Fiscal Crises in U.S. Cities: 
Structural and Non-structural Causes 

Guntram B. Wolff∗  
Bonn, August 2004

Third version.¹

Abstract

Financial difficulties of U.S. cities have recently become a major issue of concern. However, there is little agreement on why certain cities experience crises while others do not. Two arguments are put forward: Cities suffer from (1) structural problems like high immigration, congestion etc. (2) non-structural political problems like the weakness of the mayor, union-power etc. Starting from a common pool model of municipal goods we estimate demand equations for spending and debt with structural variables. The estimation is based on 900 US cities in 1985, 1991 and 1999. Structural factors predicted by the model explain most of the variation of spending and debt levels. Furthermore coefficients are stable over time. However, excessively high debt burdens as indicators of potential crisis, and high spending levels are outliers and not explained by structural factors.

Remaining errors are mine.
1 Introduction

Fiscal distress and crises have become issues of considerable concern for U.S. states and cities. Mayors ask for state aid to compensate for revenue short falls (The Economist May 22nd, 2003) and (Herbert January 16, 2003). Some argue that New York City now faces the worst fiscal crisis since the mid-1970 (Cooper May 7, 2003). In Oregon, school districts consider shortening the school year to avoid large deficits. Even states are affected by the fiscal distress and lay off employees. While media coverage of fiscal distress and crises is substantial, systematic evidence on determinants of crises and, at an earlier stage, distress is quite scarce.

The present paper investigates the determinants of fiscal distress in 900 U.S. cities in the mid 1980s, early 1990s and late 1990s. Since no systematic data-set on the occurrence of fiscal crises in U.S. cities exists, we identify cities in fiscal crises with a cluster analysis. The cluster of cities with a high debt-per-capita level is in state of distress, while low debt-per-capita levels are a sign of fiscal health. We argue that fiscal distress is a situation from which fiscal crisis is likely to result. Potential determinants of fiscal distress are derived from a common pool resource model. In this model, the budget of a city is considered to be a pool from which the inhabitants of a city want to get as many services as possible. Since many services benefit only limited groups, while the burden of financing is spread on all tax payers through the common budget, voters will demand more than they would if they incorporated the full cost of the service. Thus, spending will be higher than in the case of an optimal planner. In an intertemporal setting, it is shown that the common pool problem will in addition lead to higher debt levels. The degree of the common pool resource problem is operationalized by structural factors such as economic performance and socio-demographic characteristics. As these characteristics vary across cities, expenditure and debt of cities will be different. We empirically test the model and show that cross-city variation of spending and debt is well explained by the model. In a second step, we assess the importance of the factors identified by the model to explain extreme fiscal outcomes of crises.

Views on what constitutes a fiscal crisis are diverging in the literature. Inman

---

2A large political economy literature investigates debt accumulation at a country level, for surveys see Alesina and Perotti (1995) and Woo (2003). In contrast, Barro (1979) explains the accumulation of public debt in a neoclassical model by a now standard tax-smoothing argument. Sustained accumulation of debt can, however, not be explained by his model.

3Honadle (2003) in a survey of State auditors finds that only 10 States have a formal definition of crises, 21 States made clear that their states do not define fiscal crises in any way. 36 States reported that they had cities in a crises recently. McConnel and Picker (1993) discuss municipal bankruptcy from a legal point of view.
(1995) defines a fiscal crisis as a situation when a city’s potential to raise revenues is insufficient to cover the city’s legally required expenditures. Case studies have shown that a fiscal crisis is usually characterized by the refusal of lenders to give any additional credit. In the case of Philadelphia, the lenders of the city government refused further credit, since part of the credit was to be used to repay accumulated debt. The refusal to give further credit to a local government certainly constitutes an important criterion for fiscal crises.

The credit worthiness of a city is evaluated among others on the basis of the debt burden. The city of New York ran current account (as opposed to capital account) deficits for more than ten years before the outbreak of their crisis and accumulated a large debt burden. Lenders then stopped to give further credit and a fiscal crisis resulted. As Capeci (1991, 1994) shows, the interest rate charged for newly issued bonds reacts to the current fiscal stance of a city, most notably to the borrowing and debt level. Higher debt levels result in higher nominal interest rates, reflecting the increased default risk. Bayoumi, Goldstein, and Woglom (1995) also argue that the probability of default is an increasing function of the absolute debt level and the interest payment. They find empirical support for this hypotheses for a sample of American States. Debt levels are therefore a good indicator of fiscal distress of a city as also argued by (Fuchs 1992, p. 30) and (Clark 1994). Ultimately long lasting fiscal distress can lead to a fiscal crisis. Thus, fiscal crises can be identified empirically by looking for cities with very high debt burdens.

Following the period of fiscal crises in the mid-1970s, numerous papers have investigated the determinants of fiscal crises. Most of these papers are case studies of single cities. For example Gramlich (1976) and Shefter (1992) study the crisis of New York in 1975, Inman (1995) studies the case of Philadelphia in 1990. The case studies usually emphasize a combination of factors to be responsible for the crisis. On the one hand, changes in socio-economic conditions are mentioned. On the other hand, specific political actors (e.g., a mayor) are seen to be at the root of the problem. In a series of articles, Bradbury (1982, 1983a, and 1983b) investigates fiscal distress and its causes in a number of major American cities. Bradbury (1982) distinguishes two types of fiscal distress. The first relates to the city government’s short-run difficulty in balancing its budget. The second is labelled ”Citizens’s fiscal distress” and measures bad performance in providing adequate services. It is mostly determined by structural factors outside of the control of city officials. Bradbury (1983a) calls this structural fiscal distress. Besides these structural factors, city management and unmeasured costs determine fiscal difficulties of a city. Fuchs (1992) compares the fiscal policies of New York City and Chicago. Chicago avoided
fiscal instability in 1975\(^4\) while NYC did not. This difference, in the view of Fuchs (1992), can be attributed to the role of politics, especially the role of local party organization. "New York mayors were unable to centralize authority over the budget process(...) Without a strong party organization New York mayors relied on interest group support to create winning electoral coalitions;" (p.6). This result is in line with Poterba (1994), who shows that political and institutional factors matter for adjustments to fiscal shocks. A State with a governor of one party and a congress with opposing political party majority is slower to react to shocks. Poterba further shows that U.S. States react to unexpected expenditure and revenue shocks already within the fiscal year.\(^5\) The First National Bank of Boston (1981) points out that, while socio-economic indicators cause fiscal conditions, they are not the main cause for fiscal distress. Fiscal distress is not inevitable but within the "grasp of management control of most cities". Their analysis thus supports the view that structural factors are important for fiscal performance, but it also highlights the role of political and management factors for crises. Honadle (2003) summarizes the answers of state government officials on the causes of fiscal crises. Similarly, officials mention structural (economic, demographic and institutional) factors, and non-structural factors (management and politics) as reasons. However, the relative importance of these factors is not assessed. The survey of the literature thus shows that there is little systematic evidence on the main determinants of fiscal crises in a large sample of U.S. cities.

The present paper contributes to the literature by presenting a coherent theoretical framework for the determinants of public spending and debt in cities and testing it with a recent, large data set of U.S. cities. We show that a large percentage of cross-city variation in spending and debt can be explained by this model. In addition the estimation results present systematic evidence on the importance of structural factors and non-structural factors as determinants of crises. An analysis of the identified distressed cities shows that extreme fiscal outcomes of distress can not be explained by this common pool model based on measurable socio-economic factors. It is therefore argued, that extreme fiscal outcomes are the result of non-structural factors such as mismanagement, union-power in public administrations and weak mayors.

The remainder of the paper is organized as follows. The next section presents the common pool model and develops the empirical strategy. We then discuss the available data. Section 4 presents the estimation results for the determinants of

\(^{4}\)Cohen (1989) points out that municipal defaults are strongly correlated with the business cycle. While it is true that fiscal distress becomes most obvious in recession years such as 1975, the question remains unanswered why some cities then do have such problems and others do not.

\(^{5}\)Ex-post budget data therefore only report part of the true crisis.
public spending and debt. Section 5 discusses the cluster of fiscally distressed cities and compares them with the non-distressed cities. The last section concludes.

2 Framework: the common pool resource problem

Consider a city with several population groups, which differ in their preferences for local public goods. The members of each group mainly benefit from the specific good provided for them. The goods are financed by the general budget of the city, which is a common pool. An example are swimming pools which are typically financed out of the common budget, while their benefits accrue exclusively to those who go swimming. Similarly, social services for the poor benefit a restricted group of people, while the related costs are paid out of the common budget. The common pool resource literature shows that these constellations lead to an inefficient over-provision of the public good, if individual groups manage to influence the government in their interest. The intuition for this result is the following. The cost of each municipal good is spread to all tax-payers, while the benefit accrues to the individual only. Thus the individual will demand more of the municipal good, since the benefit from the good in the view of the beneficiary is larger than it is for the general public.\(^6\)

In the following we present a model of municipal demand for public goods, in which there is no heterogeneity of preferences. Then, we introduce heterogeneity and calculate the resulting allocation when a benevolent planner maximizes joint utility given a joint resource constraint. It is shown that preference heterogeneity will lead to higher demand for municipal goods if these goods are public goods. A public good is defined as a good with limited rivalry in consumption. The normative benchmark of a benevolent planner maximizing the joint utility of all individuals living in the city is compared with the allocation resulting from individual maximization of each interest group. In this case, the common pool problem arises and leads to higher spending and higher debt levels than optimal. In section 2.3 we derive our estimation equation from the model.

Our model is based on a two-period economy with a municipal and a private

\(^6\)This intuition follows the model by von Hagen and Harden (1994, 1995).
good. An individual consumer $i$ receives the fraction
\[ g_i^* = n^{-\gamma} g, \]  
\hspace*{1cm} (1) of the municipal good $g$, where $n$ is population size and $g$ is the total amount of the municipal good provided. Thus $g_i^*$ characterizes the actual quantity received by an individual consumer. If $\gamma = 0$, the municipal facility is a pure Samuelson (1954)-type public good, there is no rivalry in consumption. 10 people can consume as much as 100 people of the good. If $0 < \gamma \leq 1$, there is a limited degree of rivalry in the use of the good, $\gamma > 1$ indicates considerable crowding out in the use of the good. In the latter case a city with a larger population needs to provide over-proportionally of the municipal good in order for the individual consumer to enjoy the same level of municipal good consumption as she would in a small city.

The utility of an individual $i$ is given by
\[ V_i = U(c_{i,1}, c_{i,2}) + H(g_{i,1}^*) + H(g_{i,2}^*), \]  
\hspace*{1cm} (2) where $c_i$ denotes private consumption and the subscript period 1 and 2 respectively. $H$ is a usual strictly concave utility function for the municipal good. Further it is assumed that first period municipal consumption is financed by issuing debt $b = \sum b_i$. Furthermore the public sector cannot default.\(^8\) The city raises a tax rate $\tau$ on second period income in order to repay the debt and to cover second period public consumption. Every individual pays a fraction $0 < \zeta_i < 1$ of the public good, which has a relative price $q$. Given that $r$ is the interest rate the budget constraint of individual $i$ can be specified as follows:
\[ c_{i,1} = y_{i,1} - b_i \]  
\hspace*{1cm} (3)
\[ c_{i,2} = (1 - \tau)y_{i,2} + (1 + r)b_i \]  
\hspace*{1cm} (4) where $y_{i,t}$ denotes the income of person $i$ in period $t$. Thus, first period income of an individual is used to consume and to buy city debt, in the second period, private consumption equals the sum of after tax income and the repaid debt.

\(^7\)It is similar to the model by Persson and Tabellini (2000, pp.345). A model with infinite periods is presented in Velasco (2000), the main insights, however, remain the same. In the present paper the model by Persson and Tabellini is augmented in such a way, that we can derive demand functions for municipal goods, as done in Bergstrom and Goodman (1973) and similarly in Borcherding and Deacon (1972).

\(^8\)The last assumption is not as strict as it might appear as pointed out by Inman (2001). In fact, the number of American cities going bankrupt in recent years was very limited. In the last years, the main defaults were incurred by NYC, Camden, Philadelphia, Bridgeport, Miami and Orange County and Washington D.C. (p.60). Of these cities, only Camden and Washington D.C. received bail-outs.
The tax income received from the individual $i$ is thus equivalent to the share of the municipal good in period 1 and period 2 paid by individual $i$:

$$\tau y_{i,2} = q_1 \zeta_i g_1 + q_2 \zeta_i g_2 \quad (5)$$

and we assume that first period bonds bought by individual $i$ correspond to her paid share of the municipal good in period 1.

$$b_i = q_1 \zeta_i g_1 \quad (6)$$

The consolidated budget constraint is, assuming for simplicity an interest rate of zero ($r = 0$) and no discounting, then given by:

$$c_{i,1} + c_{i,2} = y_{i,1} + (1 - \tau)y_{i,2} = y_{i,1} + y_{i,2} - q_1 \zeta_i g_{i,1}^* n^\gamma - q_2 \zeta_i g_{i,2}^* n^\gamma \quad (7)$$

The maximization problem for the optimal level of $c_{i,2}$, $g_{i,1}^*$, and $g_{i,2}^*$ can then be expressed as

$$\max U(y_{i,1} + y_{i,2} - q_1 \zeta_i g_{i,1}^* n^\gamma - q_2 \zeta_i g_{i,2}^* n^\gamma - c_{i,2}, c_{i,2}) + H(g_{i,1}^*) + H(g_{i,2}^*) \quad (8)$$

### 2.1 A benchmark: the benevolent planner’s allocation

#### 2.1.1 One municipal good

Suppose that all individuals $i = 1, \ldots, n$ have the same preferences. The benevolent planner maximizes welfare defined as the sum of all the individual utilities. Thus, as a normative benchmark, we calculate the utilitarian optimum, which is obtained by maximizing the Benthamite welfare function, subject to the resource constraint. The first order conditions are given by:

$$-nq_1 \zeta_i n^\gamma U_1(c_{i,1}, c_{i,2}) + nH'(g_{i,1}^*) = 0 \quad (9)$$

$$-nq_2 \zeta_i n^\gamma U_1(c_{i,1}, c_{i,2}) + nH'(g_{i,2}^*) = 0 \quad (10)$$

$$-nU_1(c_{i,1}, c_{i,2}) + nU_2(c_{i,1}, c_{i,2}) = 0 \quad (11)$$

where $U_t$ is the first derivative of $U$ with respect to $c_{i,t}$ at time $t = 1, 2$ and $H'$ is the first derivative of $H$ with respect to its argument. If the price of the public good is constant over time $q_1 = q_2$, then optimal municipal consumption of individual $i$ is flat over time $g_{i,1}^* = g_{i,2}^*$, and given constant population size, $g_1 = g_2$. This directly results from the strict concavity of the utility function. Private consumption will also be equal in both periods. This benchmark thus characterizes the case of a homogenous population, that has a common preference for one public good, such as a public swimming pool.
2.1.2 Two municipal goods

Now assume that the population is split into two groups \( j = A, B \) with differences in their preferences regarding the public good. Group \( j \) prefers public good \( g^j \), where \( j = A, B \) and \( \gamma^A = \gamma^B = \gamma \). Thus, one group would like to have only a swimming pool, while the other group derives utility only from public parks. The two groups are of equal size. The joint maximization problem is then:

\[
\max 2 \cdot \frac{n}{2} U(X - c_{i,1}, c_{i,2}) + \frac{n}{2} H(g_{i,1}^{A*}) + \frac{n}{2} H(g_{i,1}^{B*}) + \frac{n}{2} H(g_{i,2}^{A*}) + \frac{n}{2} H(g_{i,2}^{B*})
\]  

(12)

where

\[
X = y_{i,1} + y_{i,2} - q_1\zeta_i \left( \frac{g_{i,1}^{A*}}{n} \right)^\gamma + g_{i,1}^{B*} \left( \frac{y_{i,2}}{n} \right)^\gamma - q_2\zeta_i \left( \frac{g_{i,2}^{A*}}{n} \right)^\gamma + g_{i,2}^{B*} \left( \frac{y_{i,2}}{n} \right)^\gamma
\]  

(13)

which gives the following five first order conditions:

\[
-nq_1\zeta_i \left( \frac{n}{2} \right)^\gamma U_1(c_{i,1}, c_{i,2}) + \frac{n}{2} H'(g_{i,1}^{A*}) = 0
\]  

(14)

\[
-nq_1\zeta_i \left( \frac{n}{2} \right)^\gamma U_1(c_{i,1}, c_{i,2}) + \frac{n}{2} H'(g_{i,1}^{B*}) = 0
\]  

(15)

\[
-nq_2\zeta_i \left( \frac{n}{2} \right)^\gamma U_1(c_{i,1}, c_{i,2}) + \frac{n}{2} H'(g_{i,2}^{A*}) = 0
\]  

(16)

\[
-nq_2\zeta_i \left( \frac{n}{2} \right)^\gamma U_1(c_{i,1}, c_{i,2}) + \frac{n}{2} H'(g_{i,2}^{B*}) = 0
\]  

(17)

and

\[
-nU_1(c_{i,1}, c_{i,2}) + nU_2(c_{i,1}, c_{i,2}) = 0
\]  

(18)

Proposition 1. The benevolent planner equalizes public good provision across time and across goods.

Proof: This follows from Equations 14-17, as the levels of \( g_{i,t}^j \) have to be equal so that the functions \( H' \) are equal to the same term \( -nq_2\zeta_i \left( \frac{n}{2} \right)^\gamma U_1(c_{i,1}, c_{i,2}) \).

2.1.3 One municipal good vs. two municipal goods

In addition we can compare the amount of public good provided if there is only one public good as opposed to two different goods. Does heterogeneity in preferences for different goods increase total spending or decrease it? If we compare the first order condition of Equation 14 with the first order conditions of Equation 9 (the case with no heterogeneity), then one can show that

\[
\frac{H'(g_{i,1}^{A*})}{H'(g_{i,1}^{A})} = \frac{2(n/2)^\gamma}{n^\gamma} = \frac{2}{2^\gamma}
\]
If $\gamma < 1$ then the term above is larger than 1, and therefore $g_{A,1}^* < g_{A,1}^*$.

The intuition to this result is quite simple. If the good provided by the city has some public good character in the sense that there is limited rivalry in consumption, then the city which only provides one good has a size advantage. Since $n$ instead of $n/2$ individuals pay for the municipal good, the enjoyed level of the public good by an individual is larger. If however there is considerable crowding out, $\gamma > 1$, then the smaller size of the group benefitting from good A contributes to a higher level of received good. This means on the other hand, that comparing the absolute quantities provided, that if $\gamma < 1$, $g_{A,1}^* + g_{B,1}^* = g_1 > g_{nh}^*$, where $g_{nh}^*$ is the level of municipal good provided if there is no heterogeneity ($nh$) of preferences. Thus, if the consumption of the municipal goods is non-rival, an increase in the diversity of preferences will increase the total amount of spending for municipal goods. For example, if everybody living in a city has a strong preference for swimming pools, and if swimming pools are of limited rivalry, then less has to be spent for the public good than if one half of the population wants swimming pools and the other half only wants public parks. Population heterogeneity thus requires higher public spending if the public goods are non-rival ($\gamma < 1$). This result picks up the point made by Oates (1988), who commented on the debate whether municipal goods are rival or non-rival. The empirical studies performed with aggregate expenditure data usually found that municipal goods are rival, thus quasi-private. Oates argued that this measured effect could just reflect that larger cities offer a greater variety of goods, which are each non-rival in nature.

### 2.2 Common pool resource problem, individual maximization

After deriving the optimal allocation for the case of a benevolent planner who maximizes the sum of individual utilities, we now consider a society divided into two interest groups, each of which maximizes their utility. Each of these groups derives utility only from the municipal good provided specifically for them, taking as a budget constraint the common pool of resources of both groups. It is assumed that the results of the individual maximization, the actual individual demand functions will actually be realized by the city government. Thus, we disregard the role institutions might play to reduce the common pool problem. One could suppose that each group has its own representatives in the city council and is thereby able to achieve its interest. These representatives then try to get as many resources for their constituency as possible.\(^9\) To figure out the solution to this problem, we start from the second

\(^9\)Hallerberg and von Hagen (1997), von Hagen and Harden (1995) and von Hagen (1992) investigate the importance of the common pool problem in the context of budget processes and show
period maximization problem.

\[ \max \frac{n}{2} U [X - c_{i,2}, c_{i,2}] + \frac{n}{2} H(g_{i,2}^*) \]  \hspace{1cm} (19)

where \( X \) is defined as above and \( j = A, B \). The two resulting first order conditions are:

\[ -\frac{n}{2} q_2 \zeta_i \left( \frac{n}{2} \right)^\gamma U_1(c_{i,1}, c_{i,2}) + \frac{n}{2} H'(g_{i,2}^*) = 0 \]  \hspace{1cm} (20)

\[ -\frac{n}{2} q_2 \zeta_i \left( \frac{n}{2} \right)^\gamma U_1(c_{i,1}, c_{i,2}) + \frac{n}{2} H'(g_{i,2}^*) = 0 \]  \hspace{1cm} (21)

**Proposition 2.** *Public spending in the second period is higher, if each group individually maximizes its utility, than if a benevolent planner maximizes joint utility.*

Proof: In the common pool model with two goods and individual maximization, the optimal quantity provided of each good is defined by equation 21 or dividing by \( n/2 \)

\[ q_2 \zeta_i \left( \frac{n}{2} \right)^\gamma U_1(c_{i,1}, c_{i,2}) = H'(g_{i,2}^*) \]  \hspace{1cm} (22)

while in the case of a benevolent planner and two goods it is defined

\[ 2q_2 \zeta_i \left( \frac{n}{2} \right)^\gamma U_1(c_{i,1}, c_{i,2}) = H'(g_{i,2}^*). \]  \hspace{1cm} (23)

The proposition directly follows from the strict concavity of the \( H \) utility function.

Turning to first period demand for municipal goods, we must account for the fact that agents in their maximization problem know that second period consumption depends on the consumption in the first period. With the help of the implicit function theorem it is easy to verify that \( g_{2}^* = g_{2}^*(g_{1}^A, g_{1}^B) \), where the first derivative of \( g_{2}^* \) with respect to first period consumption is negative. Second period consumption will be lower, the higher the inherited debt from the first period. Higher debt levels increase the marginal cost of second period spending, since a tax on income needs to be raised to pay back the debt and cover the spending of municipal goods in the second period. In the first period, the individuals take into account that second period public consumption is influenced by first period consumption. The first period maximization problem is:

\[ \max \frac{n}{2} U [X^{cp} - c_2, c_2] + \frac{n}{2} H(g_{1}^*) + \frac{n}{2} H(g_{i,2}^*(g_{1}^A, g_{1}^B)) \]  \hspace{1cm} (24)

for \( j = A, B \) where

\[ X^{cp} = y_1 + y_2 - q_1 \zeta_i \left( g_{1}^A \left( \frac{n}{2} \right)^\gamma + g_{1}^B \left( \frac{n}{2} \right)^\gamma \right) - q_2 \zeta_i \left( g_{2}^A(g_{1}^A, g_{1}^B) \left( \frac{n}{2} \right)^\gamma + g_{2}^B(g_{1}^A, g_{1}^B) \left( \frac{n}{2} \right)^\gamma \right). \]  \hspace{1cm} (25)

that budget institutions are a way to reduce this problem.
The resulting optimality condition, using the results of 21, is

\[-q_1 \zeta_i \left(\frac{n}{2}\right)^\gamma U_1(c_1, c_2) + H'(g_{i,1}^{A^*})(1 - g_{i,2}^{A^*}) = 0 \]  (26)

Comparing this optimality condition with the one of the benevolent planner shows that public consumption in the first period is higher. As this public consumption is financed by issuing debt, also the debt level will be higher. Since the first derivative of second period consumption, \(g_{i,2}^{A^*}\), is negative, the term in brackets is larger 1. Thus, while in the case of a benevolent planner the optimal quantity of \(g_{i,1}^{A^*}\) is given by

\[q_1 \zeta_i \left(\frac{n}{2}\right)^\gamma U_1(c_1, c_2) = \frac{1}{2} H'(g_{i,1}^{A^*}) \]  (27)

in the case of individual maximization

\[q_1 \zeta_i \left(\frac{n}{2}\right)^\gamma U_1(c_1, c_2) = H'(g_{i,1}^{A^*})(1 - g_{i,2}^{A^*}) \]  (28)

First period public consumption is higher than in the case of the benevolent planner for two reasons: First of all, in the case of individual maximization more funds are spent than optimally because individuals maximizers only have to pay half of the additional costs. The second effect stems from the fact that second period consumption is negatively influenced by first period consumption. As both groups decrease their municipal spending demands for inherited debt of the first period, the cost of first period municipal consumption appears lower since all individuals share the cost in the second period. Both groups reduce future spending because of current debt accumulation. From the point of view of group A, the cost of borrowing is reduced since group B also reduces spending in the second period. Comparing this result with the resulting level of municipal good in the second period, it can be seen that first period consumption of municipal goods is higher than second period consumption. Thus, the common pool problem not only increases municipal spending, but also leads to an intertemporal common pool problem. Thus, \(g_{i,1}^{A^*} > g_{i,2}^{A^*}\) and therefore \(g_1 > g_2\), because of the intertemporal common pool problem. Velasco (2000) shows that this result also holds in a model with infinite horizon. Debt is accumulated up to the level at which the present discounted value of all available future taxes equals the debt level. Thus, the common pool problem leads to a higher accumulation of public debt than socially desirable.

The introduction of a common pool resource problem increases spending and debt accumulation. Decentralized spending in a common pool of tax revenues entails that more is spent than optimal. The same common pool factors, leading to higher spending will also increase the accumulation of debt.
2.3 Estimation strategy

To derive an equation, which we can estimate, we have to make some assumptions concerning the utility function $V$. For ease of exposition we chose the function

$$V_i = \ln c_{i,1} + \ln c_{i,2} + \ln g_{i,1} + \ln g_{i,2} \tag{29}$$

Maximizing this function subject to the budget constraint (Equation 7), it follows immediately, that $c_1 = c_2$ and $g^*_1 = g^*_2$. Let $\delta$ be the constant price elasticity and $\epsilon$ the constant income elasticity and abstract from the common pool problem, using the first order conditions from the above maximization problem yields

$$g_1 = n^\gamma g^*_{i,1} = k(y_1 + y_2)(q_1 \zeta_i n^\gamma)^\delta$$

where $k$ is a constant. It simplifies to

$$g_1 = n^{\gamma(1+\delta)}(y_1 + y_2)(q_1 \zeta_i)^\delta \cdot k. \tag{30}$$

Taking logs, the following equation can be estimated:

$$\ln(g) = c + \alpha \ln(n) + \epsilon \ln(y) + \delta \ln(q_1 \zeta_i) + \beta CP \ldots \tag{31}$$

where

$$\alpha = \gamma(1 + \delta). \tag{32}$$

from which the degree of crowding out $\gamma$ can be calculated.\(^{10}\)

Demand for municipal goods thus depends on the population size, income, the price of the municipal good in terms of taxes and CP, which is a vector of variables capturing the importance of the common pool problem. In addition, the common pool resource model predicts that those factors that increase spending will also lead to higher debt accumulation. Thus, we also regress the debt level on the common pool factors.

$$\ln(debt) = c + \alpha \ln(n) + \epsilon \ln(y) + \delta \ln(q_1 \zeta_i) + \beta CP \ldots \tag{33}$$

However, we do not assume that income and the tax rate should determine the debt level, since they do not constitute factors of the common pool problem. Differences across cities in the debt level should be explained by the scale variable population size and the degree of common pool problem, CP.

\(^{10}\)Oates (1988) argues that the estimated coefficient of 1 (the quasi-private nature of public goods) can be the result of the so-called "zoo-effect". Larger communities offer a greater variety of goods and services. Therefore, there is no congestion but rather a greater range of services. However, most expenditure categories, like social services, policing, fire, sewerage, and highways do not appear to be subject to Oates' point.
In the following we will briefly discuss the variables $q_1\zeta_i, n, y$ and ways to operationalize the common pool problem $CP$.

$q_1\zeta_i$ represents the share of the municipal good paid by individual $i$. It corresponds to the taxes paid by the individual. The median house value is the tax base, on which the most important municipal tax, the property tax, is levied.\textsuperscript{11} The property tax represents a substantial part of municipal revenues (48.1\% in 1984/85 of municipal tax revenues and 20.8\% of total municipal revenues in the whole of the sample of cities), increases in the demand for municipal spending therefore will probably lead to higher taxes on property. The median house value might be an endogenous variable, since increased spending might positively affect the median house value through better security, nicer parks etc. Since appropriate instruments for IV regressions are not available, we performed robustness checks by dropping the median house value. All the other coefficients stay stable. In addition, one can calculate the direction of the bias and show that given some assumptions, the reported coefficient on the median house value is an upper bound of the true price elasticity of demand.\textsuperscript{12} If the house value of the decisive voter increases, his demand for public goods falls because he will have to pay a higher tax for this good. In addition to the median house value we control for the percentage of people living in their own houses. We suppose that people renting an apartment will expect that changes in the property tax will not be immediately reflected in the rent paid. Thus a higher percentage of people living in their own houses (a lower percentage of people renting a flat) will lead to lower demand for municipal services.

The income $y$ is measured as mean income per capita. Higher income moves the budget constraint and should in general result in higher demand. Population size $n$ increases the demand for public goods and public debt. It can also be a measure for

\begin{itemize}
  \item Ideal one would want to have the property tax payment, however it is very difficult to get data on tax rates and the tax base. In the state of California, for example, there are two property tax rates, an ad valorem rate and a yearly rate. Furthermore the rates differ across counties. In addition for most real property, the tax base is the adjusted base year value or the property’s current market value, whichever is lower. Since property taxes are usually linear taxes, the estimated coefficient should be a linear transformation of the coefficient we would get if we took the property tax as a regressor. See also: http://www.boe.ca.gov/proptaxes/faqs/generalinfo.htm
  \item Suppose that $E = \beta MH + \epsilon_1$ and $MH = \gamma E + \epsilon_2$. $\epsilon_{1,2}$ are uncorrelated error terms with the usual properties. Under these assumptions the bias is given by $E(b) = \beta + \frac{\text{cov}(\epsilon_1,\epsilon_2)}{\text{var}(X)} = \beta + \frac{\gamma \sigma_1^2}{\sigma_2^2 + (1 - \beta \gamma) \sigma_2^2}$. The bias is positive, if the nominator is positive. The nominator is positive if $(1 - \beta \gamma) > 0$. Suppose that the true price elasticity is negative, while the influence of spending on the median house value is unambiguously positive (for example Barrow and Rouse (2002) find that additional school spending leads to increased property values.), so $\beta < 0$ and $\gamma > 0$, then the bias is positive. If the bias is positive, the estimated coefficient represents an upper bound. Thus the price elasticity is $b$ or lower.
\end{itemize}
the common pool problem since larger cities possibly have a larger set of interest
groups with diverse preferences. Intergovernmental general city revenue per capita 
(grantpc) will increase the available pool. Therefore consumption of public goods will 
increase since it will be costless for all interest groups accessing this pool.

As we have shown in subsection 2.2, the introducing of the common pool model 
\((CP)\) increases spending and debt. If more interest groups with diverse preferences try to access the common pool of tax resources, the resulting demand will be higher. In order to operationalize the degree of the common pool problem, we include social and demographic variables (Ladd and Yinger 1989).

Higher employment per capita will increase the demand for roads, public transport, policing, etc., because higher employment will generate more driving and other activity.

The percentage of Hispanics is added as an independent variable in our regression, since Hispanics represent a specific interest group. Alesina, Baqir, and Easterly (1999) develop a model to show that the level of spending on municipal goods is lower, the larger the median distance of preferences from the median voter’s preferences. The more diverse preferences, the less likely voters will be satisfied with the actual provision of public goods. Thus, voters will prefer private consumption and thus a lower level of public spending. Alesina, Baqir, and Easterly (1999) find that more ethnically diverse cities (representing diversity of preferences) have significantly lower share of spending on public goods. Their empirical result, however, has to be interpreted with caution. As pointed out in their paper, more ethnically diverse cities receive more intergovernmental grants. These grants are very often

\[ \beta \ast 0.01 \ast 100\% \] 

percent. The coefficient can thus be interpreted as semi-elasticities.

\[ \begin{align*}
\text{Beyond this effect, larger populations will increase the demand for debt, as larger cities have a higher creditworthiness, because they are "too big to fail". The fiscal crisis in NYC has shown, that it is just impossible to leave a city like NYC completely alone. The federal government provided a credit of$2.3 billion in short term loans at 1 percent above the treasury rate of 6 percent as compared to the borrowing rate of the city at the time of 13.2 percent. Nevertheless bondholders incurred significant losses (Morris 1980, p.234). Therefore, their interest rates for bonds should be lower, making deficit-financing cheaper. However, the evidence on the interest rate effect is rather weak. Asefa, Adams, and Starleaf (1981) argue that the variance of interest rates is too low to explain differences in deficits.}
\end{align*} \]

\[ \begin{align*}
\text{There might be an endogeneity problem. Higher public spending might also positively affect employment. To account for this problem we performed separate regressions without this variable. In addition we believe that current employment does not depend on current expenditure for highways but rather on past expenditure for highways, since only finished highways are productive and generate employment.}
\end{align*} \]

\[ \begin{align*}
\text{We measure the variables hispanic, seniors, birth, crime, poverty, ownerhouse and public employment in percent as data between 0 < x < 1. Thus a 1 percentage point increase of Hispanics in a city will have the impact of decreasing spending by } \beta \ast 0.01 \ast 100\% \text{ percent. The coefficient can thus be interpreted as semi-elasticities.}
\end{align*} \]
tied to specific programs like social assistance and thereby necessarily reduce the share of spending on public goods like roads. In addition, many public goods like spending on roads can be targeted by the median decision maker to benefit areas dominated by the median. A different interpretation appears to be plausible. Ethnic minorities, that do not participate in the political decision process, do not receive any benefits. However they do pay taxes. Therefore the disposable funds for the majority increase. Given usual assumptions on the income elasticity and cross elasticity of private and public goods, we expect part of the funds to be used for public goods and part of it to reduce taxes. Thus, we would expect cities with a larger ”minority” of non-voters to spend less per capita. Therefore, we control for the percentage of Hispanics, since the voting participation rates of Hispanics differs substantially from those of Whites and African Americans. We suppose that the difference in voting behavior should be reflected in the spending of the city government, with cities spending less if they have many Hispanics. At the presidential elections in 1988, 59.1 and 51.5 percent of the eligible white and black voters voted, whereas only 28.8 of the eligible Hispanic voters did so (U.S. Census Bureau 1989).16 Shaw, de la Garza, and Lee (2000) show that in the 1996 presidential election the Latino turnout was much lower than the aggregate turnout. Miranda and Walzer (1994) find that the percentage of African American significantly increases spending in the 1970s, it is however of no significance in the 1980s. This might reflect the fact that during the 1970s the black ”sector” (Clark and Ferguson 1983) had been more active. The percentage of blacks is also insignificant in our regressions reflecting missing differences in voting participation, while the percentage of Hispanics is significant.

Furthermore we include variables on demographic characteristics. The percentage of seniors living in a community will influence spending and debt. Seniors are quite active in demanding specific services for themselves. Therefore we will expect higher spending in a city with more seniors. On the other hand, seniors are less likely to leave the city and will therefore probably prefer lower debt levels. Voters and taxpayers are mobile and have the option to escape cities with high debt. Inman (1982) argues that mobility of workers plays indeed a role.17 We can therefore

16In 1994, the current population survey gives the following: whites 47.3, black 37.1, hispanic 20.2 (http://www.census.gov/population/socdemo/voting/profile/ptable1.txt) 1998: 46.5, 40, 20.
17He analyzes the funding decisions for public employee pensions in the framework of two models. In one model, taxpayers are immobile and try to shift tax burden on the future by under-funding pensions. Given the assumptions of perfect information Inman shows that implausible parameter values would be necessary for this model. His favored model, on the other hand, depends on the assumption of mobility. Taxpayers have an incentive to under-fund public pensions in order to save taxes. The debt burden will be paid back by inhabitants of the city later, when the taxpayer who benefited from the under-funding, moves. The only market mechanism which would prevent
suppose that cities with a younger population are more likely to have higher debt levels, since young people are more likely to leave the city, or alternatively the more old people live in a city, the less likely they are to leave, the lower the debt level.

The birth rate per capita will positively affect the demand for municipal goods and services like kindergarten and thereby increase overall spending. Also debt levels will increase with the birth rates, reflecting voiced demand by young families. Poverty will increase the demand for service programs for poor people. Similarly, the debt level will increase with the poor trying to access the common pool. Higher crime rates will increase the price for the provision of public security and thereby increase demand for policing.

A city with high population growth will have to spend a lot on infrastructure. This spending is an investment, from which the whole population in the future will benefit. Thus, fast growing cities rationally finance these additional expenditures through debt issuing. We would therefore expect that voters will favor higher debt, since they want the immigrants to the city to participate in the financing of municipal spending. Public employment will increase debt levels and spending. The more public employees, the stronger are public employee unions, which represent a very strong interest group with very specific preferences. Unions will successfully negotiate for higher salaries and other benefits for their members. In addition we include a dummy for those cities that are involved in providing school services. Obviously, we expect those cities that provide schooling to have a substantially larger budget. An additional dummy is used for those cities providing health services from their

---

18Cukierman and Meltzer (1989) propose a different model of intergenerational redistribution. In their model the poor would like to leave a negative bequest, while the rich leave a positive bequest, and thus for the rich Ricardian equivalence holds. It is not possible to leave a negative enforceable debt, therefore the poor will vote for a public debt in order to borrow from future generations. Thus, in a voting model, one group is indifferent while the other favors debt, thereby leading to debt accumulation. The debt level is thus expected to positively correlate with poverty in a city.

19There is a body of literature investigating whether crime rates and policing are linked. It is difficult to estimate whether higher police spending reduces crime rates, since police spending also depends on crime rates. To solve the endogeneity problem, Levitt (1997) proposed to instrument police spending by electoral cycles in police spending. He finds that police substantially reduces violent crime, however it has little effect on property crime. McCrary (2002) however points to a mistake in Levitt’s estimation procedure. A corrected estimation shows that it is impossible with this data set to learn about the causal effect of police on crime. We are aware of the problem of endogeneity, therefore we performed the same regressions without including the crime rate, the other results stay the same.
States have created tax and expenditure limits (TEL) (Advisory Commission on Intergovernmental Relations and Center for Urban Policy and The Environment, Indiana University 1995). TELs have gained some popularity in the late 1970s and 1980s. Their purpose is to limit the size of governments. However, their effectiveness is frequently questioned. Joyce and Mullins (1991) study the effects of TELs on budget outcomes. They point out that TELs have limited effects on aggregate spending and tax burdens. Knight and Levinson (2000) discuss the difficulties in estimating the effect of TELs, most notably the endogeneity problem. After accounting for this problem, the evidence on the effects of TELs is mixed. TELs lead to increased dependence on state aid and on fees and worsened fiscal conditions for larger cities. von Hagen (1991) finds little evidence for the effectiveness of formal fiscal restraints in reducing the likelihood of extreme outcomes in fiscal performance in US states. Our empirical results do not find any significant effect of TELs on city spending. States have also tried to limit debt accumulation of cities. Some states have imposed debt limits. In addition, the separation of a current account budget and a capital account budget is supposed to ensure that the deficit does not exceed the investment of a city. Sbragia (1996) discusses in depth, how cities have tried to avoid limits on their fiscal freedom by creating public authorities or public special districts and by creating new bonds (revenue bonds) not subject to the law. Chicoine and Walzer (1985) point out the complex relationship among several different layers of government, like special districts and authorities which sometimes fulfill similar functions. It is found that institutional limits on debt and taxes have lead to the creation of additional governments. In 1982 more than 82,000 local governments existed in the United States. Their study is restricted to the state of Illinois. Increased fragmentation is found to be positively associated with the level of property taxation and there is some evidence for increased spending as well. Overall the effect of TELs and debt limits appears to be unclear our regression analysis did not show any effect and we therefore do not report the results.

\[\text{von Hagen and Eichengreen (1996) investigate the effect of borrowing restrictions in the European Union, which are put down in the Excessive Deficit Procedure (EDP) of the Maastricht Treaty and argue that it should increase the demand for funds from upper level governments. Intergovernmental grants have increased substantially between 1960 and 1990 (Stotsky and Stunley 1997).}\]

\[\text{The capital account budget is the budget for investment activities of a city. It is financed by issuing debt. The current account budget should be financed exclusively by revenues and not by deficits. New York is the most famous city, which over a 10 year period preceding the fiscal crisis in 1974/5, borrowed to finance current account deficits and thus broke this rule (Gramlich 1976).}\]
3 Data

The data set is taken from the County and City data book (CCDB (U.S. Census Bureau 1988, 1994, 2000)) and includes data for 971 (CCDB 1988) incorporated cities, boroughs, towns, and villages (short: cities) in the United States that had 25,000 or more inhabitants in April 1980, 1070 (CCDB 1994, 2000) cities with more than 25,000 inhabitants as of April 1, 1990. The data set consists of a compilation of different data, collected by the U.S. Bureau of the Census. It includes data on the city budget (tax income, grants, expenditure, debt), the economic conditions of the inhabitants (income, employment, unemployment, poverty, employment in different industries), and socio-demographic data (population, age, education, housing, races and ethnic composition, birth rates, crime rates).

Since the data are taken from different censuses, the dating of the variables is not uniform. The precise dates are given in Table 1. The slightly differing dating, however, poses only minor problems, since the variables measured for example in 1980 instead of 1985 are highly autocorrelated in time. The percentage of, e.g., seniors in a city only slightly changes within 5 years. The correlation between the number of seniors in a city in 1990 and 1980 is for the sample of 947 cities 0.91. The cross-sectional information therefore is rather stable.

The county and city data books for 1994 and 2000 do not report debt levels. However, the County and City Extra book (1994, 2002) provides the debt level and the percentage of expenditure on interest payments.

Table 1 presents summary statistics of the most important variables in the data set. The average municipality spent 584 US dollars per year per inhabitant in 1985, in 1997 this figure increased to 1040, representing an increase of 78 percent in nominal terms and a real increase of 29 percent. The minimum spending in one community increased from 107 dollars to 177, while the maximum increased from 2835 dollars to 5612, thus the spread increased. Of the 943 cities in our data set in 1985 (1990, 1997), only 116 (113, 103) engage in education spending. All other cities spend virtually nothing on education. In these cities, schooling services are provided through special school districts, which raise their own taxes. The mean expenditure per capita in cities providing school services is 1132$ (1801, 2313), while it is only 507 (744, 933) dollars in cities having separate school districts for the year 1985 (1991, 1997). In our regression analysis we control for this “school”

\[22\] 44 cities were meeting the criterion of 25,000 inhabitants in 1980 but not in 1990. On the other hand, 143 cities had increased in population to be included in the later sample.

\[23\] Fuchs (1992) recommends the use of census data since they create a uniform classification scheme for the purpose of reliable comparative study between cities. Official city budgets are not recommended since they essentially represent “political documents” (p.298).
effect by including a dummy for all cities spending more than 10 percent of their budget on education. The mean (un-weighted) general revenues slightly exceed the mean expenditures. Tax revenue represent less than 50 percent of the general revenue. A significant amount (around 25%, 24.7% and 29%) of the general revenue is intergovernmental revenue.

Variation in general expenditure between cities stayed constant in the investigated period (coefficient of variation: 0.59, 0.59, 0.60) and is slightly smaller than inter-city variation in tax revenue (0.66, 0.70, 0.64). This probably reflects the equalizing role played by intergovernmental grants.

The average debt per capita is 850 (1197, 1490) dollars. Debt includes all long-term debt obligations of the government and its agencies (exclusive of utility debt) and all interest-bearing short-term (repayable within one year) debt obligations. The data set does not differentiate between general obligation and revenue bonds. The city with the largest debt burden (Farmington, NM) has more than 30,000 dollars debt per capita, the largest debt level dropped to 25,599 dollars in 1991 (Farmington, NM) and decreased further to 24,682 dollars in 1999 (Farmington, NM). The average interest payments as a percent of general expenditure amount to more than 7 percent in 1990/91 and more than 6 percent in 1999.

The average income per capita was 11,267 (14,799) dollars in 1985 (1989). For the last cross section, no income data are presently available. The variation is substantial, ranging between 4,600 (Prichard, AL) and almost 34,000 dollars (Beverly Hills, CA) in 1985. For the unweighed average, real income growth in the period 1979-1985 was slightly negative. However some cities gained more than 20 percent real income, while others lost almost 20 percent. During 1985-1989, real income per capita increased on average by 13 percent. The city size varies between 23,000 and more than 7 million inhabitants. Population increased in the cities by 6 percent from 1980 to 1986, in the second half of the 1980s it increased by 7.8 percent and in the whole decade of the 1990s by 11.5 percent.

On average, 43 percent of the inhabitants were employed in 1980 increasing to around 47 percent in 1990. The average civilian labor force increased from 50

---

24If we take as a threshold 1 percent, the number of cities increases by less than 5.
25For the abbreviations see appendix, table 11.
26The USA was in a recession in 1981 and 1982.
27The data set includes cities with more than 25,000 inhabitants in 1980, the population data are for the year 1986, therefore the city with 23 thousand.
28For an extensive study on urban population growth in the U.S., see Glaeser and Shapiro (2001).
29The data on employment are for persons 16 years old and over in the year 1980 and refer to employment in the calendar last week of March 1980. People, who worked more
to 53 percent. Unemployment varies considerably across cities ranging between 0 and 22 percent of the labor force, with a mean of 6.8 percent (6.6 in 1991; 4.1 in 2000). Employment in the manufacturing sector represents around 9 percent of the population. Around 1 out of 100 inhabitants is employed by the city, the figure raises in some cases to almost 8 out of 100.

In 1980, the percentage of Hispanics in the investigated cities varies greatly between less than 1 percent and 93 percent. The mean percentage of Hispanics in the population increased from 7.2 to almost 15 percent. Similarly there is considerable cross city variation in the percentage of African Americans. 11.6 percent of the average population was 65 years and older (seniors) in 1985 increasing only slightly to 12.7, also with substantial variation across cities. Birth rates vary between 3 and 53 per 1000 inhabitants increasing from 16.9 (1984) to 18 (1988) new born per 1000 inhabitants. The average number of serious crimes per 100,000 inhabitants amounts to almost 6000 in 1985, (1991:6375; 1999:5246). In 12 percent of the population are poor in 1979 and 13 percent in 1989. Poverty is defined by an absolute dollar income threshold adapted to family size. On average 60 percent of the population live in a house which they own, a figure changing only little over the years.

842 of the 943 cities used in our analysis are in a metropolitan statistical area (MSA). The general concept underlying metropolitan areas is that of a core area containing a large population nucleus together with adjacent communities having a high degree of economic and social integration with that core. This data set contains 33 MSAs, which have more than 3 cities, of which some are classified as central and some are not central. In almost all 33 MSAs, the central city/cities

---

than 1 hour in that week, are considered employed. People are also asked for their place of work, however the census data refer to the place of residence of people working. see http://www.census.gov/prod/cen2000/doc/sf3.pdf page 1017. This can introduce a problem, since many people commute to different places for work. However, usually people are taxed on the residence principle. We divided the total number of employed by the population size.

Crime refers to murder, non-negligent manslaughter, forcible rape, robbery, aggravated assault, burglary, theft, and motor vehicle theft. Some cities report 0 crimes, a very unlikely outcome. We therefore performed the same analysis, dropping the few cities reporting "0" crime. The results do not change.

For details on the historical development of poverty thresholds, see: http://www.census.gov/hhes/poverty/povmeas/papers/orshansky.html An important issue is the revision of prices in calculating this threshold and the counting of non-cash benefits. For our analysis, however, these issues are of minor importance since we are interested in a relative measure across states. It is important to know that this measure is not a measure relative to an income distribution. Jared Bernstein discusses the short comings of this poverty measure in a recent article in the New York Times, September 26, 2003 (http://www.nytimes.com/2003/09/26/opinion/26BERN.html?th).

In some cases, the data set only has the nucleus city, since the surrounding cities are all smaller.
spend considerably more and also have a higher debt burden per capita.

Table 1: Summary statistics of variables in the mid 1980s, early 1990s and late 1990s.
4 Regression analysis

4.1 Municipal expenditure

Table 2 presents estimation results of equation 31. For reasons of comparison we limited the sample to those cities for which we had observations in all three years. Regression results only slightly change if all available cities are included as observations (Appendix Tables 12+13). More than 90 percent of the variance can be explained by the independent variables. Municipal spending is thus largely determined by price, income, population size and additional demographic and control variables reflecting common pool problems. The income elasticity of demand is 0.9, the price elasticity is negative, however not always significant. Remarkable is the coefficient for the population size. It is significantly different from 1 in those regressions, that do not include the tax base. This indicates that to obtain the same level of service, larger cities need to spend over-proportionally more. There are thus diseconomies of scale to the production or consumption of local municipal goods. This result is confirmed, if we compute the coefficient $\gamma$ of crowding out according to Equation (32). In all regressions it is larger than 1. Thus, the advantages of sharing costs are overcompensated by increased costs of either production or the sharing of these goods. There are no economies of scale to larger municipalities. The first two regressions present the results for all variables available in 1985 and 1991. Spending reacts to employment. Cities with 1 percentage point more employment per capita spend around 0.85 percent more. Poverty and birth rates are also factors increasing spending as predicted by the common pool model.

Coefficients of the variables are relatively stable over time. We tested formally for equivalence of coefficient and had to reject the $H_0$ that the difference of coefficients is zero. The Chow (1960) test on all variables except intergovernmental grants, however, did not allow to reject the hypothesis of constant coefficients in time. We therefore present results of pooled regressions allowing for flexibility of the coefficient intergovernmental grant in time (last column).

House ownership significantly reduces spending of cities. Cities taking care of

---

33 To account for possible heteroscedasticity problems, we performed robust estimation (White 1980). The results did not change. We also controlled for those cities performing county functions, since they do not have an overlying county government. However, the coefficient for this dummy is insignificant and therefore we do not report this result.

34 We do not present the specific values because the coefficient of median house value is not equal to the theoretical $\delta$. To receive the correct coefficient one would have to multiply the reported coefficient with the applicable tax rate. This would considerably reduce the absolute size of the coefficient, however $\gamma$ will remain larger than 1, since the price elasticity is always negative.
schools (education) on average spend 28 percent more than those that do not. Health spending is a strong factor of city spending. Cities engaged in the provision of health services, spend 50 percent more than cities which do not. Each additional 100 dollars per capita intergovernmental grants will significantly increase spending by 0.07 percent, the effect of intergovernmental transfers on spending is thus negligibly low, they are apparently used to reduce tax burdens. The difference in voting participation of Hispanics is indeed reflected in lower spending the higher the percentage of Hispanics. The percentage of seniors increases the demand for municipal spending. Crime rates significantly increases the spending of municipalities. Central cities also have higher spending needs, since probably they have to provide a lot of infrastructure for neighboring communities.

The system of municipal organization in form of a council-manager (CM)\textsuperscript{35} system or a mayor-council (MC)\textsuperscript{36} had no influence on spending. We therefore do not report the regression results. However, the system of MC is more common in larger cities, which also have higher spending per capita.

The high degree of explained variance can be taken as an indication of the low importance of political factors like the degree of organization of municipal employees, the ”fiscal liberalism” of the mayor or the party membership of the mayor, factors not included in the regression. In fact, Miranda and Walzer (1994) find that these variables are insignificant in regressions explaining the level spending of common functions and also the change in this spending for a limited set of cities.

\textsuperscript{35}The council-manager form is similar in structure to a private corporation, with the voters, council, and a manager being organizationally similar to the stockholders, board of directors, and corporate general manager. There are few elective officers – usually only a council – with the mayor generally selected by and from the council to serve as a titular and ceremonial leader and to preside at council meetings. The policy-making legislative body is the council. The manager is a full-time professional executive charged with the administration of municipal affairs, appointed by, responsible to, and subject to dismissal by the council. The manager’s tenure is based solely on performance.

\textsuperscript{36}The mayor-council form of government is characterized by a directly elected mayor, who in many cases has the right to veto legislation. She/He is a strong political leader, who can be held accountable for political decisions.

Table 2: Determinants of general municipal expenditure, comparison of the different years for the same set of cities and if possible the same set of regressors. Standard errors are reported below the coefficient.
Table 3 reports the results for the estimation of the demand for specific municipal goods. The income elasticities for the different goods differ substantially. The point estimate for parks and recreation areas is larger than 1, indicating that they are luxury goods. The crowding parameter $\gamma$ (see Equation 32) is larger than 1 for the demand of police services and sewerage and sanitation services, there are thus no economies of scale for these two goods. For parks and recreation areas $\gamma$ is 1. The price elasticities are negative, except for the luxury good, for which the elasticity is statistically not different from zero. Interestingly, the percentage of people living in their own house has a negative impact on demand for police services, but not on sewerage services. This probably reflects the fact, that usually the fees for sewerage services are directly imposed on the tenant, increased taxes (e.g. for police spending) however are not directly added to the rent. Cities engaged in

Table 3: Determinants of specific municipal expenditure, different years. Standard errors are reported below the coefficient.

providing school services spend significantly less on police. This can be interpreted as evidence that in cities with broad responsibilities, the opportunity-costs of spending for police vs. spending for schools are taken into account, see also Bradbury (1983a,
The result is valid if there are no efficiency differences in the provision of schooling between city governments and school districts, since then given the same expenditure for schooling less is spent on other services. Intergovernmental grants increase spending for all four goods, though for highways it is only significant at a 10 percent level. Higher employment per capita increases police spending and park spending, but has no effect on sewerage spending. The percentage of Hispanics has no impact on police and park demand, although it is associated with a lower demand for sewerage services. Seniors want more police and more parks, but their demand of sewerage services is not different from the rest of the population. Birth rates are insignificant. Crime and poverty rates have a significant effect on police spending\textsuperscript{38}, however, crime rates leave the demand for sewerage and parks unchanged and poverty increases the demand for sewerage, but not for parks. Central cities spend more for sewerage and parks, but the police spending is the same. The size of the city in terms of square miles (area) matters for spending on sewerage and highways, but is irrelevant for the police provision.

Central cities spend significantly more on highways. In addition, the crowding parameter $\gamma$ is clearly and significantly larger than 1 for highways, but not for police and sewerage. The price-elasticity is significantly negative, income elasticity is close to 1. Schooling and health provision have no influence on the provision of highways, nor do employment per capita and income growth in the last 5 years. Cities with higher Hispanic population and with higher percentages of elderly spend less on highways. Cities with greater poverty demand more highways.

To summarize the section on municipal spending: A great part of the overall variation in spending can be explained by economic and socio-demographic factors. There is a considerable degree of congestion in the use or provision of municipal goods. Central cities spend around 10 percent more than cities outside of the center (which in most cases belong to a Metropolitan area). Central cities thus appear to provide goods and services for surrounding areas. However the demand equations do not reveal, whether central cities can export taxes to the degree of their increased cost. In the next section, we will see that central cities appear to finance their increased spending burden partly through higher deficit accumulation. Responsi-

\textsuperscript{38}There is a body of literature investigating whether crime rates and policing are linked. It is difficult to estimate whether higher police spending reduces crime rates, since police spending also depends on crime rates. To solve the endogeneity problem, Levitt (1997) proposed to instrument police spending by electoral cycles in police spending. He finds that police substantially reduces violent crime, however it has little effect on property crime. McCrary (2002) however points to a mistake in Levitt’s estimation procedure. A corrected estimation shows that it is impossible with this data set to learn about the causal effect of police on crime. We are aware of the problem of endogeneity, therefore we performed the same regressions without including the crime rate, the other results stay the same.
bility of a city government for schooling implies that general spending increases by around 28 percent. However, spending for specific purposes like police and sewerage is reduced. Thus the opportunity costs of schooling are internalized in the decision process and some other spending is cut in favor of the schools. Cautiously, we can draw the conclusions, that consolidation of services in one hand will make the decision making process more transparent and improve the spending outcome, see also Chicoine and Walzer (1985, pp.225-229.).

### 4.2 Municipal debt

There are only few articles on the determinants of municipal debt. Sharp (1986) studies the politics and economics of new city debt. She differentiates between general obligation as opposed to revenue bonds. The findings indicate that while general obligation bonds and taxation are largely influenced by longer-term factors, such as population, functional scope and regional location, the revenue bonds decision is a strategic arena, in which city officials maneuver to adapt to immediate fiscal strain. In our analysis we focus on total debt. Farnham (1988) estimates reduced form regressions of a model of local debt choice and the impact of State regulatory activity on the use of local government debt in a large cross section of 2000 American cities. He finds that state imposed local debt limits significantly reduce debt levels of local governments.

We run OLS regressions of the log of debt on a number of independent variables as given in Equation 33. Table 4 presents the determinants of debt in 629 U.S. cities available with this set of regressors in all three years. The first remarkable result of our regression analysis is the high degree of explained variance. 63 percent of the cross city variation in debt is explained by our model in all three years. The driving factor behind debt is the population size. Larger cities have significantly higher debt. In addition, the coefficient for the log of population is significantly larger than 1 as it was for spending. Cities, that have experienced higher population growth in the years before the cross section also have accumulated more debt. Income per capita does not explain the observed debt levels. The median house value is also insignificant in the regressions as can be seen in Table 14 in the appendix. The coefficient on population density is significantly negative, thus more densely populated cities have lower debt levels. McGuire and Sjoquist (2003) also stress that

---

39Woo (2003) reviews the literature on the determinants of national deficits and presents some new results. He finds that sociopolitical instability, income inequality, a large size of the cabinet and lack of central authority determine deficits. In addition, budgetary institutions and government institutions matter for deficits. Thereby he confirms earlier results in the literature (von Hagen 1992).
urban sprawl will increase the cost of municipal good provision. The percentage of people living in their own house significantly reduces accumulation of public debt. Again it can be argued that house-owners know about the future cost of debt. Increased intergovernmental grants increase the debt level. However, they are probably an endogenous variable and therefore we performed the regressions without them and found no considerable changes for the other variables. The higher the percentage of seniors in a city, the lower will be the debt level of a city. This probably reflects the fact that seniors are less likely to leave a city and thereby escape the debt burden of the city, as young people might intend to do. Higher crime rates are associated with higher debt levels.

Poverty significantly explains debt levels (Table 14). Its significance increases after dropping the insignificant variable income. The higher debt levels can be the result of the common pool problem since poor people might successfully lobby for
additional spending and debt. Central cities all have clearly higher debt burdens in 1985 and 1999, the coefficient is however not significant in 1991. Cities with a larger public labor force per capita also have chosen significantly higher debt levels. A city with 1 additional city employee per 100 inhabitants will have a 37 percent higher debt burden in 1985, which dropped to 27 percent in 1991. The level of formal education of the population has no significant influence on the debt level.\textsuperscript{40}

The estimated coefficients look very stable in time. We performed Chow test for stability of coefficients and had to reject the $H_0$ of equal coefficients.\textsuperscript{41} However, if we test for equality of coefficients omitting the coefficient of "central", the $H_0$ of coefficient equality could not be rejected with an $F(20,1805) = 1.15$, giving a $p$-value of 0.29. Therefore, we present the results for the balanced pooled regressions allowing for different coefficients of the dummy central in 1992 and 1999.

In the pooled regression debt over-proportionally increases with population size, the coefficient is significantly different from 1. More densely populated cities have a comparatively lower debt level. If population density increases by 1000/square mile, the debt level will decrease by 0.04 percent. An increase of 1 percentage point of house owner will decrease the debt level by $-0.5$ percent. Cities providing health services have higher debt levels. A city with 1 percentage point additional seniors will have a $-1.6$ percent lower level of debt. Cities with higher crimes rates have significantly higher debt burdens. This captures in part the effect of poverty, a variable which we expected to be associated with higher debt levels. Central cities have a 17 percent higher debt level. The debt levels increased in time by 27 and 56 percent as indicated by the time dummies. This captures exactly the change of the price level, which was 26.6 and 54.8 percent in the period 1985-91 respectively 1985-99.

To summarize the section on determinants of municipal debt: We find that a large percentage of debt variation across cities is explained by our structural common pool model. Central cities have significantly higher debt burdens (around 23 percent higher after controlling for population size). However, in 1991 central cities do not have a different debt level from the non-central cities. Apparently, some of their higher spending as compared to the surrounding cities is not financed through higher taxes or tax exports, but by issuing debt. Cities with a higher percentage of seniors have significantly lower debt levels, house ownership also reduces debt levels. Crime rates and poverty rates lead to higher debt levels.

\textsuperscript{40}We do not report this regression result. Results are available from the author.

\textsuperscript{41}This result holds in the case of constraining the residual variance to be the same each year and in the case of not constraining the variance to be equal.
5 Fiscal crises

5.1 Cluster analysis

The previous section has shown that economic and socio-demographic factors explain almost the entire variance of municipal spending and a large percentage of the variance of debt. This section is intended to identify cities in fiscal crises. We then want to investigate whether these cities are in a crisis-situation because of the identified economic, social and demographic factors, or whether the causes of crises must be sought in non-structural factors. There is no data set available reporting the occurrence of crises in American cities. Therefore we must employ indicators of crises. In all reviewed case studies of municipal fiscal crises, a high debt level was mentioned as a symptom of a fiscal crisis. High debt implies that the financial independence of a city is limited. Resources must be used to pay the interest, the credit worthiness is reduced. Thus, cities with a high debt burden can only to a limited extent react to financial challenges.

Cluster analysis allows to partition observations in subgroups, which are very homogenous within and heterogenous relative to the other groups. We cluster cities in two groups according to the minimal distance to the group mean. The distance is measured by Euclidian (Minkowski) distance, which is characterized by the root of the sum of squared distances. The relevant variable of the budget for clustering is a high accumulated debt burden per capita.\(^{42}\) Applying the described method to our data set results in the cluster characterized in Tables 5 to 7. We limit our analysis to the same set of cities for all three years, for which we were able to run both regressions in the previous section, in total 592 cities.

The cluster of crises/distress cities is characterized by an average debt burden 10 times as high as the average debt burden in the rest of the cities in the sample, in later years the ratio is still 4 to 1. 14 cities have a very high debt burden in 1985, in 1991 the cluster analysis calculates a lower threshold and the distressed cluster has 37 cities. Finally, in 1999 the threshold is even lower and 75 cities are clustered to be high debt cities. Over the 15 years considered, the average debt level increased with inflation. The distribution of debt levels stayed roughly constant in the sense that the standard deviation did not change. However, the extreme cases of high debt levels went down. Farmington, NM, reduced its nominal debt level from more

\(^{42}\)We also performed the clustering with debt as percent of income. The resulting cluster is almost the same. Another possible way to cluster the cities is to take the debt level per house per median house value. The higher this ratio, the lower the possibility to raise funds to pay back the debt. Using this variable as a cluster variable, however, gives very similar results (available from the author).
Variable | Obs | Mean | Std. Dev. | Min | Max

than 30,000 US$ to less than 25,000 US$ per capita. Public expenditure per capita is twice as high at 1100 dollars and statistically significant in 1985, and roughly 50 percent higher in the later years.

Income per capita is almost the same in the two clusters. Income growth in the last 5 years was somewhat lower in 1985 but not in 1991, population growth in the preceding 5 years was more than 11 percentage points higher in 1985 and 5.7 percentage points higher in 1991. The ten year population growth in the 1999 cluster does not differ. Distressed cities also have larger population in 1991 and 1999, the difference is however not statistically significant. Nevertheless, in 1991 the population size is three times as high and in 1999 almost four times as high. A possible explanation might be, as indicated by Buettner and Wildasin (2003), soft budget constraints for larger cities. Taxes raised by the city government per capita are the same except for 1999, so are intergovernmental general revenue and federal grant awards and procurement contract awards.

Although the structural factors seem to be different in the crises cluster, the difference is statistically not significant. Are the debt levels respectively spending decisions of the crises-cities well predicted by the regression model? A closer look at the data shows, that all 14 cities in 1985 have a positive residual in the spending

</table>

and in the debt regressions. Their absolute mean error is 1.4 as compared to the mean absolute error of the remaining 578 cities of 0.59. The mean error is thus more than twice as high as the average standard deviation of the error in the sample. If we take as a threshold $2 \times \text{Std. Dev.} = 2 \times 0.56 = 1.12$ of the absolute residual error, 10 of the 14 cities in the "bad" cluster are outliers. This means, that in 70 percent of the cases, the model can not explain the overly high debt burden well. In 1991, the threshold is $2 \times 0.63 = 1.26$ and even with a broader set of cities defined to be in distress, roughly 50 percent are outliers. The mean absolute residual is larger than in the non-distressed cluster. In 1999, the threshold is $2 \times 0.50 = 1.00$ and also 50 percent of the distressed cities are outliers. The mean absolute residual is higher in the distressed cluster for all years. As concerns spending, the analysis of residuals yields similar results. The fit in the distressed cluster is much lower than in the non-distressed cluster.
Table 7: Summary statistics of cities in the crises and the non-crises cluster in 1999.

5.2 Robustness check

As a further robustness-check we identified distressed cities as the upper 2 percentile of the distribution of debt per capita (see Tables 8 - 10). This allows to compare the 13 cities with the highest per capita debt with all the other cities. Again the difference in average debt is roughly between 5 and 10 fold. In 1985, income per capita in the two groups is roughly the same, also income growth in the preceding years is similar.\footnote{The cities in 1985 are: Corona, CA; Pittsburg, CA; Pomona, CA; Gainesville, FL; Lakeland, FL; Orlando, FL; Bowling Green, KY; Lafayette, LA; Owensboro, KY; Burnsville, MN; Minneapolis, MN; Farmington, NM; Galveston, TX.} Population growth in the high debt group is higher at 13 percent in the last 5 years, compared to 7.7 percent in the low debt cluster, while average population size is the same in the two groups. Expenditure per capita is higher in the distressed group. Of the 13 cities ten cities have an absolute mean error of the residuals of the debt regressions larger than the threshold of two standard deviations. Thus, the debt levels of these cities are not well explained by the regression analysis.
Similarly spending levels are not well explained for the distressed cities. Public employment in the two groups does not differ much, as a single factor it therefore cannot explain the differences in fiscal outcomes. For the later years, a similar picture emerges, the regression fit is quite bad for the cities with high debt levels.\textsuperscript{44} In 2000, the composition of cities changes quite dramatically, as New York and San Francisco now belong to the 2 percent of cities with the highest debt burden per capita.\textsuperscript{45} As a result, the average population size jumps and distressed cities are now 6 times as large as the other cities. Looking at the five percent upper tail of

\end{tabular}
\caption{Summary statistics of cities in the crises and the non-crises group, 2 and 5 percent upper tail of the distribution in 1985.}
\end{table}

The predictive power of the structural

\textsuperscript{44}The high debt cities in 1994 are: Fontana, CA; Paramount, CA; Pleasant Hill, CA; Pleasanton, CA; Lakeland, FL; Orlando, FL; Bowling Green, KY; Burnsville, MN; Minneapolis, MN; Farmington, NM; Hamilton, OH; Harrisburg, PA, Austin, TX.

\textsuperscript{45}The high debt cities in 2000 are: Beverly Hills, CA; Brea, CA; Denver, CO; San Francisco, CA; Lakeland, FL; Owensboro, KY; Kalamazoo, MI; St. Louis Park, MN, Farmington, NM; New York, NY; Fairfield, OH; Hamilton, OH; Austin, TX.
Thus, while part of the high debt burden in the "crisis cluster" can be explained by structural factors, a considerable part of the outcome is left unexplained by structural factors. Similarly, the regression analysis explains the spending decisions of the distressed cluster far worse than the non-distressed cluster. There appears to be a large non-structural component to a crisis. The common pool model of municipal spending and debt does not explain extreme fiscal outcomes well.

Our results are in line with the result of case studies, which emphasize non-structural factors like negotiation power of public employees/unionization (the case of New York and also Philadelphia), excessively high social security programs be-
Table 10: Summary statistics of cities in the crises and the non-crises group, 2 and 5 percent upper tail of the distribution in 1999.

cause of political preferences of the mayor (New York: John Lindsay in the 1960s, for Philadelphia see Inman (1995)) as determinants of excessive spending, debt and ultimately crisis. Miranda (1994) for example investigates the importance of strong party organization (SPO) to impose fiscal discipline. SPO allows the mayor to be more independent of the influence of interest groups and thus ensure total fiscal discipline. Thus, fiscal distress and crisis has a large non-structural element.
6 Conclusions

Why do some US cities experience a fiscal crisis and others do not? This paper proposes an indirect approach in comparing and assessing the relevance of economic and socio-demographic (structural) factors on the one side and non-structural (management and political) factors on the other hand. We ask the question whether cities are in distress, and therefore likely to experience a crisis, because of measurable structural factors or because of other factors.

In a first step we present a common pool resource model. The model shows that municipal expenditure is caused by simple demand factors like income per capita, the population size and the value of the tax base and in addition by factors measuring the possible degree of the common pool problem, like employment per capita, poverty, birth rates, percentage of seniors, hispanics and crime rates. All these factors are measurable structural factors. The common pool model further predicts that debt levels are higher the worse the common pool problem is.

We test this model in a regression analysis explaining municipal expenditure. The model is able to explain more than 90 percent of the cross city variation in municipal spending. The coefficients are shown to change little from 1985 to 1991 and 1997. Thus, municipal spending is a result of measurable structural factors. Similarly, we show that municipal debt levels are determined by the same common pool factors. However, the explained variance is lower at around 67 percent.

Cities in fiscal distress are identified by means of a cluster analysis. The criterion for distress are high debt levels. It is shown that distressed cities can be characterized by debt levels 10 times as high as the average debt level. Spending is around twice as high. However, the socio-demographic and economic factors of distressed cities appear to have fairly average values. Spending and debt levels of distressed cities can not be well explained by the common pool model of spending and debt. They constitute outliers in the regression analysis. Thus, the structural, measured factors can only to a limited degree account for their specific debt and spending outcomes. We therefore conclude that distress and ultimately crisis is a result of non-structural factors. This is in line with political research on individual cities in distress. These studies often emphasize the role of strong party organization (Miranda 1994), dependence of the mayor on support from interest groups and the like. Fiscal crisis thus appears to have a large non-structural component, socio-demographic and economic factors can not account for extreme fiscal outcomes.

Future research should investigate the interactions between political factors and economic factors and their relevance for fiscal crisis. Glaeser and Shleifer (2003), e.g., study the effect of mayors appealing on feelings of strong minorities (in their
example the Irish) that a mayor of the minority can better represent their interest, with bad consequences for the local economy. How is fiscal outcome affected by these and other political factors?

An additional avenue for future research concerns intergovernmental relations and their effect on crises. Inman (2001) argues that the American system is rather successful in preventing cities from receiving bail-outs. The moral hazard issue thus seems to be solved. However, it remains to be investigated whether intergovernmental transfer rules can be improved in such a way as to prevent crisis and not to fall in the trap of moral hazard problems. A further extension of this line of research would look at the effects of an increased number of local authorities on fiscal outcomes. Our research suggest that consolidation of schooling and health services in the municipal budget leads to lower spending for other services. Are crises more likely to occur in smaller public authorities with a limited number of responsibilities? Or does, on the contrary, consolidation of all local responsibilities in one authority increase the likelihood of crises?
