard recording errors, while the other due to the way Nielsen constructs the price data. We then show how the validation data can be used to correct the impact of recording errors on estimates obtained from Nielsen Homescan data. We use a simple application to illustrate the impact of recording errors as well as the ability to correct for these errors. The application suggests that while recording errors are clearly present, and potentially impact results, corrections, like the one we employ, can be adopted by users of Homescan data to investigate the robustness of their results.

Keywords: Measurement error, validation study, self-reported data

1 Introduction

Nielsen Homescan (Homescan) is a rich data set that provides information about household purchasing patterns, allowing researchers, practitioners, and policymakers to study questions that cannot be addressed using other forms of data.[1] For example, Homescan covers purchases at retailers that traditionally do not cooperate with scanner data collection companies, such as Wal-Mart and Whole Foods. In addition, due to its national coverage the data provide wide variation in household location and demographics, compared to other panels in which most households are from a small number of markets with relatively limited variation in demographics.

However, questions have been raised regarding the credibility of the data since the data are self-recorded and the recording process is time consuming. Two concerns are most common. The first is potential sample selection; given the time commitment, households who agree to participate in the sample might not be representative of the population of interest. Second, households who agree to participate in the sample might record their purchases incorrectly.

This paper reports and analyzes a validation study of the Nielsen Homescan data set. Our primary goal is to examine the second concern. To do so, we use a unique research design which allows us to use scanner data from a single retailer as a validation data; we construct a data set that allows us to match records from Homescan with detailed transaction-level data from the retailer. That is, we are able to observe the same transaction twice. First, we observe the transaction as it was recorded by the retailer, just before the items left the store. Second, we observe the transaction as it was recorded by the Homescan panelist, just after the items reached the house. By comparing the two data sources we can document inaccuracies (or lack thereof) in Homescan and propose ways to correct for them. In particular, we compare the data sets along three dimensions. First, we can document if the household did not report a trip to the retailer or misrecorded the trip information (store and date). Second, within a trip we can document if the household did not record, or misrecorded, the product (Universal Product Code, henceforth UPC) information. Third, for a given product, we can document misreporting of the price, quantity, and deal information.

Our goal in this paper is threefold. First, we document the accuracy of Homescan data by describing the magnitude of mistakes, for each of the above potential recording errors. Second, we investigate whether and how errors are correlated with household or trip characteristics, which would be suggestive of which type of analysis may be more sensitive to such errors, and how. For example, we ask whether a correlation between a price "paid" and demographics can be driven by systematic measurement errors. Third, we show how our validation study can be used to correct for the reporting errors and provide the sufficient information from our study that will allow future users of Homescan to do so. In light of the growing popularity of Homescan among researchers, we view this as an important contribution of this paper.

Before we summarize our findings, we should clarify two important issues related to terminology. First, through most of the paper we treat the retailer's data as the "truth," allowing us

[1] Indeed, there has been a recent surge in the use of Homescan in the academic literature. See, among others, Dube (2004), Aguiar and Hurst (2007), Hausman and Leibtag (2007), Katz (2007), and Broda and Weinstein (2008 and forthcoming).

to attribute any differences between the data sets to "errors" or "mistakes." Of course, to the extent that there are recording errors in the retailer's data, these words should be interpreted accordingly. We discuss this further in the context of the results. The second terminology issue is related to what we mean by "errors," "mistakes," or "misrecording" in Homescan. As will be clear, this could be driven by various mechanisms: recording errors by the Homescan panelists themselves, misunderstanding of the Homescan instructions, or errors that are generated due to the way Nielsen puts together its data. As we discuss later, this latter case seems most important for the price variable, but here we simply note that by using the words "errors," "mistakes," or "misrecording" we mean any of these possible mechanisms.

In Section 2 we describe the study design and the data construction process. In Section 3 we then document the recording errors along the three dimensions previously mentioned. For approximately twenty percent of trips recorded in the Homescan data we can say with a high degree of certainty that there is no corresponding transaction in the retailer's data. This suggests that either the store or date information is recorded with error. Using the retailer's loyalty card information, we find that there also seem to be many trips that are found in the retailer's data with no parallel in the Homescan data. Therefore, there seems to be evidence that households do not record all of their trips.[2] For the trips we matched, we find that roughly twenty percent of the items are not recorded. For those items recorded, we find that quantity is reported fairly accurately: 94 percent of the quantity information matches in the two data sets, and conditional on a reported quantity of 1 in the Homescan data, this probability goes up to 99 percent.

The match for prices is worse. In about half of the cases the two data sets do not agree. However, the correlation between the Homescan price and the retailer's price is 0.88, and the recording error explains roughly 22% of the variation in the reported price. We document two types of price errors. When the item is not associated with a loyalty card discount, the price recording errors are similar to classical errors, and are roughly normally distributed around the true price. In this case the correlation between the two prices is 0.96 and the error explains only 8.5% of the variation in the Homescan price. In contrast, when the item is associated with a loyalty card discount, prices in Homescan tend to significantly over report the actual price, sometimes by a large amount. It seems likely that much of this second case is driven by the way Nielsen imputes prices; when available, Nielsen uses store-level (average) prices instead of the actual price paid by the household. Thus, the lower accuracy of the price data may be primarily driven by the data construction process. We note that this type of error might not be present for data from other retailers that, for example, do not offer loyalty card discounts and where all consumers pay the same price in a given week.

We also investigate the heterogeneity across households in the quality of their data recording. We find that some households are extremely accurate, while others are much less so. We show that these latter households are more likely to be larger households in which the head female of the household is fully employed. We suspect that this points out to the opportunity cost of time as an important determinant of recording errors in Homescan. Since we find that recording errors

[2] In this latter case, we are more cautious in providing specific numbers, as the retailer's algorithm that matches trips to households could be prone to errors, and therefore likely to be further from the "truth."

are not mean zero and are correlated with different household attributes, using the Homescan data may result in biased estimates of coefficients of interest, and may lead to inaccurate conclusions. This motivates us, in Section 4, to investigate how these recording errors may affect results, as well as to propose ways that allow to correct for it. We illustrate this point in the context of an example that uses both data sets to study how the price paid vary with demographics; indeed, we find that in some cases the results are quite different. We also use this example to illustrate how the validation sample can be used to correct for recording errors. This example is both simple and a case in which classical measurement error would be inconsequential. Indeed, we show that results using the true data and the Homescan data could be vastly different, and that our correction procedure makes it closer.

In Section 5 we conclude by emphasizing that our correction method relies on the assumption that the distribution of the recording errors is the same in our validation study and in the rest of the Homescan data. Since, as we show, our matched sample does not seem fully representative of the entire Homescan data, corrections should be done with caution, and are probably best viewed as robustness checks.

This paper fits into a broader literature of validation studies. Responses to surveys and self-reported data are at the heart of many data sets used by researchers, executives, and policymakers. For example, the Panel Study of Income Dynamics (PSID), the Current Population Survey (CPS), and the Consumer Expenditure Survey (CEX) are used heavily by economists. One concern with self-reported data is that the data is recorded with error, and that the error is systematically related to the characteristics of the respondents or to the variables being recorded. From the theory side, econometricians have developed models to examine the consequences of measurement error. To study the magnitude of the measurement error and to document the distribution of the error, an empirical literature has emerged that compares the self-reported sample to a validation study.[3] This paper adds to this literature by examining a different data set and using a different validation method. While most of the literature has focused on data sets that record labor market decisions and outcomes, we study a data set, the Nielsen Homescan data, that documents purchase decisions. We compare the recording errors we document to errors in these commonly used economic data sets and find that errors in Homescan are of the same order of magnitude as errors in earnings and employment status.

2 Data

2.1 Data sources

2.1.1 Homescan

The Nielsen Homescan data consist of a panel of households who record their grocery purchases.[4] The purchases are from a wide variety of store types, including traditional stores, online merchants, and mail order catalogs. Consumers, who are at least 18 year old and interested in participating,

[3] Bound at el. (2001) provide a detailed review of this literature.

[4] See also http://www.nielsen.com/clients/index.html for additional information about the Homescan data.

register online and are asked to supply demographic information. Based on this information, Nielsen contacts a subset of these consumers. Consumers selected to become panel members are not paid for participating in the program. However, every week a panel member who scans at least one purchase receives a set amount of points. The points can be redeemed for merchandise. Panelists can earn additional points for answering surveys and by participating in sweepstakes that are open only to panel members.

Each participating household is provided with a scanner. For each shopping trip the panelist records the date and the store. They then scan the barcodes of the products they purchased, and enter the quantity of each item, whether the item was purchased at the regular or promotional ("deal") price, and the coupon amount (if used) associated with this purchase.

Nielsen then matches the barcode, or UPC, with detailed product characteristics. The recording of price is particularly important to understand some of the findings below. If the household purchased products at a store covered in Nielsen's store-level data ("Scantrack") – and we think (but could not verify) that all stores operated by the retailer who provided us with the data are covered in the store-level data – Nielsen does not require the household to enter the price paid for each item (as a way to make the scanning process less time-consuming for the household). Instead, the price is imputed from the store-level data. To construct this price, our understanding is that Nielsen uses the (quantity weighted) average weekly price paid at the store for the corresponding item (UPC). If the same item could be transacted at different prices within the same store during the same week, this imputation process can introduce errors into the price data. As we will see, these errors are frequent and sometimes large. A common reason for such price variation across transactions (of the same item within a store-week) is loyalty card discounts that are only applied to the subset of consumers who use cards.

In the analysis below we use data from 2004. We consider only households that are part of the "static" sample.[5] Overall, the data include purchases of almost 250 million different items by just under 40,000 households. We will focus on two markets, where the retailer has a significant presence, that have 1249 households who report over 900,000 items purchased.

2.1.2 The retailer's data

The second data set comes from a large national grocery chain, which we will refer to as "the retailer." This retailer operates hundreds of stores across the country and records all the transactions in all its stores. For each transaction, the data record the exact time of the transaction, the cashier number, and the loyalty card number, if one was used. The data list the UPCs purchased, the quantity purchased of each product, the price paid, and the loyalty card discount (if there was any). The retailer links loyalty cards that belong to members of the same household, primarily by matching the street addresses and telephone numbers individuals use when applying for a loyalty card. The retailer then assigns each household a unique identification number. Clearly, this definition of a household is more prone to errors than is Homescan's definition, in which a household

[5] This sample considers only households that report purchases in at least 10 months of the year. These households are generally considered more reliable than those who report for fewer months, and these are the only data available for research from Nielsen..

is simply associated with the house at which the scanner resides. We return to this later.

In principle, we could try to match our Homescan data with all the retailer's data in 2004. Due to constraints on the size of the data we could obtain from the retailer, however, we had to limit our analysis to only a subsample of it. We therefore obtained the retailer data in two steps, as a way to maximize potential matches subject to the size constraint. In the first step, we identified a set of consumers who claimed to go to the a retailer's store on a particular date. We then obtained complete transaction level data – including exactly what was bought and how much was paid – from the retailer for 1,603 distinct store-days. We developed a simple algorithm to match between the purchases recorded in the Homescan data and one of the many transactions recorded in the retailer's data (on that day at that store), and found 1,372 likely matches that are associated with 293 distinct households.

In a second step, we asked the retailer to use the loyalty card identified in these 1,372 shopping trips and to provide us with all the transactions available for the households associated with these cards (in the retailer's data during 2004). Figure 1 provides a schematic chart that sketches the key steps in the data construction process. The full process is described in more detail in the Appendix.

2.2 Record-matching strategy

Having obtained the retailer's data, we now describe our strategy for matching records from Homescan with record in the retailer's data.[6] We start by analyzing possible matches in the data obtained in the first step. Recall that a Homescan record contains all products purchased by the household on a particular day in a particular store. The retailer's data contain the products purchased in each of the (more than 2,500 on average) shopping trips at the same store and day reported by the household. The goal is to match the Homescan trip to exactly one of the trips in the retailer's data, or to determine that none of the trips in the retailer's data is a good match. The latter case would be indicative of the household not recording the trip in Homescan or possibly recording the trip but misrecording the date or the store.

Since this procedure relies on the coding of the items (UPCs), one may be concerned that certain items, especially non-packaged items, may have different codes at the retailer's stores and at Homescan. An additional concern is that, as mentioned, the Homescan data we use only include the food items scanned by the household, while the store data also include non-food items. To deal with these concerns, we generated the universe of UPCs used by Homescan panelists in our entire data and, separately, the universe of UPCs that are used by the retailer in our entire data. We then restricted attention throughout the rest of the analysis to only the intersection of these two lists of UPCs by eliminating from the analysis all data related to UPCs not in the intersection. In other words, in the analysis below, if a certain UPC in, say, the retailer's data cannot be matched to the Homescan data, it is not because it could not have been matched: there is at least one Homescan household who transacted and recorded that UPC.

[6] Earlier we mentioned a simple matching algorithm we used for the data construction. This was only used to speed up the data requesting process from the retailer, and we do not use its results further. In this section we describe a more systematic matching strategy that is used for the rest of the paper.

After reducing the data set as described above, we continue as follows. Our unit of observation is a reported shopping trip in Homescan. For each such trip, for which we have the retailer's data for that store and that day, we count the number of distinct UPCs that overlap between the Homescan trip and each of the hundreds of trips in the retailer's data (in the same date and store). We then keep the two trips (in the retailer's data) with the largest number of UPC overlap, and define ratios between the UPC overlap in each trip and the number of distinct UPCs reported for this trip in Homescan. The first, $r1$, is the ratio of the number of overlapping UPCs in the retailer trip with the highest overlap to the total number of distinct UPCs reported in the Homescan trip. The higher this ratio, the higher the fraction of products matched, and the more likely that this trip is a correct match. The second ratio, $r2$, is similar, but is computed for the retailer trip with the second-highest overlap. By construction, $r2$ will be less than or equal to $r1$. A higher $r2$ makes it more likely that the second trip is also a reasonable match. Since, in reality, there is, at most, a single trip that should be matched, this statistic tries to guard against a false positive. Our confidence in the match between the Homescan record and the first trip increases the higher is $r1$ and the lower is $r2$. As will become clear below, in practice it turns out that false positives resulting from this algorithm do not seem to be a concern once the trip includes a large number of distinct UPCs.

Using these two statistics, $r1$ and $r2$, and the number of products purchased during a trip (as reported in Homescan), we separate each trip in the Homescan data into one of three categories: reliable matches, matches that with high probability do not have a match, and uncertain matches (i.e., we cannot classify these trips into either of the other groups with a reasonable level of certainty). The first group of transactions will be used to study recording errors in the price and quantity data. The second group will be used to document unrecorded trips or errors in recording trip information. We applied different criteria to define the three groups and verified that all our findings are robust to reasonable modifications of these criteria.

Matching records with the trips reported in the second step of the data construction process is a different problem. Recall that here we are not supplied with a list of all trips recorded in the retailer's data for the day and store. Instead, we are given a single trip that the retailer believes represents the household's purchases on that day. Thus, the matching problem here is not which trip (out of many) matches the Homescan trip, but rather whether a given trip is a good match or not. We match the transactions by computing the ratio $r1$, which is, as before, the number of distinct UPCs that overlap divided by the number of items in the Homescan data. Using the statistic $r1$ and the total number of distinct items purchased we will classify the Homescan trips into three categories, as we do with the first step data. In principle, in this step the thresholds for $r1$ used to classify the trips can be different from the thresholds used in the first step. It turns out, however, that the vast majority of $r1$'s we compute are either close to one or close to zero, making the choice of a threshold largely irrelevant. As an additional guard against false positives, we also report some of the results when eliminating from the data certain households that seem to be inconsistent in the way they use their loyalty cards.

3 Documenting recording errors

In this section we summarize our main finding of recording errors in the Homescan data. More details and further cuts of the data can be found in Einav, Leibtag, and Nevo (2008). We organize the discussion around the three dimensions of potential errors: trip information, product (UPC) information, and price/quantity information. As mentioned earlier, for most of what follows we treat the retailer's record as the "truth" and ask if, or how well, the Homescan record matches it. In that sense, Homescan recording "errors" are defined as records that do not match the retailer's data. However, it could be the case that the retailer's cashier is the one making the error, rather than the Homescan panelist. We think that this latter case is less likely, especially for analysis at the product level and the price and quantity level. At the trip level, when we rely on loyalty card information, it is not clear that the retailer's data are necessarily more accurate. For example, if a household borrows a loyalty card once, then all the shopping trips associated with that card will be linked to the household's record. We discuss this further below.

3.1 Trip and product information

We separate trips according to the number of distinct UPCs in the Homescan data. A small trip is defined as one with 4 or fewer (distinct) UPCs, a medium trip has 5-9 UPCs, and a large trip is a trip with 10 UPCs or more. A potential concern is that we have false positives, i.e., that we match trips incorrectly. Our preliminary analysis, in Einav, Leibtag and Nevo (2008), found that for the medium and large trips mis-classification of a match is not a concern.[7] The real issue is whether a match exists at all, which can be diagnosed by focusing on $r1$.

The distribution of $r1$ is displayed in Figure 2. The information in the top panel helps us address the question of how many of the trips, collected in the first step, seem to have misrecorded store and date information. Focusing on large trips, we find that there are 150 trips with $r1$ less than 0.2, 175 with $r1$ less than 0.3, and 180 with $r1$ less than 0.4 (corresponding to 18.5, 21.6, and 22.4 percent, respectively). For medium trips the corresponding numbers are 113, 155, and 223 (or 9.5, 13.0, and 18.7 percent). Taken together, these numbers suggest that for about 20 percent of the medium and large trips reported in Homescan we can say with a high degree of certainty that they do not match any trip in the retailer's data. Therefore, we conclude that approximately 20 percent of the trips have misrecorded date or store information.[8] The bottom panel of Figure 2 shows a similar pattern for the second step data, with the distribution of $r1$ being even more bimodal.[9] Here, again, we cannot find a match for about 20 percent of the trips

[7] Recall, when possible, for each record in the Homescan data we compute two ratios in the data from the first step: $r1$ is the fraction of UPCs matched in the trip with the highest UPC overlap, and $r2$ is the same ratio for the trip with the second highest UPC overlap. We found that when we focus on medium and large trips, conditioning on $r2$ adds essentially nothing to the classification.

[8] A natural speculation is that perhaps most of these misrecorded trips simply mis-record the date by a day (e.g., because they shop at 11:30pm). Using the retailer's data from the second step we found that while such cases occur, they do not account for a large fraction of the 20 percent misrecorded trips reported here.

[9] This is not surprising. A-priori, for good matches, the distribution of $r1$ should in principle be the same in both panels. However, when there is no good match, $r1$ from the first step will pick up a best match among hundreds of

reported in Homescan, likely due to misrecorded trip information.[10]

The preceding paragraph looked for trips reported in Homescan that cannot be matched in the retailer's data. The data from the second step also allow us to look for the opposite case: trips reported by the retailer's data that cannot be found in Homescan. Recall that the data obtained in the second step include all the trips, according to the retailer, associated with certain households. We find that only 40 percent of these trips appear in Homescan, but we suspect that this number is over estimating the fraction of missed trips, and that at least part of it is driven by the retailer classifying multiple loyalty cards as belonging to the same household, or by multiple individuals (of different households) sharing the same card. To address this concern, we focus on 273 households that seem to have more reliable loyalty card use.[11] On average, across these households, 53 percent of the trips in the retailer's data are not reported in Homescan.

There is heterogeneity across households in their accuracy of reporting. In Figure 3 we plot, for these 273 households, the ratio of trips reported in Homescan to the number of trips in the retailer's data (on the horizontal axis) and the fraction of Homescan trips that are matched well on their UPCs (on the vertical axis). We consider a match as good when the $r1$ is greater than 0.7. Given that these are trips of the same household to the same store on the same day then even trips that do not match well on UPCs are very likely to be the same trips, only with significant misrecording of items.

Figure 3 suggests that there are two types of households, as the correlation between the two ratios is highly positive (0.47). The first group includes those in the upper right corner, who do not miss many trips and also record the trip information fairly accurately. Households in the second group are those that do poorly on both counts: they fail to report a large fraction of their trips and even when they do report a trip, they do not record its items accurately.[12] Using this rough classification, we use the metric of Figure 3 to classify households as "good" or "bad" depending on how far they are from perfection, which is the point (1,1) in the figure. Table 1 then summarizes the key characteristics for each group and highlights those demographics that are significantly different between the groups. The quality of recording is associated with household composition, as well as with whether the female at the household is fully employed. The pattern

unmatched trips while $r1$ from the second step will be computed for a given trip, so should be very close to zero.

[10] In the bottom panel this could also be due to misuse of loyalty cards (for example, if the household forgot the card at home and didn't use it, the trip would be reported in Homescan but will not show up in the second step retailer's data.) However, given that the fraction of unmatched trips in the top panel (where misuse of loyalty cards is not an issue) is very similar, we suspect that much of these unmatched trips are due to misrecorded trip information.

[11] For each of the 291 Homescan households for which we obtained data in the second step, we compute the fraction of their trips that produced a match, where a match is defined as a trip, of any size, with $r1$ greater than 0.7. A higher fraction implies that this household made fewer errors in recording the store and date. The distribution of this fraction is bimodal. We define a poor match household as one in which the fraction is less than 0.3. This procedure eliminated 18 households and left us with 273 households, who used the same loyalty cards (or matched cards, as linked by the retailer) consistently. We then applied a similar procedure to specific cards of these households, which made us drop a small number of cards.

[12] While smaller trips are more likely to be missing or to be misrecorded, the difference is small so the overall nature of trips is similar between matched (and well recorded) trips and other trips by the same households.

is likely driven by the opportunity cost of time of carefully recording purchases. This cost is likely higher for fully employed females and for larger households. In contrast, other demographic variables, such as income and race, are not systematically correlated with the quality of recording.

We now turn our attention to mistakes in recording items (UPCs) conditional on a trip being matched. Since we do not want matching errors to drive our findings we focus on reliable matches only. We use two different criteria for defining a reliable match. First, we look at large trips, involving 10 or more products in the Homescan data, with $r1$ greater than 0.7. There are 2,477 such trips. Second, we examine medium size trips, with at least 5 but no more than 9 distinct UPCs in the Homescan data, and with $r1$ greater than 0.7. There are 3,168 such trips. We do not use the remaining, small trips for the rest of the analysis.

We see that for the typical trip almost all the products (98 percent in both groups) scanned by the Homescan panelist exist in the retailer's transaction. Selection into the sample was conditional on this fraction being at least 70 percent ($r1 > 0.7$). Nevertheless, we still view this as a remarkably high number. This may not be surprising, as the products are scanned, so it is, in fact, hard to imagine how misrecording at this level could take place.

On the other hand, on average there are about 10 percent (14 percent for medium transaction) of the items that show up in the actual transaction, but are not recorded by the Homescan panelist. Recall that we eliminated from the analysis products with UPCs that only show up in one of the data sets. Thus, these missing items cannot be attributed to categories that the Homescan panelist was not supposed to scan.

We qualitatively tried to analyze which items are more likely to be missing in the Homescan trip, by grouping the missed items into product categories, and investigating whether particular categories stand out. While there are many items that belong to various categories that are occasionally missing, two specific types of items are common. The first group includes consumable products: small bottles of drinks, snacks, etc. It seems likely that such items are often consumed on the way home, before the purchase is scanned. The second group includes items that belong to product categories that include many distinct, yet similar UPCs. Yogurts of different flavors and baby food of different flavors are typical examples. In such cases, it seems likely that individuals simply scan one of the flavors and enter a large quantity instead of scanning each of the flavors (which has a distinct UPC) separately.[13]

In order to check if the mistakes in recording products are systematic, we regress the missed expenditure on the total trip expenditure and find that a larger fraction of the expenditure is missed on larger trips. On large trips the household is more likely to forget to scan, not go through the trouble of doing so, or consume items on the way home.

[13] These will appear as missed products, but in reality might not matter, unless we care about the exact flavor bought. To measure this we examine the total number of items bought in the trip. In this example, the total quantity would match even if the distinct UPC count does not. This slightly reduces the differences, but not by much, implying that misrecorded quantity cannot fully explain the difference in the number of products.

3.2 Price and quantity information

We now focus on errors in the price and quantity variables. For this purpose we look at the products that appeared in both data sets from the reliably matched trips using the two definitions of reliable trips. It turns out, that the statistics we present below hardly vary across the groups, so match reliability does not seem to be a concern. For the rest of this section we will refer to the first set of matched products, those from trips with at least 10 products and $r1$ greater than 0.7, as "matched large trips," and for products matched from medium transactions as "matched medium trips." For matched large trips we have 41,158 products purchased, an average of 16.6 products per trip. For matched medium trips we have 21,386 matched items, for an average of 6.8 products per trip (recall that these are trips with 5-9 products).

We present summary statistics for the key variables first and then discuss in more detail additional patterns. Table 2 presents the fraction of observations of quantity, expenditure, price, and deal indicator, that match between the reports in the Homescan data and in the retailer's data. We present results separately for large and medium trips to illustrate the robustness of the patterns, but given that the summary statistics are so similar across these two types of trips, we focus the discussion and the subsequent analysis on large trips alone. For quantity we find that 94 percent of the time the two data sources report the same quantity. The total expenditure on the item is the same in both data sets much less frequently, and only 48% of the times the two data sets report identical prices. On average, the expenditure reported in Homescan is about 10% higher than the expenditure recorded by the retailer, although there is wide dispersion around this average (see Table 2). The pattern for price is similar to that of expenditure. It is slightly better matched (50% match rate and 7% higher prices in Homescan on average), possibly because the expenditure variable (price times quantity) is further prone to errors due to (less frequent) misrecorded quantities. Finally, we examine the deal indicator. In the retailer's data the deal variable equals one if the gross and net price differ. In the Homescan data this is a self reported variable. Overall, this indicator matches in 80% of the observations, a worse match than the quantity data, but better than the price.

We now explore in more detail the patterns we found for each of the variables. We start with quantity. The overall match rate is reasonable. However, for 73 percent of the Homescan data and 76 percent of the retailer's data (in matched large trips), reported quantities are 1, so a high number of cases in which the two quantities are the same might not be surprising. Indeed, conditional on the Homescan data reporting a quantity of 1, the probability of this report matching the retailer's data is 0.99, while conditional of the Homescan data reporting a quantity larger than 1 the probability of a match is only 0.86. So a reported quantity of 1 seems to be very reliable, while a quantity greater than 1 might be somewhat more prone to mistakes, but still reasonable.

Using the data from the matched large trips, conditional on quantities not matching, 82 percent of the time the quantity reported in Homescan is higher. Recording errors seem to be of various types, including six-packs that are recorded as quantities of 6 (the fraction of mistakes for reported quantities of 6, 12, 18 and 24 are 0.60, 0.85, 1.00 and 0.78, respectively), typing errors (e.g., 11 instead of 1), and occasional "double scanning" (quantity of 2 instead of 1). Together,

this suggests that the Homescan data might be problematic for studying the quantity purchased. It seems to be better suited to measure whether or not a purchase occurred. Overall, the variance of error in the quantity variable constitutes 48.7% of the variance in the Homescan reported quantity. The correlation coefficient between the two quantity variables is 0.72.

While in the case of quantity, recording errors are likely driven by the panelist's recording error, the case of price is somewhat different, given our understanding of how the Homescan prices are generated. As described in Section 2, if the consumer purchased the product at a store for which Nielsen has store-level data (and we think that all the stores in our matched data are such), then the Homescan data reports this price, and not the price reported by the consumer. The store level price is the average weekly transacted price for a given item. If some of the shoppers in that store during that week paid the full price and some got a discount then the average will be between the discounted price and pre-discount price, and the Homescan data will over report or under report the actual transaction price, depending on whether the panelist used her loyalty card or not. Analysis of the retailer data suggests that loyalty cards are used in about 75-80 percent of the transactions, and that about 60 percent of the transacted items are associated with loyalty card discounts, so errors due to this data construction process could be important. Moreover, it also suggests that the recording errors in price may be either due to panelist's recording error or due to the price imputation, and the statistical properties of these errors are likely different. Other retailers might not offer loyalty card discounts; thus, the second source of error might not be present in data from these retailers.

To examine this issue, we present in Figure 4 the distribution of the logarithm of the ratio of log price in the Homescan data to the price in the retailer's data. The overall distribution is presented for comparison in both panels (dashed grey line). The solid black line in the top panel presents this distribution for transactions for which the store did not have a loyalty card discount for that item on that day, while the bottom panel repeats the same exercise for the cases in which a loyalty card discount was present. The overall pattern largely follows our discussion above. That is, the solid black line in the top panel is close to a standard "classical" error, with mean close to zero and most of the mass around zero. In other words, in these cases, even when the price does not match, the differences are small. In contrast, in the bottom panel there is a very fat right tail of the distribution, and the average recording error is more than 14%. This is consistent with the fact that all our data is associated with users of loyalty cards (this is how we matched them), while the price imputed for them is aggregated over a population of which some do not use the loyalty card. Therefore, imputed Homescan prices are higher in such cases.

Overall, the variance of the error in the price variable constitutes 21.8% of the variance in the Homescan price (8.5% if no loyalty card discount is offered). The correlation coefficients between the two price variables is 0.88. The correlation increases to 0.96 if we condition on the Homescan deal indicator equal to 0 (and to 0.96 if we look at observations where no loyalty card discount was offered), and it decreases to 0.83 if the Homescan deal indicator is equal to 1 (0.84 if a loyalty card discount was offered). The variance in the error of the expenditure data explains 37.1% of the variation in the per item expenditure of the Homescan data. The correlation coefficient is 0.79.

In summary, we find that for the matched products, quantity is reported fairly accurately, although, when quantity reported is higher than 1, the reported data are less accurate and therefore the correlation between the two quantity variables is quite low. Prices and expenditures are reported with less accuracy. We suspect that this is due mostly, but not completely, to the Nielsen matching procedure that imputes store-level prices when possible. This procedure cannot fully explain the difference, as we saw by examining the matching quality when the item is not on sale.

Comparison to errors in other data sets It may be useful to compare the magnitude and frequency of recording errors to those reported in other validation studies. To do so, we use Bound et al. (2001, Section 6), who summarize the evidence on measurement errors in labor related data. They report errors in earnings, transfer program income, assets, hours worked, unemployment status, industry and occupation, education, and health related variables. While it is hard to compare across contexts and over a large set of variables, our overall impression is that the magnitude of recording errors we document above for Homescan are on the lower end of the range of recording errors reported by Bound et al. (2001). For example, Bound and Krueger (1991) compare the annual earnings reported in the CPS with Social Security administrative records. They find that the variance of the log of the ratio of earnings reported in the two data sets is 0.114 for men and 0.051 for women. The correlation coefficient between the two variables is 0.884 for men and 0.961 for women. Ashenfelter and Krueger (1994) study the years of schooling reported by twins: they compare the own report to the report of the twin. They find a correlation coefficient of 0.9. We, on the other hand, find that the overall variance in the log of the ratio of the Homescan and retailer price is 0.139. The variance is as low as 0.046 when the Homescan deal indicator is equal to zero, and 0.092 if no loyalty card discount is offered. So overall it seems like the errors we document in Homescan are comparable to what is found in other commonly used economic data sets.

4 Correcting for recording errors

Up to this point we used the validation study to document recording errors. Here we discuss how the validation study can be used to control for recording errors, and then illustrate this in the context of an application.

4.1 Methods

Our discussion follows Chen, Hong, and Tamer (2005), who provide more details and additional references. The basic idea is to use the validation sample to learn the distribution of the error, conditional on variables observed in the primary data. One can then use this distribution and "integrate over" it in the primary data. Of course, a key assumption is that the (conditional) distribution of the error is the same in both the validation data and in the primary data. This assumption can be evaluated on a case-by-case basis, and we revisit it below in the context of our application.

Formally, suppose the model we want to estimate implies a moment condition:

$$E[m(X^*, \beta_0)] = \int m(x^*, \beta_0) f_{X^*}(x^*) dx^* = 0 \tag{1}$$

where $m(\cdot)$ is an $r \times 1$ vector of known functions, X^* are variables, which might not be fully observed, and $\beta_0 \in B$, a compact subset of $\Re^q$ with $1 \leq q \leq r$, is a vector of the true value of unknown parameters that uniquely sets the moment condition to zero. We observe two data sets. In the first, "primary" data set $\{X_{pi} : i = 1...N_p\}$, we do not observe X^*, rather we only observe X, which is measured with error of unknown form. In our context, Homescan is the primary data set. In the second, "validation" data set we observe $\{(X^*_{vj}, X_{vj}) : j = 1...N_v\}$, i.e., both the variable that is measured with error and its true value. The matched Homescan-retailer data is the validation sample in our case. We denote by $f_{X^*_p}$, f_{X_p}, $f_{X^*_v}$, and f_{X_v}, as the marginal densities of the latent variable and the mismeasured variable in the primary and validation data sets. We also denote by $f_{X^*_p|X_p}$and $f_{X^*_v|X_v}$ the conditional densities of the latent variable given the mismeasured variable in the primary and validation data sets, respectively.

The key assumption is that

$$f_{X^*_v|X_v=x} = f_{X^*_p|X_p=x} \text{ for all } x. \tag{2}$$

That is, that the distribution of the true variables, conditional on the observed variables, is the same in both the primary and the validation samples. This is not a trivial assumption. For example, to use our validation sample for the entire Homescan data, it would require that the recording error is the same for the retailer we observe and for all other retailers. Even though we assume that $f_{X^*_v|X_v=x} = f_{X^*_p|X_p=x}$, we note the marginal density f_{X_v} might be different than f_{X_p} and therefore $f_{X^*_v}$ might be different than $f_{X^*_p}$.

We do not observe X^* in the primary data set and therefore cannot directly use the moment condition in equation (1) to estimate β. However, we could use the validation sample to estimate $f_{X^*_v|X_v}$, and the primary data set to estimate f_{X_p}. Thus,

$$f_{X^*_p}(x^*) = \int f_{X^*_p|X_p=x}(x^*) f_{X_p}(x) dx = \int f_{X^*_v|X_v=x}(x^*) f_{X_p}(x) dx \tag{3}$$

where the second equality uses the key assumption that $f_{X^*_v|X_v=x} = f_{X^*_p|X_p=x}$. We can estimate this density by $\widehat{f_{X^*_p}}(x^*) = \int \widehat{f_{X^*_v|X_v=x}}(x^*) \widehat{f_{X_p}}(x) dx$ where $\widehat{f_{X^*_v|X_v=x}}(x^*)$ is the estimate of the density of X^*_v conditional on $X_v = x$, and $\widehat{f_{X_p}}(x)$ is the estimated density of X_p in the primary data. Now, we can use the moment condition to estimate the parameters of interest by

$$\widehat{\beta} = \arg\min_{\beta} \left(\int m(x^*, \beta) \widehat{f_{X^*_p}}(x^*) dx^* \right)' \widehat{W} \left(\int m(x^*, \beta) \widehat{f_{X^*_p}}(x^*) dx^* \right), \tag{4}$$

where $\widehat{W}$ is a positive definite symmetric weight matrix.

While intuitive, this estimator involves estimating two distributions, $\widehat{f_{X^*_v|X_v=x}}(x^*)$ and $\widehat{f_{X_p}}(x)$, potentially non-parametrically, and then using them in a non-linear moment condition. Instead, Chen, Hong, and Tamer (2005) propose to define

$$g(x, \beta) \equiv E[m(X^*_p, \beta)|X_p = x] = \int m(x^*, \beta) f_{X^*_p|X_p=x}(x^*) dx^*. \tag{5}$$

Note, that $g(\cdot)$ is a function of the variable measured with error X_p, that is observed in the primary data set, rather than with respect to the true (latent) variable X_p^*. We can now apply the law of iterated expectations, so that

$$E_p[g(X,\beta_0)] = E_p[E[m(X_p^*,\beta_0)|X_p = x]] = E_p[E[m(X_p^*,\beta_0)]|X_p = x] = E[0|X_p = x] = 0. \quad (6)$$

Thus, the original moment condition implies that

$$E_p[g(X,\beta_0)] = \int g(x,\beta_0) f_{X_p}(x)dx = 0, \quad (7)$$

and we can estimate the parameters of interest by

$$\widehat{\beta} = \arg\min_{\beta} \left(\frac{1}{N_p} \sum_{i=1}^{N_p} \widehat{g}(X_{pi},\beta) \right)' \widehat{W} \left(\frac{1}{N_p} \sum_{i=1}^{N_p} \widehat{g}(X_{pi},\beta) \right) \quad (8)$$

where $\widehat{W}$ is a positive definite symmetric weight matrix, and $\widehat{g}(X_{pi},\beta)$ is a non-parametric estimate of $g(X_{pi},\beta)$, estimated using the validation sample. Using the validation sample to estimate $\widehat{g}(X_{pi},\beta)$ yields a consistent estimate because of the key assumption (equation (2)). Chen, Hong and Tamer (2005) propose using a series (sieve) estimator of $g(x,\beta)$:

$$\widehat{g}(x,\beta) = \sum_{j=1}^{N_v} m(X_{vj}^*,\beta) p^k(X_{vj})'(P_v'P_v)^{-1}p^k(x), \quad (9)$$

where $\{p_l(x), l = 1,2,...\}$ denotes a sequence of known basis functions, $p^{k_{nv}}(x) = (p_1(x),...p_k(x))'$ and $P_v = (p^k(X_{v1})...p^k(X_{vN_v}))'$ for an integer k that increase with the sample size N_v, such that $k \to \infty$, and $k/N_v \to 0$ as $N_v \to \infty$. In words, $\widehat{g}(x,\beta)$ is estimated by projecting it onto the basis functions. In general, the optimization in equation (8) is non-linear, but not more complex than the optimization implied by using the moment condition given in equation (1).

In a linear model this simplifies to a fairly simple procedure. For example, suppose we want to estimate a regression of price paid p^* on demographics D, as we do in the next section. In the primary data (Homescan) we observe p and D, but we are concerned about possible recording errors in p. In the validation sample, the matched Homescan-retailer data, we observe p, p^*, and D, where p is the Homescan-reported price and p^* is the retailer-reported price. We then first use the validation data to regress the retailer's price p^* on p and D, to obtain, for example,

$$E(p^*|p,D) = D'\widehat{\beta} + \widehat{\alpha}p. \quad (10)$$

We then use the estimated coefficients, $\widehat{\beta}$ and $\widehat{\alpha}$, to construct $\widehat{E(p^*|p,D)}$ in the Homescan data. Using Homescan, we then regress this predicted price on D to obtain the error-adjusted estimates.

In may be instructive to go through the simplest case, where both the prediction and estimating equations are linear, and the set of covariates D is identical. In this case, the "naive" regression in Homescan would be to regress p on D, while the corrected regression will be to regress $D'\widehat{\beta} + \widehat{\alpha}p$ on D. If the true coefficient on D is γ, then the "naive" coefficient will be (roughly) $\frac{\gamma-\beta}{\alpha}$. That is, with no measurement errors or with classical measurement error, we would have $\alpha = 1$ and $\beta = 0$, and no bias. However, either $\alpha \neq 1$ (the case where the mean of measurement error is not zero) or $\beta \neq 0$ (which would arise if the measurement error is correlated with D) will result in a bias.

4.2 An illustrative application

In this section we illustrate the method in the context of one particular application. Recently, researchers have used Homescan to study how the prices paid vary with household demographics (e.g., Aguiar and Hurst, 2007). We perform a simple version of such a study in order to evaluate the impact of the recording errors. Our goal is twofold. First, we use this application to demonstrate how one could use our validation study to correct for recording errors in Homescan, and hope that future users of Homescan will do so too, at least as a robustness check. Second, the application provides a more meaningful way to evaluate the importance of recording errors. That is, while describing the recording errors is potentially interesting, it is not sufficient for whether the recording errors is something one should worry about. In this section we therefore ask if the recording errors matter for conclusions drawn from the analysis.

We note that our goal here is not to replicate any particular study, just to demonstrate that the errors could have important implications for certain bottom lines, and to show how the validation study can be used to address these errors. We chose this particular application for two reasons. First, it is important and active line of work, making it more likely that researchers who use Homescan will perform a similar analysis. Second, it is simple. That is, the key regression here is linear, and has price (the Homescan variable which is measured with error) on the left hand side. This makes this analysis robust to classical recording errors, and it is only non-classical recording errors that would matter. Other settings, in which the model is non-linear or the variable of interest is on the right hand side will make the analysis more sensitive to errors, and the correction slightly more complex.

The regression of interest in this application is

$$p_{ik} = \alpha_k + \beta' D_i + \varepsilon_{ik} \tag{11}$$

where i is a household, k is a specific product (distinct UPC), p is the unit price paid for this product,[14] and D_i is a vector of demographic characteristics. The α_k's are a set of UPC fixed effects, and β is a vector of coefficients of interest. The economic question is whether certain demographic groups pay more or less for the same product, relative to the rest of the population. Aguiar and Hurst (2007), for example, focus on the price paid over the life cycle and emphasize their finding that the elderly pay lower prices for the same item, compared to other age groups.[15] One could in principle analyze the corresponding effect of other demographic groups, such as gender and race.

We start with Table 3, which presents results from estimating the above regression. An observation is a product (UPC) in a matched large trip, i.e., in a large trip with $r1$ greater than 0.7. The regression reported in the first column uses as the dependent variable the price, in cents, as recorded in Homescan, while the regression reported in the second column uses the price in the retailer's data. The covariates are identical in both cases. The different data sets give different

[14] The reported results do not account for coupons. Results that use prices net of coupons are qualitatively similar, and are available from the authors upon request.

[15] We note that our exact regression specification is similar but not identical to the regression estimated by Aguiar and Hurst (2007). This does not have any effect on the point we try to make in this paper.

results. Out of the twenty regression coefficients, five have different signs, nine do not agree on their statistical significance, and the point estimate (when they have the same sign) are off by an average of more than 40 percent.

It is interesting to note that in almost all the cases when a coefficient is significant in one regression but not in the other, the retailer's data generate the significant estimate, while the Homescan data do not. In many cases the difference is also economically meaningful. For example, in the Homescan data the coefficient on race dummy variable is negative and significant, which implies that non-white consumers pay a lower price. On the other hand, in the retailer's data the coefficient is positive but not significant. A researcher using the Homescan data to study discrimination would probably reach different conclusions than one using the retailer's data to study the same question, using the very same set of shopping trips. Another example is in the impact of age on price paid. The Homescan data suggest a flatter impact of age, especially for males, than the retailer's data. Once again researchers using the data to study life cycle consumption might reach wrong conclusion using the Homescan data.

As already noted in the previous section, there are two effects that cause the difference in the results. One is of pure recording errors, while the other arises from the way Nielsen imputes prices. We follow the same procedure described (see, e.g., Figure 4) to identify cases where one type of recording error is more likely than the other. We then repeat the same regressions for these two different cases, separately. In general, the regression results are quite different for each of the regression pairs, but the differences are much more subtle in the case where price imputation is likely to be an issue (when the item was associated with a loyalty card discount). For example, in this case the coefficient signs do not agree for eight out of the twenty coefficients, while in the case in which a loyalty card discount is not available for the item (so price imputation is unlikely to introduce errors) only two of the point estimates do not agree on their sign (last two columns of Table 3).

The channels by which the coefficient are biased is quite different depending on the nature of the recording errors. Consider the case where the recording errors are driven by Nielsen's price imputation, and focus, for example, on the race dummy variable. In this case, the regression using the Homescan data tells us that non-white households tend to buy at cheaper stores, i.e., stores where the average consumer in the store pays less for the same item. The regression using the retailer's data tells us that despite going to cheaper stores non-white panelists do not pay less on average. In contrast, if none of the prices are imputed and the only difference is due to recording mistakes made by the panelist then the channel is different. Once again we use the race dummy variables as an example. The regression using the Homescan data tells us that non-white consumers report a lower price. On the other hand, the regression using the retailer's data suggests that they do not actually pay less, maybe even slightly more. Together these suggest that white consumers tend to over report prices relative to non-white consumers, not that they are likely to pay more.

In order to further study the effect of recording errors and to illustrate how the validation study can be used to fix them, Table 4 presents Homescan regressions, where we only focus on the age effect. That is, we use the regression in equation (11) with only the age variable (of the female

head of the household). Column (1) uses the entire Homescan observations in one market.[16] Note that these are all the observations in the 2004 data, not just the ones we matched. The excluded category are the elderly, 65 years or older. The results is qualitatively similar to the main finding of Aguiar and Hurst (2007): older consumers tend to pay less for the same products.

Columns (2) and (3) replicate the analysis using the matched sample. Column (2) presents the results using the retailer data and column (3) uses the matched Homescan transactions for the larger market. An important observation here is that the results of *either* column (2) or (3) are quite different from the results using the full Homescan sample in column (1). For this selected set of transactions, the pattern across ages is much smaller, and often reversed (younger individuals pay less, rather than more, than the elderly). It seems likely that the different results arise due to non-random selection into our matched sample. For example, in the larger Homescan sample the elderly are *more* likely to use coupons, while in our (matched) sample they are *less* likely to use them (not reported).[17] For this reason we should probably be careful in drawing conclusions based on either columns (2) or (3) of Table 4. On the other hand, the difference between the results in columns (2) and (3) also suggests that we should be careful in drawing conclusion based on column (1): the results can potentially be driven by recording errors.

In column (4) we present results that use the validation sample to correct for the recording error. We follow the procedure described in the previous section. We first use the validation sample to predict the "true" retail price as a function of the demographics (age dummies, in this case) and the Homescan reported price, and we then use the full sample, impute predicted prices for each of the observations, and run this predicted price (rather than the reported price) on age. The resulting coefficients significantly change compared to column (1), and the age pattern is different (and economically less important). Loosely, the correction makes the estimated coefficients somewhere in between the original estimates (column (1)) and the true regression on the matched sample (column (2)).

We again note that an important assumption that makes this correction valid is that the conditional distribution of recording errors is the same in the validation sample and in the overall Homescan data (in that market). We note that although it seems likely that the matched sample is non-randomly selected, this by itself does not violate the assumption; the conditional distribution of the recording errors may be the same even if the unconditional distribution of prices is not. For this reason, we view this correction as a useful robustness test of existing estimates, rather than a recipe that should always be followed.

[16] Our analysis so far used data from two metropolitan areas (see appendix). Here we only use data from the larger metropolitan area, as a way to minimize confounding the results due to pricing differences between the two areas. Coincidentally, this is also the metropolitan area covered by the Homescan data used in Dube (2001) and Aguiar and Hurst (2007).

[17] It may not be totally surprising that the validation data is not representative of the larger Homescan data. We select on matched trips, which are associated with more "careful" individuals. The change in the results between the matched and overall Homescan sample may indicate that this selection is differential across age groups.

5 Concluding comments

In this paper we describe a validation study of the Homescan data. We described the magnitude of recording errors along several dimensions (trips, items, and price and quantities), and then demonstrated how the validation study could be used to correct estimates for these recording errors. We think that our work has two distinct implications. First, it may provide guidance to Nielsen as to where and how to improve data collection and reporting. Second, it provides guidance to users of Homescan as to how to correct estimates for possible recording errors. We discuss each in turn.

We find that prices are the variable most poorly recorded. This is due, at least in part, to the way Nielsen imputes store-level prices when available. There are several good reasons to use the store level prices. However, given our findings, it seems important to also provide an indicator that an imputed price is used. Ideally, of course, users of Homescan would know both the imputed store-level price and the price reported by the household. This information is not currently collected by Nielsen, but collecting this information, at least on an experimental basis, would allow for additional analysis of the magnitude of this discrepancy. The one place where the store level data could be very useful is to help identify purchases on deal. A deal can be defined as any situation in which the price reported by the consumer is less than the store non-deal price reported by the store.

Nielsen could also improve the quality of the data by requiring the panelists to send in their receipts. The reported data could then be compared to these receipts (we are aware of at least one other consumer panel level data that uses this procedure). Random sampling of the receipts will both make the panelists more careful, and would also allow for quality control. As we find that certain households are more mistake-prone along all the dimensions we analyze, such random sampling may be used to design better sampling weights, or even to drop out of the sample "negligent" panelists. The final analysis of the data can be improved, and bias potentially removed, by constructing a reliability index for the observations and weighting them accordingly. Given the current data available in Homescan, such an index might be hard to construct. But future data collection can be done with this goal in mind.

To users of the Homescan data (in its current form), our work provides a way to correct for measurement errors. In particular, we discussed how one would adjust parameter estimates to account for recording errors, and demonstrated how this works in one simple application. A sufficient statistic to almost any such adjustment is knowledge (through the validation study) of the distribution of the error conditional on variables observed in the primary data. To facilitate such corrections, we posted this distribution on our web pages, and we hope that researchers using Homescan will use this distribution and one of the methods that correct for measurement errors as a way to run plausible robustness checks of their results. As we emphasize throughout, when one makes these corrections, the maintained assumption is that this conditional distribution of the measurement error is the same in the validation sample and the primary data. While we think that this is often a plausible assumption, researchers who use our posted distribution to adjust their estimates should evaluate the plausibility of this assumption in their particular context.

Appendix: Detailed description of the data construction

As mentioned in the text and sketched in Figure 1, our data construction process involved two distinct steps. Below we describe each step in turn. We then finish by summarizing the resultant data set from the retailer we work with.

First step

In the first step our objective was to maximize the number of matched trips given size limitations. These size limitations arise because, without additional information, we needed to have a complete trip record from a particular store on a particular date for each potential matched trip. The size of the data file containing this information is about 3 megabytes, and due to constraints imposed by the retailer, we had to limit this step to roughly fifteen hundred store-day transaction-level records.

We therefore proceeded as follows. First, we restricted the data set to two metropolitan areas, in which the retailer has high market share. This left us with 265 different retailer stores (147 in one area, and 118 in the other). The focus on two areas helped in obtaining more data, given the way the retailer organizes its data. Using areas with high market share of the retailer was also useful, as it could raise the probability that a single store-day record would help to match more than a single shopping trip. This would happen if two households in the Homescan panel visited the same store on the same day, which is more likely when the market share of the retailer is high. Since we identify the store by the zip code of its location, we also restricted attention to retailer stores that are the only retailer stores in the same zip code. This eliminated 76 stores (29 percent), and left us with 189 stores (101 in one area, 88 in the other). We then searched the Homescan data for shopping trips at these stores, with the additional conditions that: (i) the trip includes purchase of at least 5 distinct UPCs (to make a match easier); (ii) the trip occurred after February 15, 2004 (to guarantee that the retailer, who deletes transaction-level data older than two years, still has these data); and (iii) the household shops at the retailer stores (according to Homescan) more than 20 percent and less than 80 percent of its trips. These trips were made by 342 distinct households in the Homescan data. For 240 of these households, we randomly selected a single trip for each of them. For the remaining 102 households, which included households with at least 10, and not more than 20, reported trips in Homescan data, we selected all their trips. We then requested from the retailer the full transaction records for the store-days that matched these 1,779 trips. Since 74 of these trips were to the same store on the same date, we expected to get 1,705 store-day transaction-level records.

We eventually got 1,603 of these 1,705 requested store-days (1,247 in the first area, 356 in the other), which account for 4,080,770 shopping trips. They include 122 distinct stores (74 in the first area, and 48 in the other). These 1,603 store-days are associated with 1,675 trips from the sample of 1,779 shopping trips described above. However, as already mentioned, since the retailer enjoys high market share in both areas, it is not surprising that the 1,603 store-day transaction-level data records we obtained are associated with additional 904 trips in Homescan. Given the way we constructed the sample, however, many of these additional trips include a small number of items, or households that rarely shop at the retailer's stores.

Second step

After obtaining the data from the first step, we developed a simple algorithm to find likely matches between trips in the Homescan data with trips in the retailer's data. These likely matches were only used to speed up the data construction process (as described in the text, the data analysis in the paper uses a more systematic matching procedure.) The algorithm used the first five UPCs in the Homescan trip, and declared a match if at least three of these five were found in a given trip in the retailer's data. We used this algorithm with the data we obtained in the first step and found 1,372 likely matches that, according to Homescan, are associated with 293 distinct households. Of these households, 166 were associated with more than one likely match, and 105 with four or more.

We then asked the retailer to use the loyalty card used in these 1,372 shopping trips and to

provide us with all the transactions available for the households associated with these cards (in the retailer's data during the year 2004). Only two of the requested trips were not associated with loyalty cards. For the rest, we obtained all the transactions associated with the same loyalty card, and additional transactions that are associated with loyalty cards used by the same household, as classified by the retailer. Since associating multiple cards with the same household may not be perfect, in the analysis we experimented with both the card-level and the household-level matching.

In this step we obtained a total of 40,036 shopping trips from the retailer. These 40,036 trips are associated with 384 distinct stores (139 in the first area, 109 in the second, and 136 in other areas), with 682 distinct loyalty cards (472 in the first area, 203 in the second, and 7 in other areas), and with 529 distinct households, according to the retailer's definition (380 in the first area, 140 in the other). Finally, the 40,036 trips are associated with 34,316 unique store-date-loyalty card combinations, 33,744 unique store-data-household combinations (using the retailer's definition of a household), and 27,746 unique store-date-household combinations, using the Homescan definition. Of these trips, 3,884 (9.7 percent) occurred in a store-day already appearing in the data we obtained earlier, and therefore are one of the 4,080,770 trips obtained in the first step. Recall that the algorithm we used to request these data was geared to find likely matches, and therefore may have also found wrong matches. This is one reason that the number of households we intended to match (291, the original 293 minus two that had no associated loyalty cards) is less than the number of households associated with these trips. A second reason may be multiple cards used by the same household that are not linked to each other by the retailer.

Summary

To summarize, we have two different types of data from the retailer. The first data set includes full transaction record of 1,603 distinct store-days. In these data trips are not associated with a loyalty card. The second data set includes 40,036 trips, which are associated with particular loyalty cards and households. 3,884 of these trips overlap and appear in both data sets. The first data set is designed to match multiple transactions of 102 households in the Homescan data, and isolated transactions of other households. The second data set is designed to match all transactions of almost 300 households.

Figure 1: Schematic sketch of the data construction process

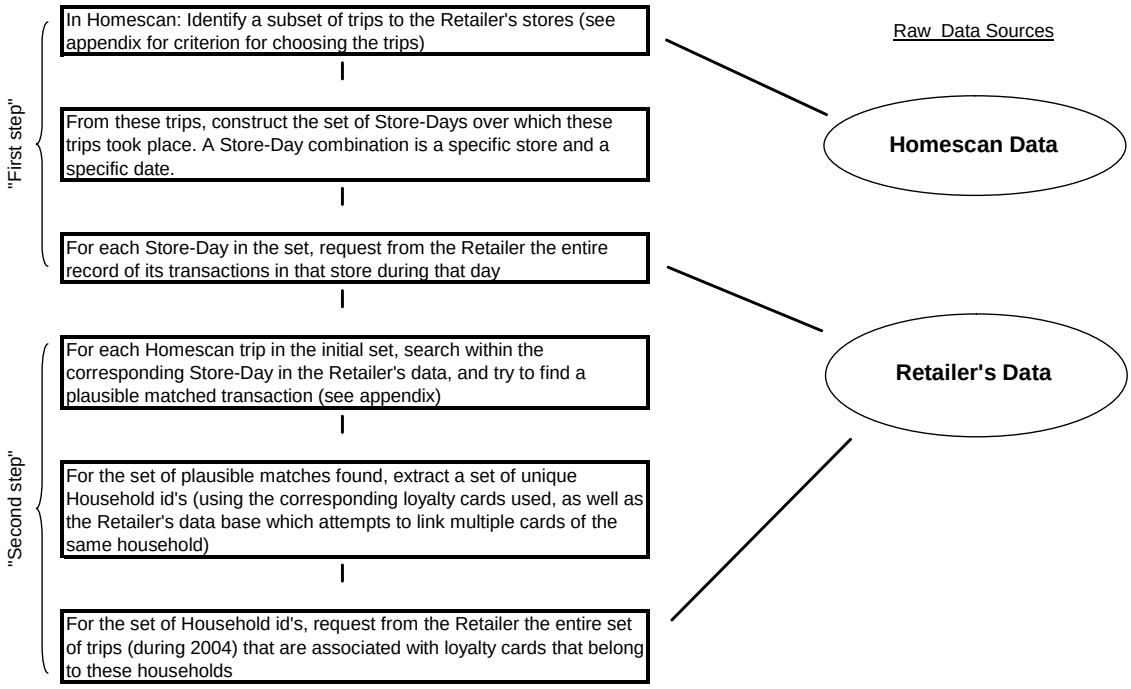

Figure 2: The bimodal distribution of $r1$

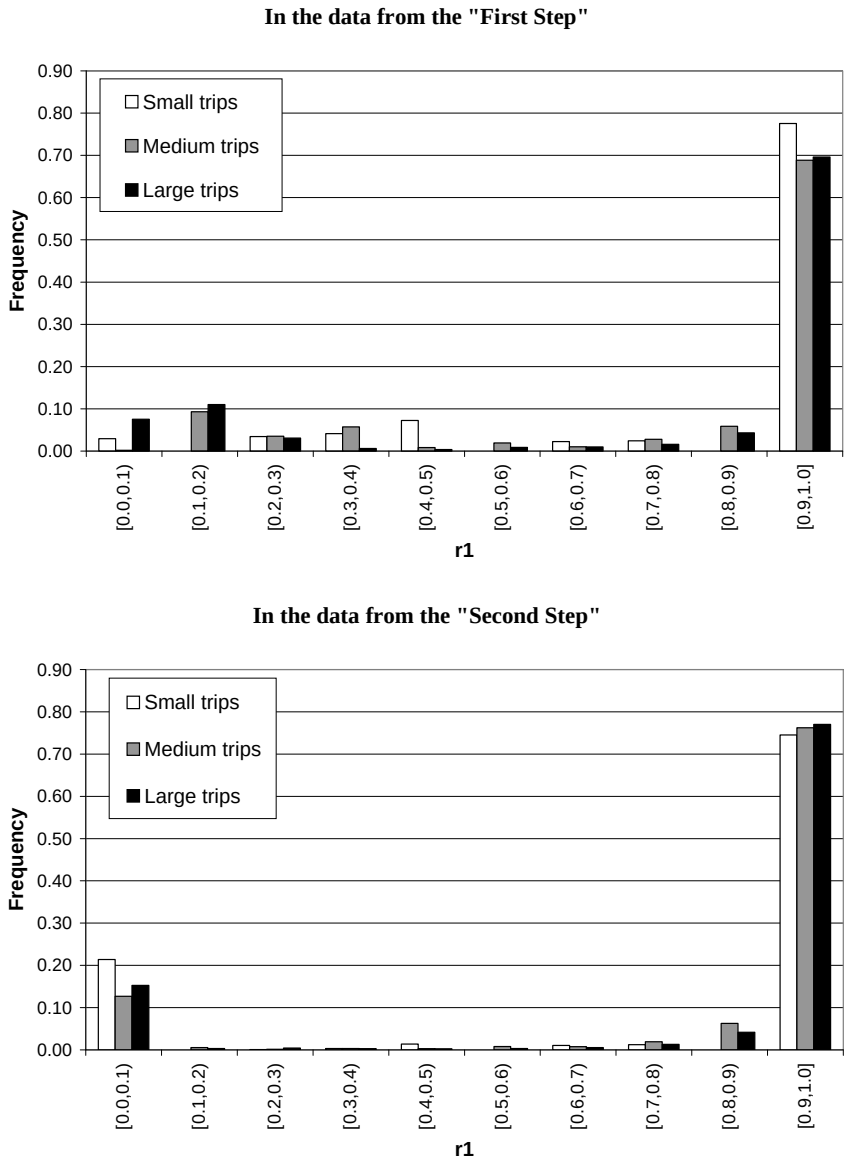
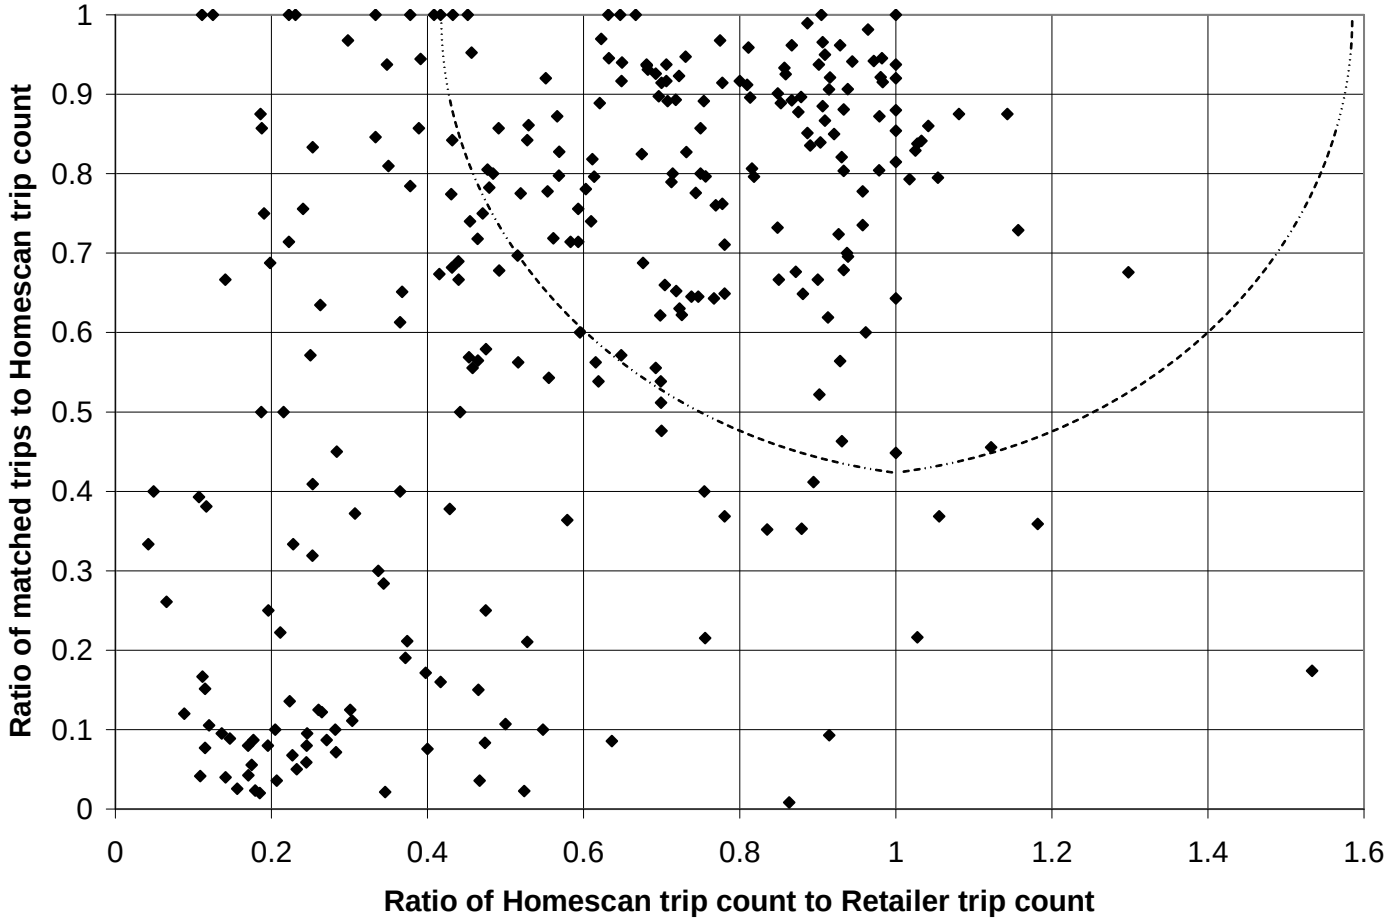


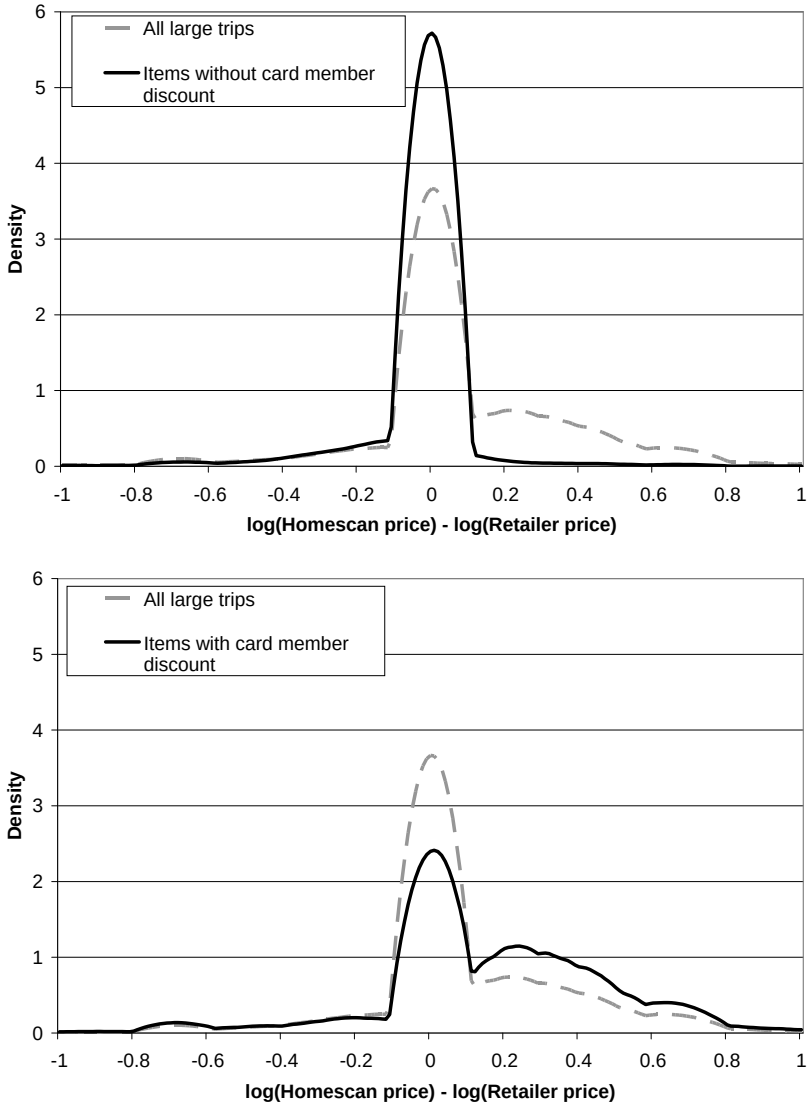
UPC counts (which are used to classify trips as small, medium, or large) are based on the number of distinct UPCs in a trip as reported in the Homescan data. Each histogram plots the distribution of the $r1$ statistic. In the "first step," this is the transaction with the highest UPC overlap in the same store and day. In the "second step," this is the specific transaction in the same store and day by the matched household. Both histograms show a very clear bimodal pattern, where $r1$ is either very close to one or very close to zero, and especially so for large trips. This makes it clear why the results remain essentially unchanged when we change the cutoff value of $r1$ above which we define a match to be successful (throughout the paper we report results that use 0.7 for this cutoff value).

Figure 3: Household heterogeneity



A data point in this histogram is a household whose transactions match consistently (see text for exact definition). There are 273 such households. The horizontal axis reports the ratio between the number of reported Homescan trips and the number of reported Retailer trips (based on the retailer's loyalty card use). Ratios below one suggest unreported trips (in Homescan). Ratios above one suggest trips to the Retailer's store without using the loyalty card (or using a card that the retailer did not link to the household). The vertical axis reports the fraction of Homescan trip for which we could match a significant number of the UPCs (at least 0.7). That is, a "prefect" household is one that each of whose trips as reported in Homescan is also found in the retailer data, each of whose trips as reported by the retailer is found in Homescan, and in all trips a high fraction of UPCs is matched. The figure shows a clear distinction between two types of household. Those with both ratios close to 1 report most of their trips, and report the UPCs in each trip relatively well. In contrast, those households that are close to the origin are households that don't report a large fraction of their trips, and don't report (or report incorrectly) many of the UPCs in those trips they do report. The dashed half circle is the cut point we use to define households as "good" or "bad" for the statistics reported in Table 1.

Figure 4: Two sources of price recording errors



This figure presents kernel densities of the log price difference between Homescan and the Retailer. The gray dashed line is common to both panels and uses all matched large trips, which parallels the corresponding row in the left panel of Table 2. The black solid line in each panel uses a subset of these data. The bottom panel uses the observations for which the item was not associated with any store discount at the time of purchase (about 34% of the cases), while the top panel uses the observations for which the item was associated with a card member store discount at the time of purchase (about 54% of the cases). In 12% of the cases we could not determine whether the item was associated with a discount (8% of the cases did not have a matched item in the store level data and in 4% of the cases it was difficult to determine whether a discount was available to all customers). Summary statistics for the solid lines in the top (bottom) panel are: mean -0.040 (0.143), standard deviation 0.305 (0.391) and 5%-95% range -0.288 to 0 (-0.434 to 0.693).

Table 1: Comparison of "good" and "bad" households

	"Good" Households	"Bad" Households	p-value
Number of Households	144	129	
Household size	1.96	2.50	0.000
HH income ($000)	48.89	53.82	0.182
No female head of Household	0.16	0.05	0.005
Age female	47.90	51.63	0.135
No male head of Household	0.28	0.21	0.191
Age male	41.08	44.90	0.232
Number of kids	0.13	0.22	0.029
Number of Little kids	0.02	0.05	0.143
Male employed	0.47	0.49	0.704
Male fully employed	0.42	0.45	0.585
Female employed	0.42	0.50	0.189
Female fully employed	0.26	0.38	0.040
Male education (category)	3.04	3.30	0.302
Female education (category)	3.46	3.92	0.017
Married (or widower)	0.58	0.78	0.000
Non-white	0.10	0.13	0.481
"15K" Homescan Household	0.07	0.08	0.799

This table compares demographics of "good" and "bad" households, as defined by their recording behavior (see Figure 3). The p-value reports a test of whether the means are equal in both columns. The highlighted demographics are those for which this test can be rejected (using a 5% confidence level).

Table 2: Summary match statistics

	Matched Large Trips				Matched Medium Trips			
	Mean	Std.	5%	95%	Mean	Std.	5%	95%
Quantity								
Homescan	1.44	1.16	1	3	1.51	1.36	1	4

UPC fixed effects (number of UPCs)	yes (10,470)		yes (6,793)		yes (5,764)	
Number of observations	41,158		22,291		13,818	

The table reports price regressions. Each column reports a different regression, with standard errors in parentheses. The first two regressions use all the matched items in the matched large trips, with the first regression using the Homescan price as the dependent variable and the second regression the Retailer price as the dependent variable. A perfect data should have resulted in identical prices and therefore in identical estimated coefficients. Classical measurement errors would have also led to the same estimated coefficients. The two other pairs of regressions repeat the same exercise for items that were sold on card member discount and those who were not (at the time of purchase). All regressions use UPC fixed effects.

Table 4: Correcting for recording errors

Dependet variable Corrected (Sample)	Homescan price Not corrected (all)	Retailer price NA (matched items)	Homescan price Not corrected (matched items)	Homescan price Corrected (all)
	(1)	(2)	(3)	(4)
Constant	282.089	237.215	249.356	274.398
	(0.487)	(1.108)	(1.026)	(0.592)

	(0.669)	(1.425)	(1.320)	(0.815)
Female age 65 or older	---------- Omitted category ----------			
Number of obs.	790,526	27,511	27,516	790,526

The table illustrates how one could correct for the recording errors. All columns present price regressions, with standard errors in parentheses, similar to those presented in Table 3. Here we focus on a single market (the larger market of the two from which we have data for) and on a single demographic (the age of the female head of the household; the small number of households with no female head are omitted). Column (1) reports regressions for the entire Homescan transactions in this market, columns (2) and (3) report the results for the matched transactions using the retailer and Homescan price, respectively, and column (4) is where we use the correction method (see text for details) to correct for the recording errors. All regressions use UPC fixed effects.
